On Van Stone work a ground joint is quite often used without a gasket, that is, the face of the joint is ground to [illegible] a fine finish. This is much more expensive than a joint having a fine-tool finish, and made up with a gasket. The corrugated copper, corrugated soft steel, and gaskets of long-fiber asbestos [illegible] or covered with copper or bronze all seem to give excellent service for all pressures and temperatures. Other gaskets containing rubber or alloys of soft metal are quickly destroyed if used in connection with superheated steam.

WELDED STEAM HEADERS

The latest practice among engineers is to do away with fittings in the main steam lines entirely and substitute what is known as the welded header, where [illegible] up to 40 feet or more in length is welded from one piece, and all nozzles or outlets welded directly to the header itself. The piping will have [illegible] per cent. [illegible] the strength at the weld in many cases, unless reinforced at this point. One of the large concerns doing this class of work makes the metal at the weld from 25 to 100 per cent. thicker than the pipe.

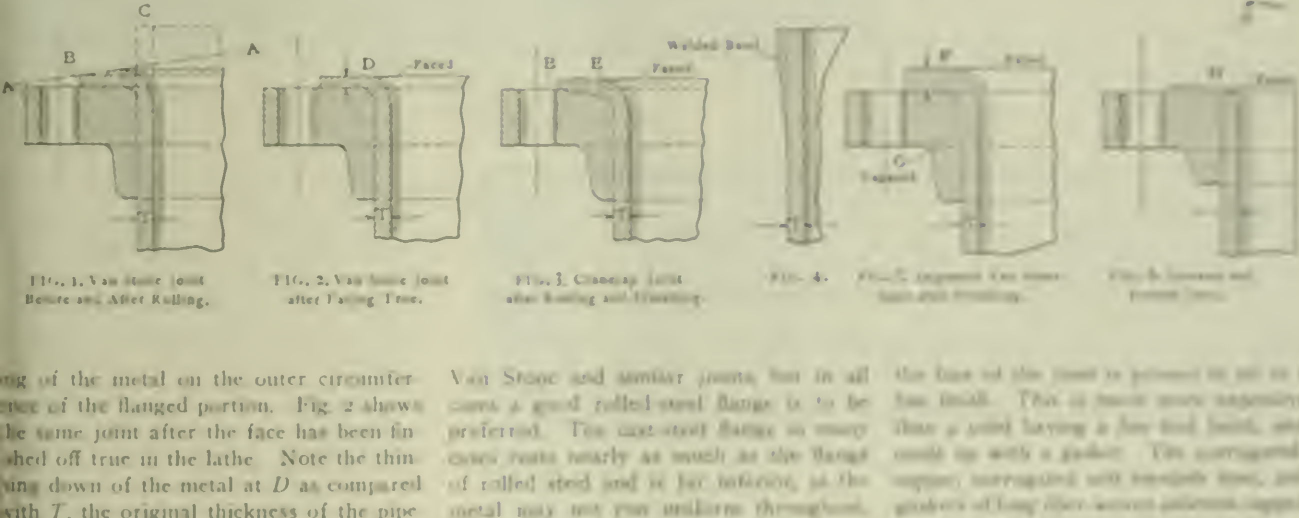

FIG. 1. Van Stone Joint Before and After Rolling.

FIG. 2. Van Stone Joint after Facing True.

FIG. 3. Cranelap Joint after Rolling and Finishing.

FIG. 4.

FIG. 5. Improved Van Stone Joint after Finishing.

FIG. 6. Screwed and Peened Joint.

to insure the joint being stronger than the pipe itself. With the welded header, rolled-steel or cast-steel flanges may be used in connection with Van Stone or similar joints, or if preferred, the welded joint, having all flanges welded to the pipe.

Some advantages of the welded header are: The lightening of the entire work, better quality of material used, decreased number of joints liable to leak and the saving of time, labor and expense in erecting. There seems to be one objection to the welded header, however, in that it is difficult to make a new connection to the header if required to do so after the piping is installed. This difficulty can be overcome by allowing one or two extra nozzles when making up and blanking them with a blind flange until needed.

Fittings and Valves for Superheated Steam

Cast iron does not seem to stand up to its record under the action of superheated steam as well as it has been doing with saturated steam, as several tests made after a few years' service show quite a reduction in strength. The following case is copied from Power and The Engineer, November 24 number: A 20-inch tee recently removed from a superheated-steam line, after three years' service under a pressure of 160 pounds per square inch, with 125 degrees of superheat, making the ultimate temperature less than 500 degrees Fahrenheit, showed cracks open as much as 1/8 inch on the outside, through which steam leaked. The casting was nearly 3/4 inch longer and 1 inch greater in diameter than when installed. The inside surface was found covered with a hard, reddish oxide, with no cracks visible.

The Crane Company recently cited a case showing where a 14-inch cast-iron high-pressure gate valve, after four years' service in a superheated-steam line, showed a loss of strength of 49 per cent. in the material in the body of the valve, and 33 1/3 per cent. in the material in the flanges. The steam pressure in this case was 200 pounds per square inch and steam temperature 590 degrees Fahrenheit. The valve was found to be 5/16 inch longer than when installed.

As a general rule for all superheated-steam work and for high temperatures, fittings and valves are specified to be of cast steel.

Making Ice Cream in a Large Ice Plant

By John N. Swartzell

On August 4, last, the Chapin-Sacks Manufacturing Company, of Washington, D. C., held a formal opening of one of the most uptodate and sanitary ice-cream factories in the country. For many years this company has operated a large ice-manufacturing establishment and only comparatively recently has been making plans and preparations for the erection of the ice-cream factory which is now run so successfully in connection with the ice-making business. The company's buildings, which occupy the entire eastern end of the block between North Capitol, First, Patterson and M streets, northeast, are two in number and are located conveniently with respect to the Union station and the tracks over which the milk arrives.

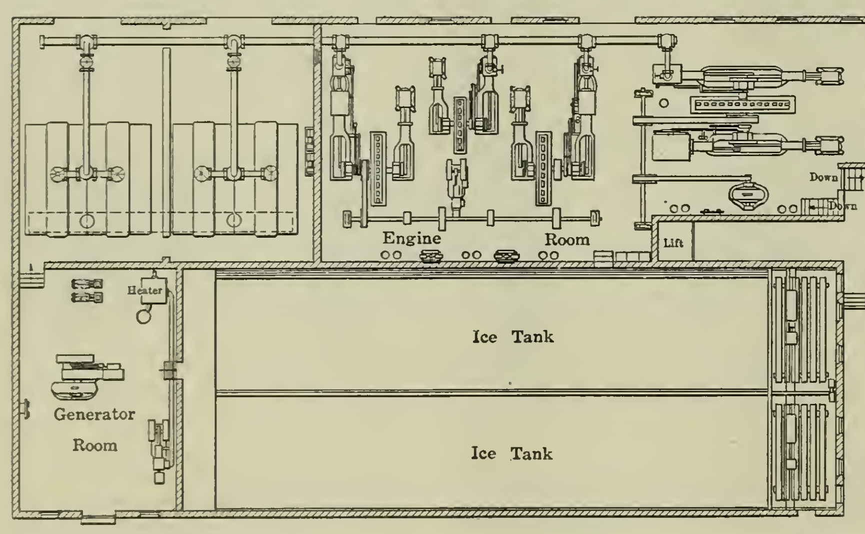

FIG. 1. PLAN VIEW OF ICE PLANT

Methods of Handling Milk

Milk used at the plant is delivered in refrigerator cans and cars from Jefferson county, New York, and is chemically tested before being used. Upon arriving at the factory it is carried to the second floor of the building and placed in a cold-storage vault until ready for pasteurization and mixing prior to being made into ice cream. Next to the storage room and communicating with it is the mixing room. This room contains the pasteurizer and the mixers. The pasteurizer heats the milk to a temperature of 175 degrees Fahrenheit, then cools it down by water to 75 degrees Fahrenheit and finally reduces its temperature to 38 degrees Fahrenheit by cool brine.

There are four machines for mixing the ingredients of the ice cream. These are huge galvanized-iron tanks, each having a capacity of 150 gallons. In the center of each tank there is a vertical shaft fitted with two dashers, these being arranged to revolve in opposite directions, and the shaft supporting them is driven by a bevel gear and shaft from a Crocker-Wheeler 110-volt direct-current motor. The mixers are set in two groups, one motor sufficing to operate each group. The driving shaft is divided and furnished with a clutch so that the mixers can be run singly when desired.

Located on the first floor of the building directly under the mixing room is the freezing room. There are six horizontal and one vertical freezer, each having a capacity of 12 gallons. The freezers are cooled by brine circulated by a small centrifugal pump, which is located in the mixing room, and is direct-connected to a 3-horsepower direct-current motor having a speed of 1650 revolutions per minute. The cream to be frozen flows by gravity from the mixing tanks to the freezers through pipes put up in short sections, so arranged that they may be taken down each day and thoroughly washed. The horizontal freezers are equipped with individual 1 1/2-horsepower Crocker-Wheeler direct-current motors while the vertical machine, used only for freezing fancy creams, is driven by a Lincoln 2-horsepower variable-speed motor. Each motor is connected to its respective freezer by a noiseless chain-and-sprocket drive.

The freezers are elevated a sufficient distance from the floor to permit the frozen cream to be drawn off by merely opening a valve, placed conveniently in one end. Cream upon being drawn from the freezer is placed in the hardening room, where it may become firm, and allowed to remain there until ready for shipment. For the purpose of crushing the ice used in packing the frozen cream for delivery, two motor-driven ice crushers are installed, one emptying directly into the shipping department, the other discharging into a chute through the outside wall of the building for filling the delivery wagons. Ice to be crushed is carried to the second floor of the building from the ice-storage room on the first floor by an ice hoist driven by a Gener

Electric 115-volt direct-current motor. Here it is dumped into a chute and delivered to the crushers.

Adjoining the freezer room is the washing and sterilizing room. The cans upon being returned by customers are brought to the rear of the building and received through a small doorway for that purpose and placed in the tubs, where they are thoroughly washed. After the process of washing is finished the cans are placed in a wire basket moving upon a track and passed into a steam sterilizer. The sterilizer was built and installed by the Kensington Engine Works, of Philadelphia, Penn., and resembles in appearance a small horizontal boiler, being about 8 feet long by 4 feet in diameter. The method of operating is as follows:

Steam at 80 pounds pressure is admitted to the reducing valve and the pressure lowered to 10 pounds. At this pressure it is permitted to enter the jacket surrounding the internal chamber. When this has been accomplished the chamber is ready to receive the material to be sterilized. After the temperature of the chamber has risen considerably the air exhauster is opened until the vacuum gage shows 15 inches of vacuum. The valve to the inner chamber is then opened slightly, and when the pressure has risen the valve is closed and the air exhauster again started. When the vacuum gage indicates 15 inches the steam valve is again opened until the thermometer reads 236 degrees Fahrenheit. The steam is then allowed to circulate through the chamber for a short time, after which it is shut off and the exhauster opened once more to draw off the steam and vapor. In a few moments, when the heat of the jacket has had an opportunity to dry any moisture remaining inside the chamber, the doors may be thrown open and the contents of the basket removed.

FIG. 2. FREEZER ROOM

FIG. 3. BOILER INSTALLATION

ICE PLANT

The plant of the company is fitted with five ice tanks, each 99 feet long, 20 feet wide and 20 inches deep for manufacturing plate ice, the direct-expansion system being employed. The blocks of ice, each weighing six tons in weight, are removed from the tanks at intervals by an overhead traveling crane. Six and one-third days are required for an entire freeze. The cranes for handling the huge blocks of ice are operated by a hydraulic pressure of 150 pounds, maintained in tanks by small duplex steam pumps located at the farther end of each crane, one sufficing to operate the cranes of two tanks.

The blocks of ice, of which there are about 96 in each tank, are cut up into blocks by means of an iron frame heated by steam. As the blocks are cut they are placed in a chute and slid into the ice house. During the summer season the total output of the plant is 140 tons per day, and in winter it varies between 80 and 90 tons per day.

There was once a time when plate ice could not be manufactured from anything but distilled water, but this difficulty has in later years been overcome by circulating air at low pressure through the ice tanks during the process of freezing. The circulator employed at this plant was built by the Bury Air Compressor Company, of Erie, Penn., and is located in a small room in the older part of the building, which also contains the boiler feeders, the heater and an electric-generating unit. This unit consists of a Buckeye single heavy-duty high-speed engine and a Sprague 40-kilowatt 110-volt direct-current generator. The circuits supplied by the company are controlled by a ten-panel switchboard located nearby, using Weston instruments and furnished by the Trumbull Electric Manufacturing Company of Plainville, Conn.

The boiler feeders consist of two Knowles outside-packed plunger pumps.

sizes 7½x5x6-inch and 7½x5x10-inch, respectively. These, as well as the compressor and generator engines, exhaust into a Cochrane open heater which raises the temperature of feed water to 210 degrees Fahrenheit before delivering it to the pumps.

Located next to this room and communicating by means of a low arched doorway is the boiler room, which is 48 feet long by 41 feet wide and is divided into two parts by a brick partition, one room being 41x23 feet and the other 41x25 feet. The larger room contains two 250-horsepower boilers fitted with Hawley down-draft furnaces. In the other room are located two of 228 horsepower each. The entire boiler equipment was furnished by the E. Keeler Company, of Williamsport, Penn., and was built to carry a working pressure of 160 pounds. The boilers have one steam and water drum 20 feet 5 inches in length by 48 inches in diameter, contain one hundred and thirteen 18-foot tubes 4 inches in diameter, and are fitted with horizontal baffles. In addition to the feed pumps located in the generator room there is another battery in the larger section of the boiler room, comprising two Snow duplex pumps, size 5¼x3½x5 inches. These are held in reserve. The waste gases are conducted to the atmosphere by a rectangular uptake and two steel stacks.

West of the boiler room in the same building is the engine room containing four Corliss-driven ice machines. These were built by the Vilter Manufacturing Company, of Milwaukee, Wis. There is one 125-ton machine, consisting of two 18x36-inch double-acting ammonia compressors driven by a 400-horsepower cross-compound condensing engine; two machines of 55 tons capacity, each consisting of one 17x34-inch ammonia compressor operated by a tandem compound-condensing engine, and one machine of 10 tons capacity operated by a simple non-condensing engine. On the cross-compound an automatic oiling system keeps the bearings flooded, oil being pumped from reservoirs under the base of the engine by a small pump operated from the rocker arm of the low-pressure eccentric. The bearings of the other engines are arranged for oil-cup lubrication, while the cylinders are furnished with Phoenix force-feed oil pumps driven from the wristplates. All the engines have heavy-duty frames, and with the exception of the simple engine are belted to a line shaft. The 400-horsepower unit drives an overhead line shaft which in turn is belted to a Westinghouse 30-kilowatt 125-volt direct-current generator. On the wall of the engine room there are gage panels indicating steam, receiver, ammonia head and back pressures as follows: Steam, 135 pounds; receiver, 15 pounds; ammonia head pressure, 210 pounds; ammonia back pressure, 18 pounds.

The ammonia condensers are of the countercurrent type and are located in a covered area upon the roof of the old building. These are two in number and are composed of 24 coils of 2-inch pipe, 24 pipes to the coil and 22 feet long. For the raising of condensing water over the cooling towers, a Goulds triplex power pump is employed and is driven by a belt from a line shaft in the engine room, which also drives the fans of the cooling towers. The two cooling towers, located above the condensers, are built of wood and are each equipped with two 60-inch fans. The steam condensers in connection with all three of the ice machines are of the counter-barometric type and are supplied with water which has previously been used for condensing purposes in the ammonia condensers. They are located on the roof of the building containing the engine room.

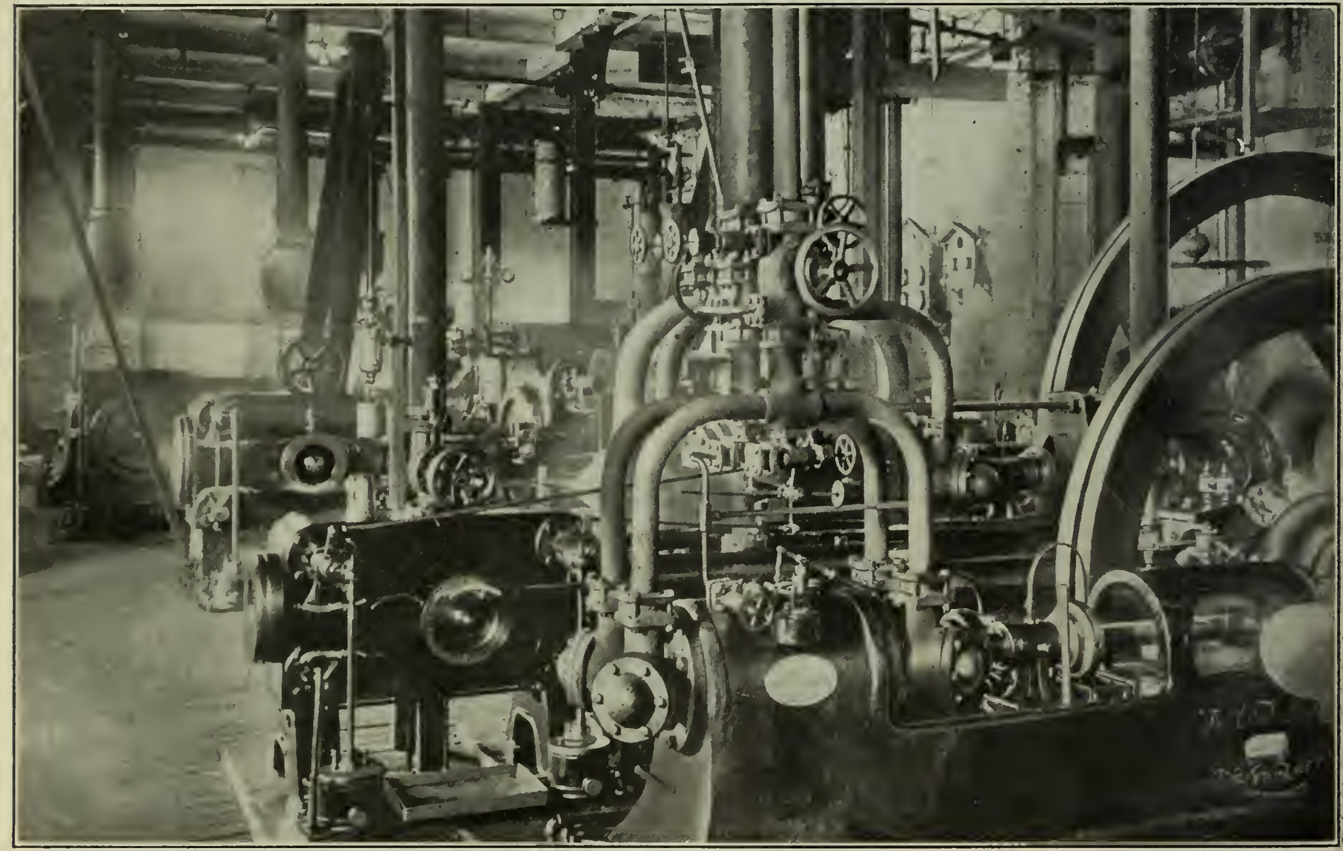

FIG. 4. ENGINE ROOM

There are three vacuum pumps on the condensing system. Two of these are located in the engine room and the other in the basement. The two in the engine room are small horizontal flywheel pumps for wet-vacuum service, while the third is a dry-vacuum pump.

For the information contained in this article the writer is indebted to A. A. Chapin, president of the company, who cordially invites public inspection of the plant.

Modern British High-Speed Steam Engines

Description of What Is Believed to Be Practically the Only Single Acting Compound Engine Built in Numbers in England, Other Makes

BY JOHN DAVIDSON

Allen. Another firm which makes a specialty of high-speed engines is that of W. H. Allen, Son & Co., Ltd., of Bedford, England. The company's design of two-crank compound engine is illustrated in Fig. 20. This engine differs somewhat from those already described, as flat guides of marine type are provided in place of bored ones. These are formed in the back of the frame and not as an extension of the distance piece carrying the cylinders. Again, the distance piece supporting the cylinder from the main frame of the engine is cast in one with the cylinders. This does away with the necessity of a joint underneath the cylinder, but somewhat complicates the cylinder casting. The two cylinders are also placed side by side and the valves on the outside. By this means the cranks are brought closer together and probably a slightly better balance is obtained.

The design of triple-expansion engine manufactured by this firm is shown in Fig. 21. Details of construction of the engine are similar in most respects to those of the two-crank compound engine. The piston valves are formed in one solid piece in the form of a tube, no rings whatsoever being fitted. The frame ends are arranged for driving as shown, and by fitting these ends, the valve can be made of uniform shape and thickness and distortion due to alterations of temperature entirely prevented.

An exterior view of a standard three-crank triple-expansion engine of 600 kilowatts capacity is illustrated in Fig. 22. One very noticeable feature is the use of the doors which are provided to give access to the working parts.

Reavell. Practically the only single-acting engine which is manufactured in any number is the Reavell engine which is made by Reavell & Co., Limited, of Ipswich. The construction of this engine is shown in Fig. 23. In a compound or two-stage expansion engine the second stage is usually obtained by transferring to a larger cylinder the steam which has completed its first stage of expansion in the smaller, or high-pressure, cylinder. The same effect, however, can be obtained by transferring only a portion of the steam which is already expanded in the first cylinder, in which case the second cylinder may be of the same size as the first cylinder, and the portion transferred will be further expanded in the second cylinder, the portion remaining in the first cylinder being utilized as will be described later. The first cylinder would be equivalent to the high-pressure cylinder, and the second cylinder to the low-pressure cylinder in an ordinary compound engine. This latter method is adopted in the Scott compound engine, the only difference being that instead of employing two cylinders, the first stage of expansion takes place at the top of the piston and the second stage on the bottom of the piston in one cylinder.

The cycle will be made clear by reference to the theoretical diagram shown in Fig. 24. Steam is admitted at B' into a cylinder having a considerable clearance volume above the piston at the beginning of the stroke. This clearance volume is already filled with steam at boiler pressure, having been compressed during the latter part of the preceding stroke. Cutoff takes place at E, the actual point being varied by the governor to suit the variations of load. The total steam in the cylinder, which includes that already in the clearance space at the beginning of the stroke, then expands during the remainder of the down-stroke to F. As the piston is nearing the bottom, where a communication is opened between the [illegible]

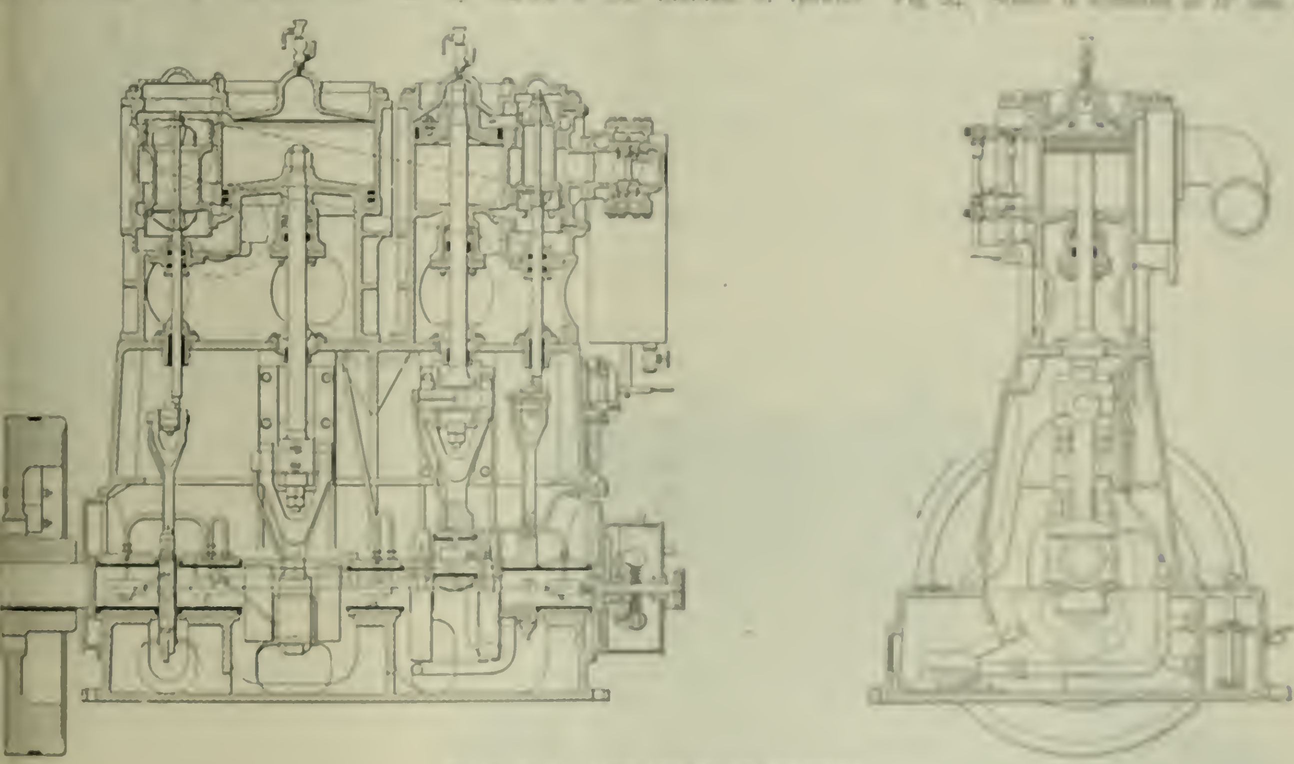

FIG. 20. W. H. ALLEN TWO-CRANK COMPOUND

and the bottom of the cylinder, which remains open to Z, transferring a portion of the steam to the under side where its second stage of expansion takes place, until the termination of the up stroke, just in the same way as it would do if transferred or exhausted to a separate cylinder.

The steam which remained above the piston at the point Z, when the communication from the top to the bottom of the cylinder was closed, is compressed up to initial pressure W.

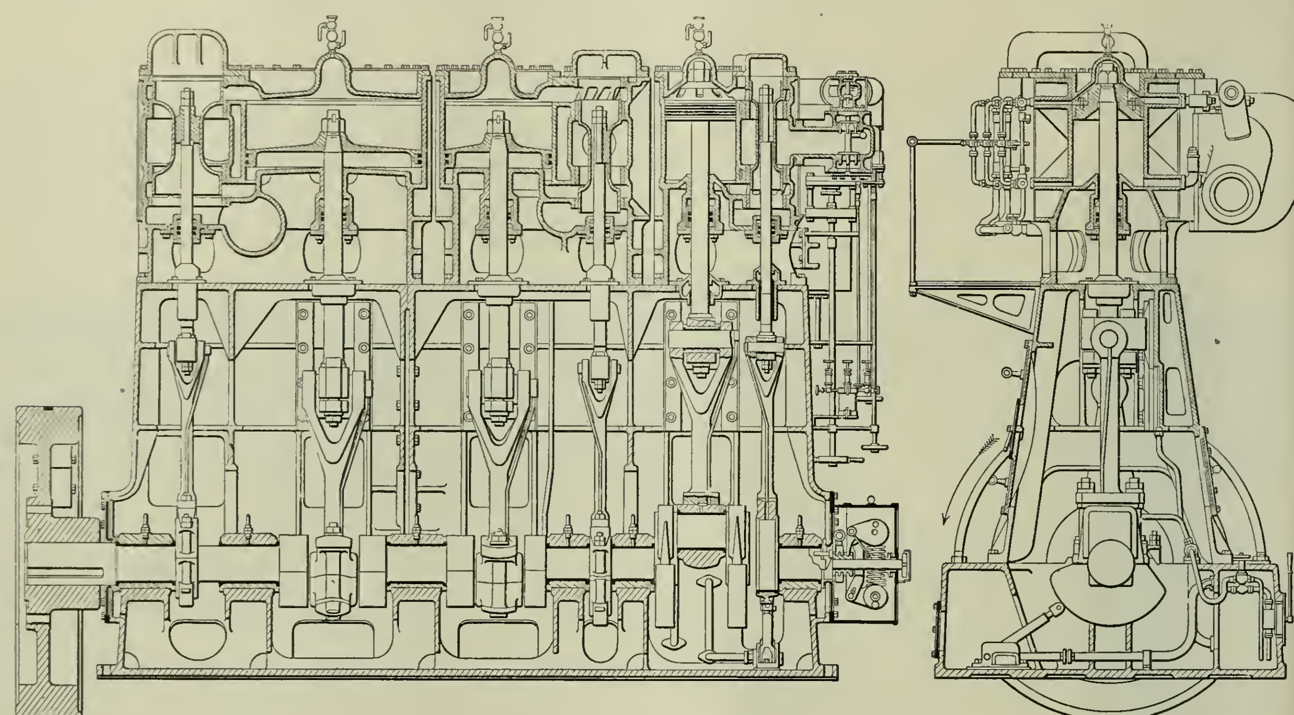

FIG. 21. W. H. ALLEN TRIPLE-EXPANSION ENGINE

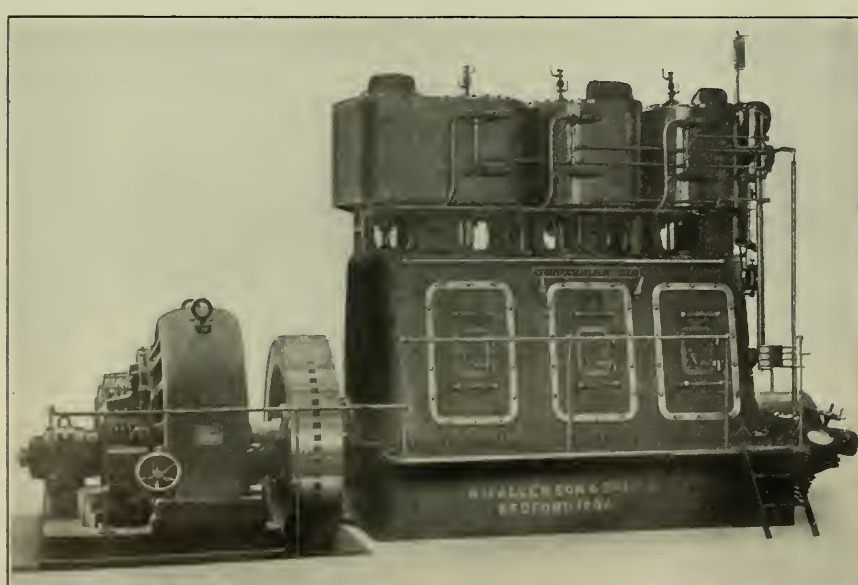

FIG. 22. EXTERIOR OF W. H. ALLEN TRIPLE-EXPANSION ENGINE

Referring to the sectional illustrations, Fig. 23, it will be seen that the steam-inlet flange is on the body of the cylinder itself, there being a steam jacket of considerable size between the working barrel and the outside of the cylinder, and between the inner and outer cover. The valves of the engine reciprocate in a central valve liner secured in the bottom of the cylinder as shown, and the piston reciprocates in the annular space between this liner and the cylinder walls. The steam, entering through the stop valve, passes up between the inner and outer cylinder walls and covers, and is admitted into the valve liner through ports A near the top. From the inside of the liner the steam passes into the cylinder through spiral ports C up to the point of cutoff, the clearance space shown above the piston being already filled with steam up to initial pressure, as before stated, and the cutoff being effected by the valve D driven by a slide rod.

After an early cutoff, the precise point of which is controlled directly by the governor, the steam expands during the remainder of the down stroke, and while the crank is turning the bottom center the ports E in the center of the liner ar[e] opened by the valve F, called the transfe[r] and exhaust valve. This valve F at th[e] same time opens the ports G at the bot[t]om of the cylinder, so that while the piston is making its up stroke a communication is made between the top and bottom of the cylinder, transferring steam a[t] equal pressure and temperature from th[e] top to the bottom of the piston. Thi[s] transfer continues for about half th[e] stroke. In other words, about one-ha[lf] of the steam which was above the pisto[n] is transferred to the other side. Th[e] transfer is closed first by the piston ove[r]running the ports E in its upward strok[e] and immediately afterward by the valv[e] F closing the ports E and G. The stea[m]

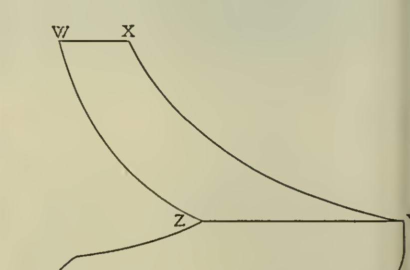

FIG. 24. TREORETICAL DIAGRAM FROM SINGL[E] ACTING COMPOUND ENGINE

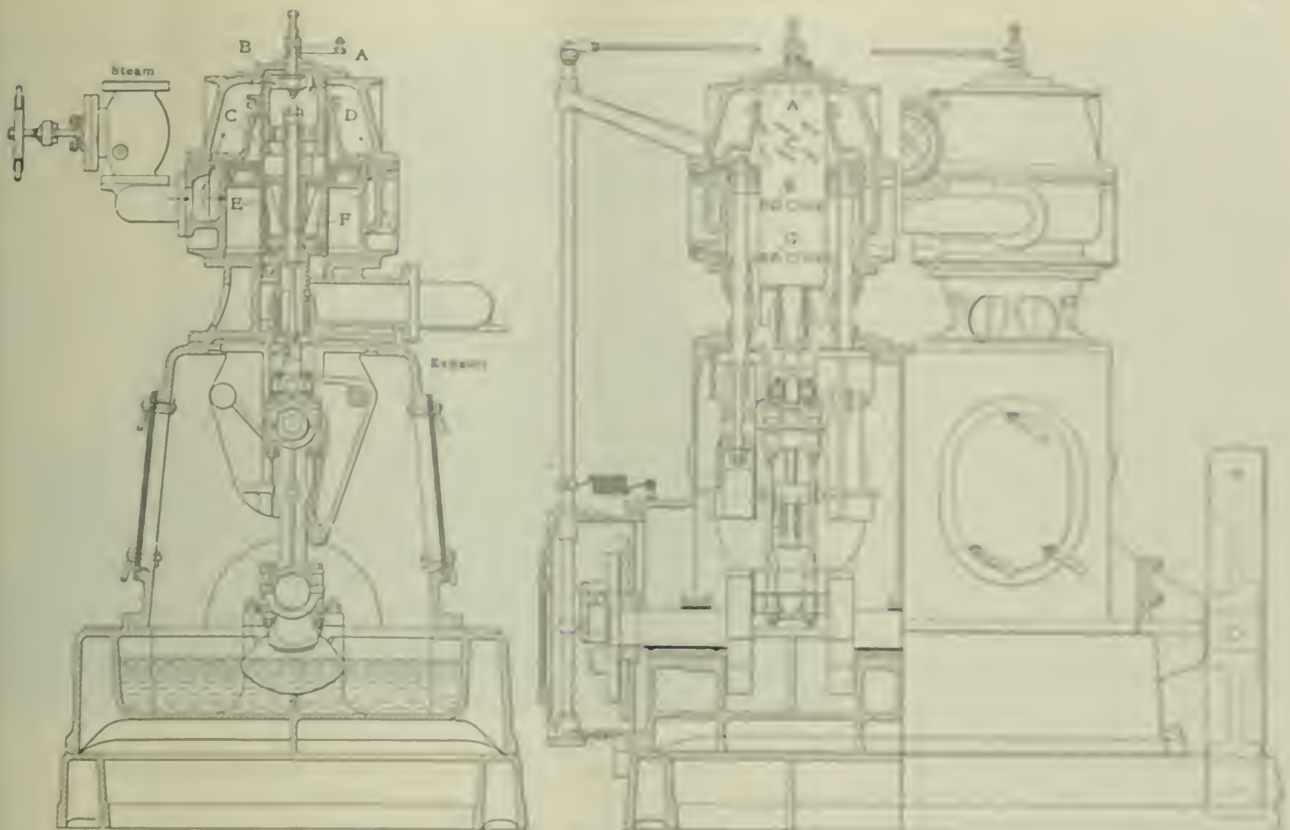

FIG. 23 REAVELL SINGLE-ACTING COMPOUND ENGINE

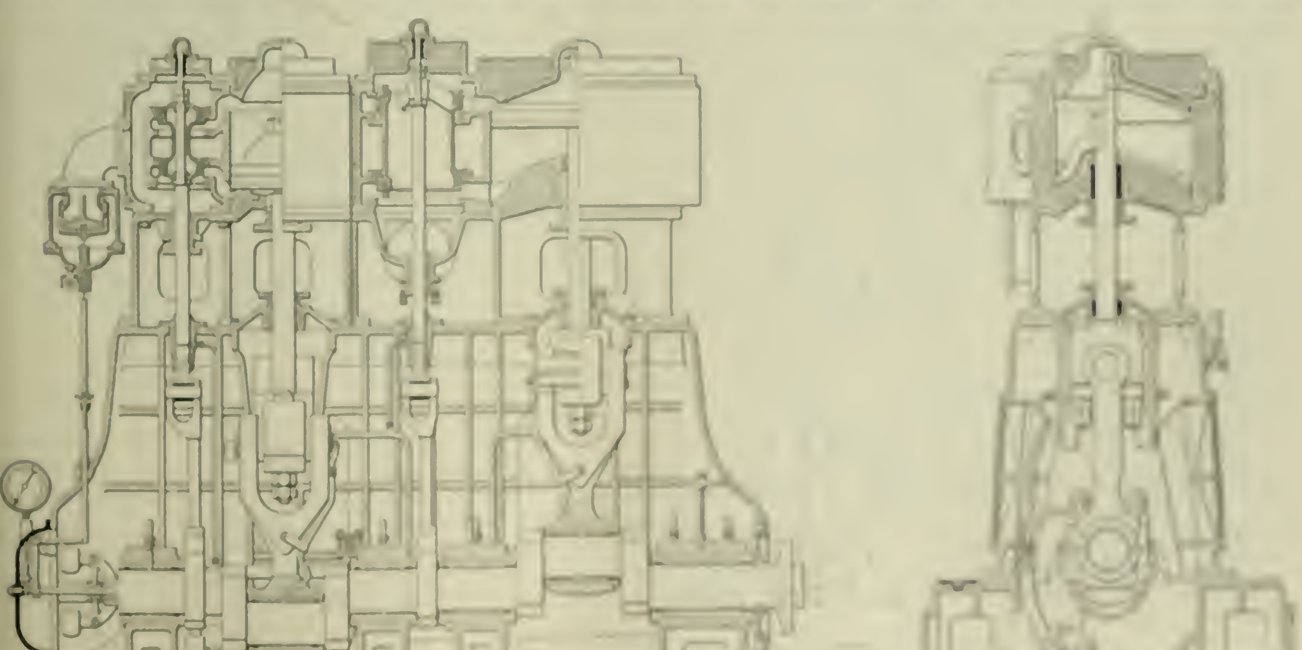
transferred to the under side then completes its second stage of expansion, and at the end of the upward stroke the exhaust valve opens and allows this steam to escape to the atmosphere or the condenser.

In the meantime, the steam which remained in the cylinder above the piston, when the transfer closed, is compressed during the latter half of the upward stroke, and the clearance space in the cylinder is so proportioned that this steam shall be compressed to initial pressure, when the termination of the stroke is reached, and the valve *D* opens for the next admission of steam. By this means the reciprocating parts are brought to rest, and the inertia is taken up by means of the working fluid itself, while at the same time the parts which will be first touched by the entering steam are already heated up to initial temperature and thus cylinder condensation is reduced.

Accurate and regular governing of the speed of the engine is obtained by a crank-shaft governor which acts through the levers and governor bridge *B* and varies the point of cutoff of the admission valve *D*. This governor bridge has two guide studs fixed to it, which pass through holes



[illegible]

in the admission valve *D*. The valve *D*, though reciprocated by the slide rod and having a constant stroke, is free to be rotated by the guide studs on the bridge *B* and the ports in the admission valve are so arranged in connection with the ports in the valve liner itself that a slight axial movement will cause an alteration in the point of cutoff.

The valves are driven by a radial form of valve gear operating from a point on the connecting rod, and the positions of the valve-gear centers are so chosen as to enable a considerable variation in the point of cutoff to be obtained, with an exceedingly slight change in the amount of lead.

Lubrication is effected by the splash system. An oil and water bath is formed in the bottom of the crank chamber into which the bottom end of the connecting rod dips at every revolution, throwing a constant stream of oil over the working surfaces.

These engines are built only on the compound principle, but they are very economical, as will be seen from the results given in Tables 1 and 2. This is no doubt due to the small port clearances and the efficient jacketing made possible with this type of engine. Also cylinder condensation is greatly reduced by reason of the high compression which heats up the surface above the piston to the initial temperature of the steam before the valve opens to lead.

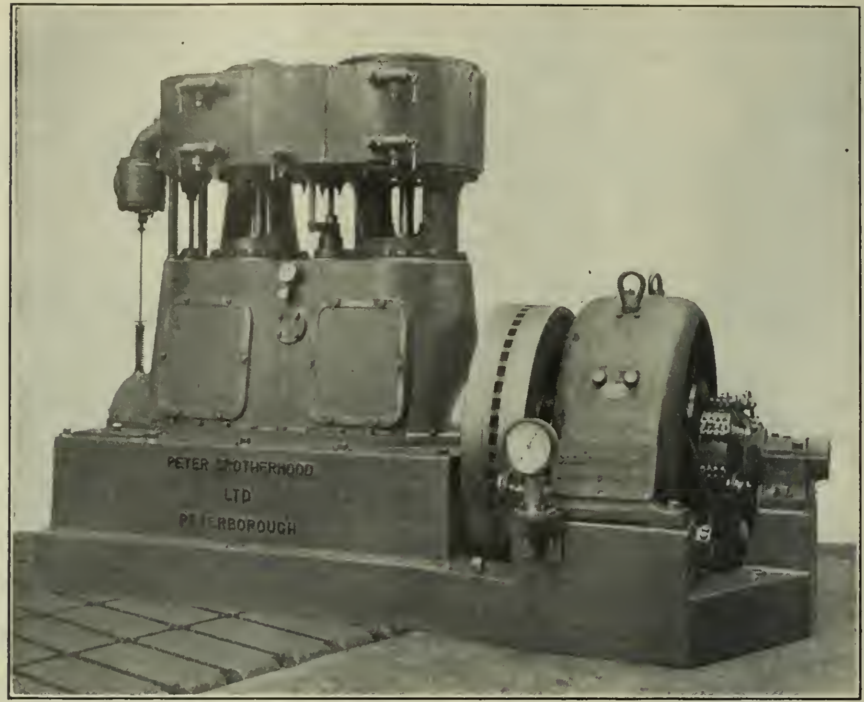


FIG. 26. BROTHERHOOD ENGINE COUPLED TO CROMPTON DYNAMO

Brotherhood. The firm of Peter Brotherhood, Ltd., whose productions are illustrated in Figs. 25 and 26, was really the first high-speed engine builder in this country. In 1883 the late Peter Brotherhood patented his three-cylinder engine. The cylinders in this engine were placed radially at equal distances round the crankshaft, and the three connecting rods were coupled to one crank pin. Further improvements were patented in 1885. A

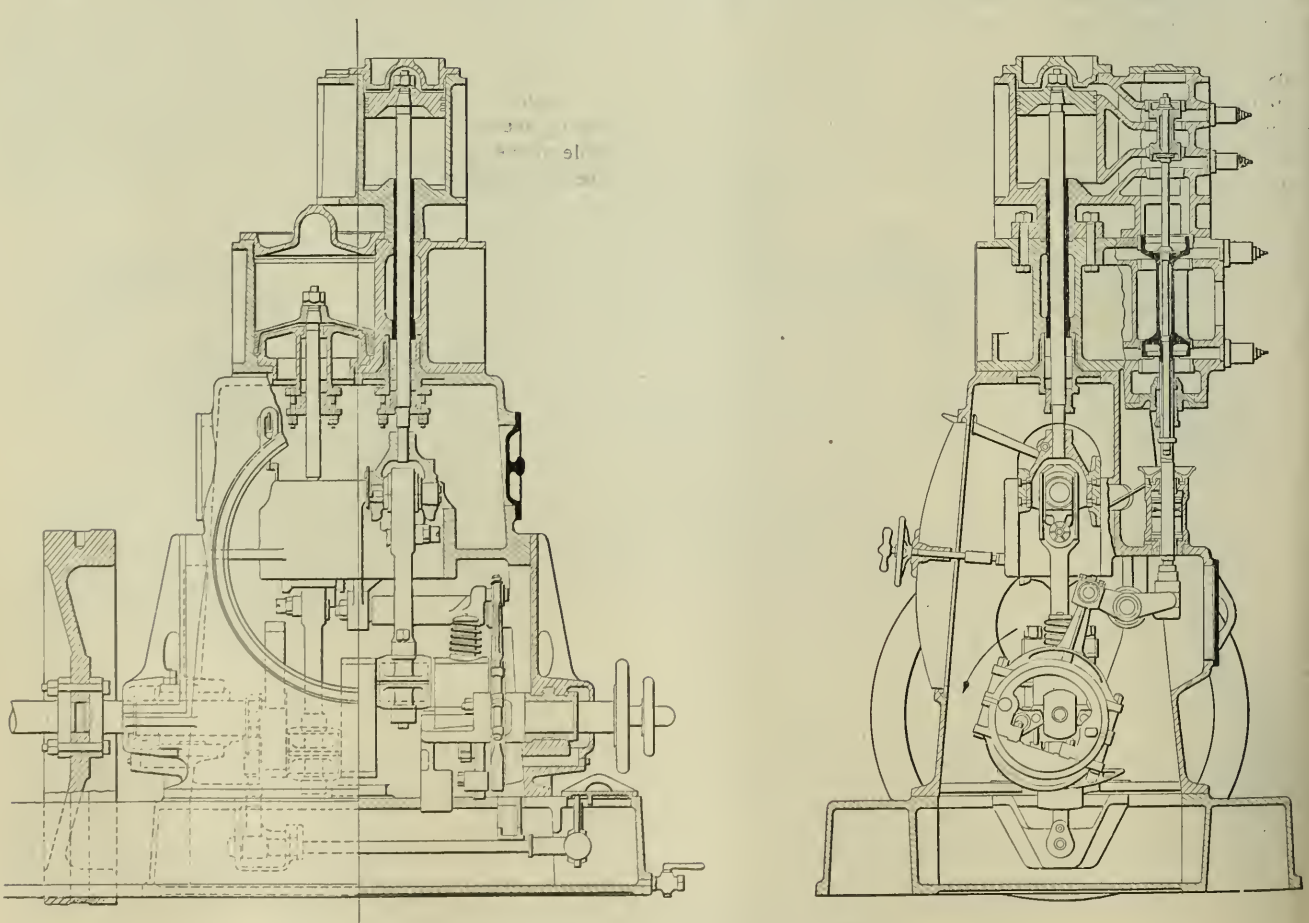

FIG. 27. SISSIN TWO-CYLINDER COMPOUND

large number of these engines were built and it will be remembered that it was only in the year 1885 that the late Mr. Willans patented his renowned central-valve engine, so Peter Brotherhood was the first to recognize in a practical way the need of a high-speed engine. This firm has manufactured a large number of inclosed forced-lubrication steam engines, and quite recently has put down a new works of much larger capacity at Peterborough. These works are fully equipped with modern machinery and are suitable for dealing with engines of the largest size.

The standard design of two-crank compound engine, as built by this firm, is illustrated in section in Fig. 25. It is built in sizes varying from 30 to 700 brake horsepower, and to run at speeds of from 550 in the case of the smallest size to 250 revolutions per minute in the largest sizes. The engines are stiffly built, and the bearing surfaces are of generous proportions. Separate piston valves are fitted to each cylinder, and the arrangement is clearly shown in the sectional elevation. This firm makes a practice of fitting [illegible] straps of bronze, the rods being of forged steel. The pistons are made of forged steel, shaped to facilitate the drainage of water, and are carefully adjusted so as to obtain a perfect balance of the moving parts of the engine.

Special attention is also given to the lubricating arrangements. Two pumps of the valveless type are fitted, except in the case of the smallest engines, and arrangements are made so that either of the strainers may be removed while the engine is running. The other [illegible] giving oil to the gauge [illegible].

Accurate governing is obtained by means of a powerful centrifugal governor acting directly on the throttle valve. The following results of governing may be of interest. Engine No. [illegible] was coupled to a Welsh coal mine, while No. [illegible] is an engine installed in one of the British Government buildings:

	Engine No. [illegible]	Engine No. [illegible]

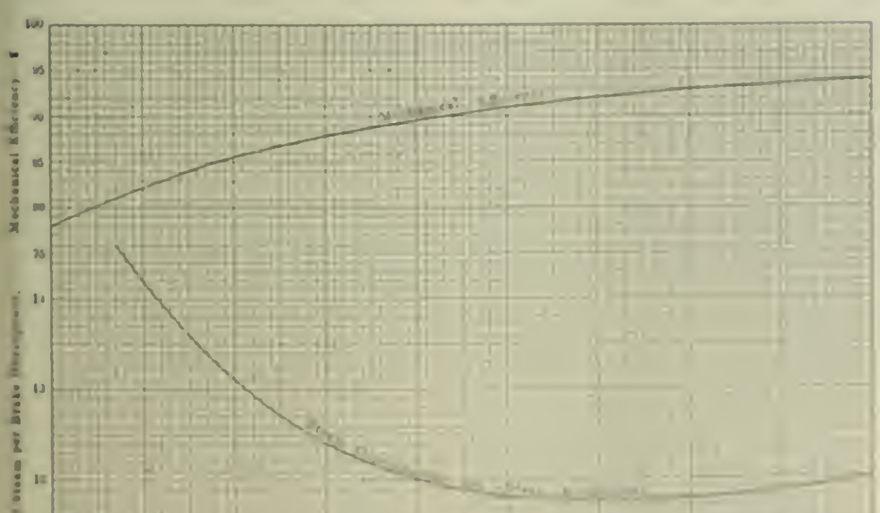

FIG. 29. STEAM CONSUMPTION AND EFFICIENCY OF BRITISH HIGH-SPEED ENGINES

No hunting or irregular working under any condition of load, speed or steam pressure.

The exterior appearance of the engine is shown in Fig. 26, which is a photograph of a Brotherhood engine coupled to a Crompton 400-kilowatt dynamo.

Sisson. An engine possessing both novel and efficient points in design is that manufactured by W. Sisson & Co., Limited, of Gloucester. The engines are made in two types: single-cylinder and two-cylinder compound. The compound engine is illustrated in section in Fig. 27. The high-pressure cylinder is partly superposed, and by this arrangement the cranks are brought so close together that there is only sufficient room for a substantial web between them. The cranks are opposite, and owing to the close distance between their centers, they balance one another almost perfectly. The engine is specially suited for superheated steam, since the high-pressure piston and piston [illegible] through a long [illegible] trunk, so that the steam-heated portion of the rod does not travel into the packing space at all.

The engine is simple. It has only two main bearings, and the arrangement of valves, in all except the largest sizes, is such that there is only one valve spindle working free, and that is only subject to exhaust steam. Both valves are actuated through a rocking lever from a powerful crank-shaft governor. The valve [illegible] are fitted with separate liners of special nickel-iron alloy.

The framing is of ample strength. The lower part forms an oil trough and is fitted with an inspection door and drawoff cork. Large openings are arranged in the ends of the frame above the shaft, which are closed by flanges attached to the main bearing caps, and when these are removed the crank shaft can be readily withdrawn through the opening at either end, for the flywheel can be disconnected from the shaft and again fixed without any difficulty, as it is spigoted onto a solid-flange coupling.

The speed of the engine is controlled by altering the cutoff, although at light loads the governor has a throttling action on the steam. These engines are economical for their size, as will be noted from the two curves given in Fig. 28, which were plotted from data on a 10½x6-inch engine. Initial pressure 150 pounds and atmospheric exhaust.

To illustrate the best results obtainable as regards steam consumption and efficiency with British high-speed engines, when working under ordinary conditions, the curves in Fig. 29 are given, which clearly show the steam consumption and efficiency of a modern triple-expansion engine at all loads from no load up to 25 per cent. overload, when working with steam at a pressure of 175 pounds per square inch, superheated 100 degrees Fahrenheit and exhausting into a condenser with a vacuum of 26 inches.

American Society of Hungarian Engineers and Architects

A number of Hungarian engineers and architects pursuing their professions in this country have organized the American Society of Hungarian Engineers and Architects. The society has two objects: First, to bring in closer touch engineers and architects of Hungarian extraction, living in this country, and to give moral support and information to newcomers; second, to encourage the exchange of engineering, technical and industrial information between the technical men of Hungary and of the United States and to foster technical societies, sciences and industries.

The society will hold monthly meetings where papers will be read and discussed. The membership consists of mechanical, electrical and civil engineers, chemists, architects and craftsmen. Following are the officers of the new society: President, A. Henry Pikler, M. E., member of the American Institute of Electrical Engineers, engineer-in-charge of the transformer department, Crocker-Wheeler Company, Ampere, N. J.; vice-president, Karoly Z. Horvay, architect, chief draftsman, building bureau of the Board of Education, Brooklyn, N. Y.; secretary, Zoltan de Nemeth, M. E., New York Edison Company; treasurer, Sandor Oesterreicher, E. E., associate member of the American Institute of Electrical Engineers and of the American Society of Mechanical Engineers, New York Edison Company; assistant secretary, Ernest L. Mandel, B. S. C. E., Bureau of Commissioner of Public Works, New York City. The society's business address is P. O. box No. 1031, New York City.

Graphite as a Lubricant for Gas Engine Cylinders

By Walter N. Durant

Becoming interested in the above subject and having access to a new 6-horsepower horizontal engine, using city gas for fuel, I determined to make some experiments. Finding it impossible to mix graphite and oil and feed it through the ordinary lubricator, the experiments were confined to feeding the graphite dry through the air intake and continuing the use of cylinder oil through the lubricator. At first about an ounce of graphite was fed through the air intake at short intervals, but after each charge the engine would show increased internal friction; however, it would quickly pick up and then appear to run smoother than before. The quantity of graphite was reduced and it was soon found that the best results were obtained when the engine was not given more graphite than could be consumed in the cylinder, or about 1/12 to ⅛ ounce per horsepower in a 10-hour run. This amount should not be fed all at once, but distributed as evenly as possible throughout the 10 hours.

The experimenting extended over a period of four months, and during that time the engine was given some severe tests. The spark plug was always in good condition and never missed fire, or became carbonized or short-circuited. The cylinder and valves were frequently examined; the latter were in fine condition and the cylinder did not show a sign of a scratch, but had that smooth, dull appearance which indicates the absence of friction. Unfortunately it was impossible to determine the amount of fuel saved by the use of graphite, as the engine was under a constantly varying load.

Desiring to know what others thought of graphite as a cylinder lubricant, I wrote to 45 prominent gas-engine manufacturers, asking if they recommended its use in their engine cylinders. The majority of replies stated that the writers had none, or very little personal experience, and declined to express an opinion. The answers containing advice were interesting, but rather conflicting, and no information could be gained from a reply like this:

"It is not customary with us to use graphite in the engine cylinders, although we sometimes use a little."

The following is a little more explicit:

"The great trouble with graphite is to apply it properly, so as not to plug the rings and make them stick. If properly applied, however, graphite is indeed an ideal method of lubrication, but, of course, must be used with oil."

A prominent firm making high-grade auto engines writes:

"We would recommend the use of graphite once in a while in your crank case. Same will do no harm. It has a tendency to close the pores of your cylinder and polish same up so as to increase the compression. It is a good thing."

A large marine gasolene motor manufacturer also says:

"Smear the cylinder walls with it. Once a month is often enough to do this. Of course, in addition the regular amount of oil should be fed through the multiple oiler. Graphite will help to retain good compression."

Another well known gas-engine company writes:

"We use more or less graphite in connection with lubrication, and where properly used much better results can be secured than with lubricating oil alone. If the cylinder has been allowed to cut slightly because of lack of oil there is nothing that will put it in shape so quickly as the use of graphite. Where good flake graphite can be mixed with oil and fed to the cylinder good lubrication is certain."

The manager of a large company making gasolene marine engines writes:

"We consider graphite the best lubricant in the world for gas-engine cylinders. The trouble in using it is in getting it into the cylinder. So far no satisfactory means have been devised. We think so much of the lubricating qualities of graphite in cylinders that we make it a rule thoroughly to coat the inside of every cylinder with it before sending our engines out from the factory. If one of our customers should ask us the question we would tell him to use it by all means if he could get it into the cylinder."

A New York City builder says:

"We think graphite lubrication is very good provided you have the proper means for furnishing the graphite in the required and constant quantity so that it will reach the parts to be lubricated."

The objections to its use were: "Forms lumpy spots on valve seats. Has a tendency to carbonize spark plugs. The expense in using it would overcome the advantages."

Nearly all of the firms which did not recommend the use of graphite, pointed out the impossibility of mixing graphite and oil and the certainty of clogging the lubricator if fed in that way. Aside from this, the only objection I can see is in using too much at one time in small cylinders.

A Boiler as a Water Supply Tank

The mistakes and absurdities that inevitably blaze the path of the inexperienced technical graduate who launches out on his own hook in an advisory or supervisory capacity are exemplified in the device described herein in connection with the water supply in a hotel building.

The house pumps in this hotel are two electrically driven centrifugals, one of which is always held in reserve. The boiler plant consists of two 72-inch by 18-foot horizontal return-tubular boilers, cross-connected by a steam drum as shown in Fig. 1, and used alternately. The genius who performs the function of consulting engineer to the owners of the property in question, thought it would be a capital idea to utilize these boilers as pressure tanks on the house water-supply system, during their periods of temporary inactivity as steam generators, instead of placing a tank for this purpose in the attic.

Accordingly, acting on the inspiration, intending to connect the blowoff pipes from the boilers to the house water system, as shown in Fig. 2.

The purpose contemplated in the installation of this contrivance was to pump

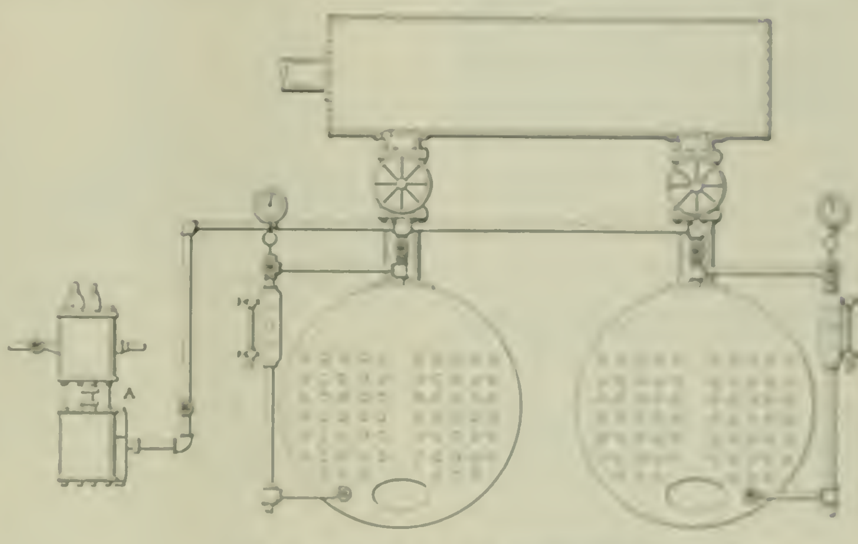

FIG. 1. SHOWING AIR-PUMP CONNECTIONS

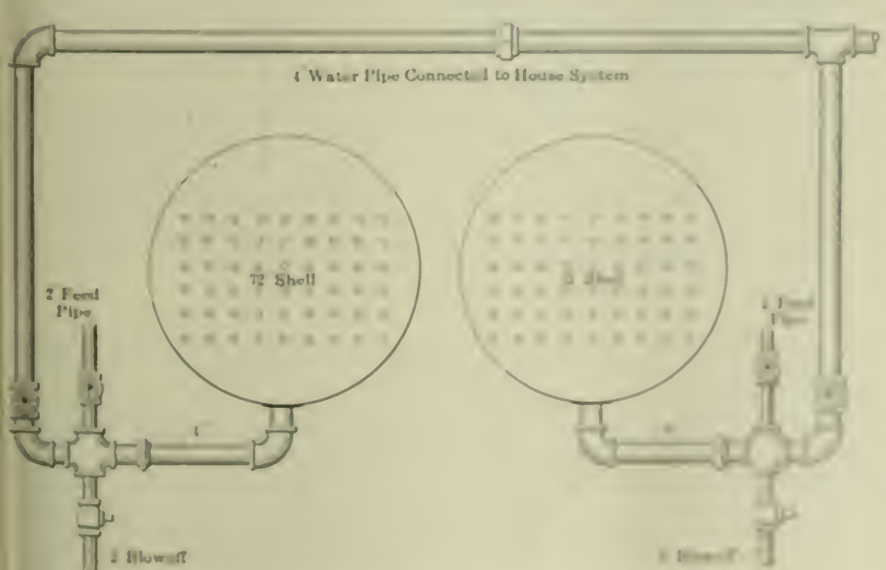

FIG. 2. SHOWING [illegible] CONNECTIONS

he had a discarded 8-inch Westinghouse air pump, of the locomotive type, rigged up as shown at *A*, with the discharge pipe coupled to the water column connection to the steam space in each boiler, further

an 80-pound air pressure on the water in the boiler out of steam service and then to cut the boiler in on the house system and permit the expansive force of the air to send the water through the pipes until the pressure would drop to 60 pounds, the house pump being cut out in the meantime by an automatic switch in the motor circuit set to open at 80 pounds, and which would again operate to close the motor circuit at 60 pounds, and thus set the pump in motion again until the 80-pound air pressure was reestablished, when the same cycle of events would be repeated. The ultimate object of the whole thing was to economize on the power expended in driving the centrifugal pump, that power being supplied from an outside source.

The job was begun some months ago, but at the time of this writing it has progressed no farther than the air connections to the water-column pipes. Whether the deviser of the apparatus got a tip from the boiler inspector, or was called off from some other source, or dropped it of his own accord, or is only holding it in abeyance, to be completed later on, is not known.

Leaving out of consideration the fact that the safety valves on these boilers are set at 80 pounds and that the air [illegible] is a [illegible] point of [illegible] without [illegible], and would probably be doing [illegible] well to give a [illegible] of the [illegible], it would be interesting to know what "practical" men think of the project on general principles.

Babbitting a Pinion

Some time ago a loose pinion, 18 inches long, required babbitting. As I was unable to babbitt it on the shaft, it was removed and a wooden roller dressed down, supposedly the same diameter as the shaft. When I tried to replace the pinion on the shaft, I found that I had dressed the roller down too much, making the babbitted hole too small for the shaft.

I had another old shaft of the same diameter with a long keyseat at one end, the edge of which was a trifle higher than the rest of the shaft. The end of the old shaft was put in the babbitted hole of the pinion, and taking a half hitch with a chain around the shaft, with the aid of two men to turn the shaft, the weight caused the shaft to work down through the babbitt as it revolved, the high side of the keyway acting as a cutting tool, making a nice fit in the pinion to the shaft.

Friction Clutch Trouble Remedied

For the benefit of those who are having trouble with friction clutches, I will cite an experience that ended my clutch troubles. One clutch in particular gave considerable trouble. Four arms holding the shoes broke one evening, and were replaced. After a few weeks one of the arms on the spider cracked, necessitating a new spider. In a few weeks more another arm on the spider broke. We replaced the old spider with the new, and proceeded to line it up. After lining up we threw the clutch in and tightened the shoes. That was as far as I had ever seen any lining done by anyone, and leaving off at this point was where we had been making our error. After tightening the shoes the clutch was released and thrown in again, and as I was watching it closely I saw the spider move a little to one side. This was where the trouble was. In tightening the shoes we had not got an even strain on all of them and on closing the clutch the tightest shoe would crowd everything out of line, there being a small amount of lost motion in the journal. We equalized the strain on all the shoes until we could throw the clutch in at any position and have it remain true.

In lining clutches on quills, the opposite end of the quill should be carefully lined. If one side is pushed out it shows that the opposite shoe is too tight. Either release it, or tighten the side that is out. A good fit is all that is necessary to do the work.

Remoh Lenoie.

Keene, N. H.

A Homemade Condenser

In the December 29 number M. D. Casper asks for a description of a homemade condenser for exhaust-steam heating. There are steam plants run on the vacuum system giving perfect satisfaction, where no condenser is used; simply a receiver tank which collects the air and water in the system; these in turn are pumped out by a vacuum pump which maintains a constant vacuum of any desired degree in the returns. In the sketch *K* is a square or cylindrical vessel, *M* is the receiver main and *P P*, etc., are the returns. The receiver main is connected to *K* by the pipe *A*. Valve *C* is for the injection water. At *B* is a perforated rose which scatters the water over the entering steam. At *H* is an auxiliary water pipe connected to a pump or city main. It is to be used should the condenser get too hot through shortage of injection water, etc. The pipe *E* is to be connected to the air pump; a check valve is shown on the end of it.

The form of a common jet condenser is immaterial, but care should be taken that the mains cannot be flooded to such extent that the water will reach the engine. A suitable relief valve attached to the condenser tank would be advisable.

HOMEMADE CONDENSER SUGGESTED BY MR. NOBLE

Kerosene in Steam Boilers

I have noticed for years first one letter and then another dealing with the use of kerosene for removing scale in steam boilers, also the devices for feeding it. While the arrangements for using kerosene show much thought and no small amount of ingenuity, the same amount of thought on the natural philosophy of the thing would convince anyone that using kerosene in a steam boiler with steam over 212 degrees Fahrenheit is time wasted.

I have tried kerosene in boilers under pressure and used it in boilers with no pressure, and the only time I have found it of any use as a scale remover is when a boiler may stand idle and empty and the kerosene put in, then slowly feed water to the boiler until full. Then, after about one hour, let the water out, so as to allow the oil to cover the tubes, heads and shell and allow the boiler to stand as long as possible. A good dose of rainwater in a steam boiler is the best scale remover I have found yet.

Regarding kerosene in boilers under steam pressure, I have noticed that a long time before I could hook the boiler to the others, the engine and boiler room were full of kerosene fumes. As I only have about 20 pounds steam pressure, how much kerosene will be left when I connect it to the other boilers?

The boiling point of fresh water is 212 degrees Fahrenheit, at sea level. I have often noticed on a barrel of the best illuminating oil the figures 150 degrees, and have assumed this was the point it would vaporize at. Now there is some difference between 150 degrees and the temperature of steam at 100 pounds pressure, and I have come to the conclusion that the kerosene in a boiler has passed off in the form of vapor long before any steam is used from it.

I am afraid a good many engineers are under the impression that kerosene can be pumped in a boiler under steam pressure and help remove scale, but it will not do the work.

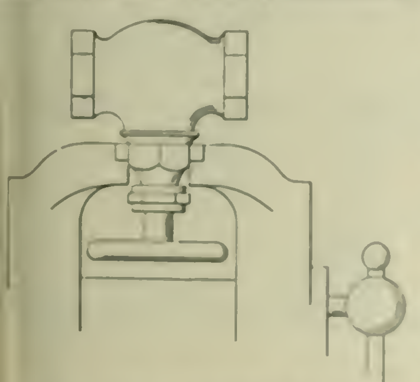
JAMES C. MELLEN.

Brooklyn, N. Y.

Globe Valves

Many practical hints were given in Mr. Wakeman's article on globe valves, published in the January 5 number. In regard to valve disks, the flat spots referred to certainly form an effective locking device, as in nine cases out of ten it is useless to try to remove the nut with a monkey wrench after the disk has been in use some time. If the disk is first split in two or three places, and a piece taken out, the rest will generally turn easily enough without doing any damage to the nut.

This operation is more simple than filing down the flat sides, as recommended



HOW TO TAKE THE BONNET OF A GLOBE VALVE OFF

by Mr. Wakeman, and as the nut is apt to work loose, due to vibration in the steam pipes, I think the locking arrangement preferable.

It is a good idea to take off the bonnet of a valve before it is put to use, but these bonnets are often screwed up so tightly before leaving the shop that a monkey wrench will not loosen them without slipping and rounding the corners.

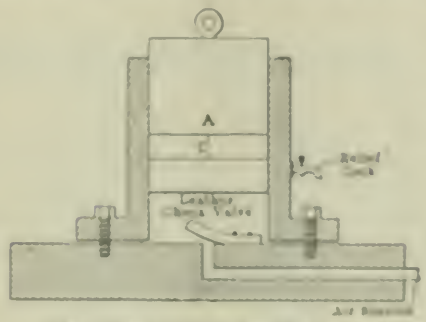
The safest way under any circumstances is to put the valve in a vise, as shown in the sketch herewith, with a piece of tin bent over the jaws to prevent marring the hexagon surface. Then screw a piece of pipe in one of the openings, or in both if the bonnet is very tight, and it is bound to come loose with the least possible chance of springing or twisting the body of the valve out of shape.

R. CEDERBLOM.

Gary, Ind.

Badly Worn Dashpots

A short time ago a young engineer was called upon to set up a large engine. The engine in question was an old-fashioned



REPAIRING A BADLY WORN DASHPOT

Corliss, and the worn dashpots gave considerable trouble. As he could not induce the firm to put in new ones, he had to devise some method of repair.

The dashpots were of the old-fashioned type, with a solid plunger, the valves being closed by a dead weight. The dashpot plunger, when new, was turned up to an easy fit in the dashpot, at the bottom of which was a leather check valve to control the air. The dashpot stood on a cast-iron base plate having a hole drilled in it from the side and connecting with a vertical hole in the center of the dashpot underneath the leather check valve. When the plunger of the dashpot was raised it created a vacuum, causing the leather check valve to be raised, thereby admitting air to the dashpot. When the valve was released and the plunger fell, thus closing the valve, the leather check valve closed, retaining a portion of the air in the dashpot and creating a cushion which prevented the plunger from striking the bottom. At the side of the dashpot was a cock to regulate the amount of air, as required. These plungers were so badly worn that the air leaked out, allowing them to pound on the bottom of the dashpot each time they seated. The regulating cocks were of no use whatever, as they were entirely closed.

As there was a small lathe on the premises, run by another engine, the engineer took out the plungers and turned a groove in them at the center, then to take [illegible] two pump packing rings with a good working fit, as at A. The rings were peened so that they were a trifle larger than the inside of the dashpot, thus causing them to be slightly pressed together when in place. When the engineer got the dashpots adjusted again he found that they worked nicely and he has had no further trouble.

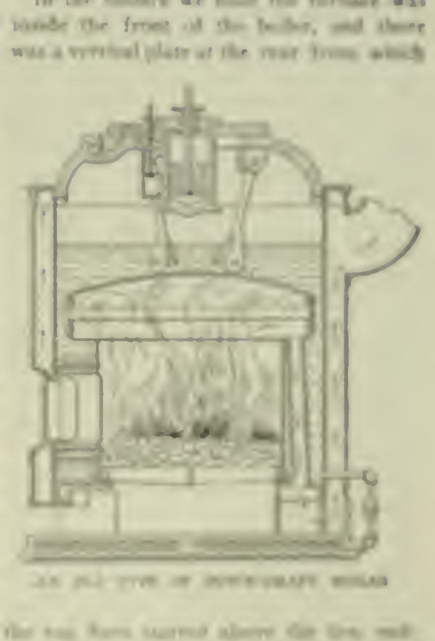
Down Draft Furnaces

The first "down-draft" furnace was patented in England in [illegible] by Lord Dundonald, a draftsman who amused himself with engine and boiler experiments. The patent expired in [illegible]; in [illegible] they began to be made in New York City and other places and were approved by leading engineers, for two reasons: First, the hottest fire was under the thinnest and most solid body of water in the boiler; second, the priming, foaming and spitting due to the up-draft furnace were not nearly as bad with the down-draft furnace.

The plans were different from ours, as the fire was under the boiler at one end and the hottest gases under the other end, whereby if there were any unequal expansion, it developed about the space of the wall dividing the two horizontal planes and gas chambers, and the solids in the water were found over that wall at the bottom of the boiler.

In the boilers we built the furnace was inside the front of the boiler, and there was a vertical plate at the rear from which



AN OLD TYPE OF DOWN-DRAFT BOILER

the top flues started above the fire, leading to a back connection surrounded with water inside the boiler shell. Another row of flues or tubes passed below the first row, from the back connection to a front one; another row below the second passed the front one to a [illegible] in the rear end of the upper side of which [illegible] the smokepipe. These three connections were [illegible] by [illegible] inches of water in the boiler, so that wherever there was heating surface the water got some benefit.

In the [illegible] boiler the rear gases [illegible] the whole end of the boiler, but did no good, because heat will not move downward, unless it is forced, and there was not heat enough at that point to raise any perceptible heat above that due to the steam already there.

There was another boiler with down draft, built for a Mr. Baxter, a sketch of which is shown herewith. It is the true Dukdonald boiler, but the engine in the top was the invention and patent of William Murdock, a Scotchman, in the year 1770. So it may be seen that Solomon was not such a fool when he said: "The thing that hath been is the thing that shall be;" and "there is no new thing under the sun." Though I quote him, I demur thereto; for if there had not been an original somewhere, there could not be copiers.

Peter Van Brock.

Jefferson, Ia.

A Remodeled Steam Plant

During the fall of 1907, when the writer came on the scene, the plant belonging to the Hoopeston Gas and Electric Company consisted of a 150-horsepower Stirling boiler, two 100-horsepower tubular boilers, one 14x14-inch Ideal and one 11x24-inch Corliss engines, three 1100-volt single-phase 125-cycle alternators and two 500-volt direct-current generators. The electrical machines were belted to the engines in such a way that one engine could carry the day load, which was comparatively light, and the other the heavy evening load until midnight. The day load consisted of a few 500-volt motors scattered around and a number of flatirons. The night peak load was occasionally as high as 80 kilowatts, and the street lighting consisted of five arcs and 128 thirty-two-candlepower incandescent lamps on a midnight moonlight schedule.

The equipment was of ample capacity for the existing load, but any considerable increase could not be handled without further additions to both prime movers and the present single-phase system, or a complete remodeling. Steam leaks were manifold and multiform. Secondary wires were of small cross-section and of great length. All lines were in bad shape, and it was no uncommon occurrence, on wet, windy nights, for the circuit-breaker to show signs of great activity.

With the advent of a new enterprise an aggressive power campaign was decided upon, and a 85-kilowatt generator was purchased and belted to the Corliss engine. Shortly after, the question arose as to new prime movers and a twin cylinder, single-acting, 280-horsepower gas engine was decided upon. Anthracite suction-gas producers were also purchased, and a 200-kilowatt generator was bought and belt-connected to the engine. Preparations for the immediate installation of the new equipment were at once made and the existing apparatus was crowded to the rear of the building. Part of the front wall was removed, one stack taken down and two tubular boilers skidded to the exterior so that foundations for the producer equipment could be constructed.

For a period of some seven months the Corliss engine struggled along under the heavy load imposed upon it, occasionally developing as high as 120 horsepower. The main-bearing pillow block was reënforced and a support placed under the guides, hoping to delay the inevitable, which finally came at 4 a.m. one morning, in the shape of a broken pillow block and cap, which allowed the shaft to drop down and forward, twisting the valve rods, breaking one steam arm and throwing one exhaust valve under. No one knew how it happened, but it was generally ascribed to old age and heavy overloads. The generator was shifted over to the piston-valve engine and for two months this engine ran continuously with only an occasional stop for packing purposes.

The old wooden switchboard was dismantled and a new five-panel marble board installed, carrying oil switches and like apparatus in keeping with the rest of the equipment. A 30-horsepower 2000-volt motor was purchased and direct-coupled to one of the old 500-volt machines, which had hitherto been belt-driven. Owing to the fact that this machine was only of 56 kilowatt capacity and that it had 150 horsepower in small motors already on its mains, no more direct-current power was solicited, but three-phase 440-volt power was pushed and at the end of six months 85 horsepower in this type of motors were connected and at the end of another six months 135 horsepower.

An uptown office was established and the supplies were taken care of from thi[s] point. Our only competitor, who ran [a] plumbing shop in connection with th[e] electric-supply business, was bought ou[t] and the light company thereafter did a[ll] wiring and furnished all supplies. A[n] advertisement was run in each of the loca[l] daily papers and changed weekly.

Owing to the fact that the primary vol[t]age was doubled and inasmuch as th[e] lines were sadly in need of repair, co[n]siderable time was spent placing these i[n] first-class shape, some 20 transforme[rs] were thrown out and all meters were r[e]adjusted for the new frequency. A num[]ber of fan motors were changed and

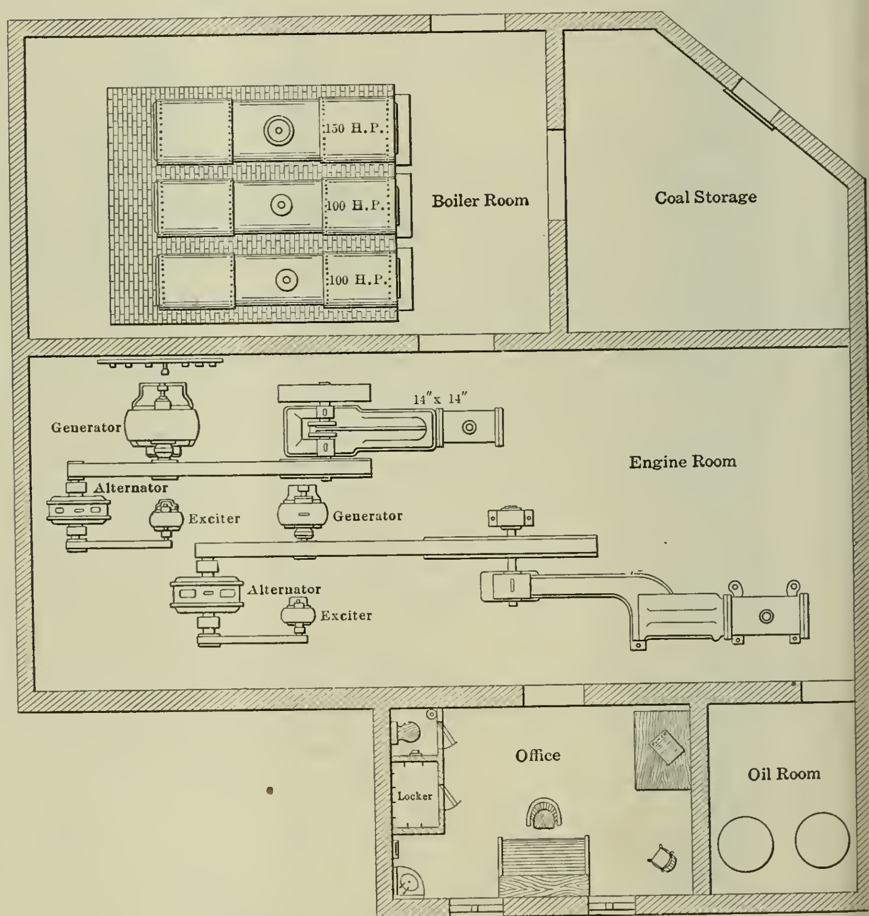


FIG. 1. THE OLD LAYOUT

[f]ew small single-phase motors were got rid of.

As is shown in Fig. 2, one boiler, engine and generator were left in complete repair so that this apparatus could be started up at once should the gas equipment be disabled. It has been found necessary to resort to this arrangement two or three times for a day or so at a time in order that minor adjustments might be made on the gas engine.

Seeing the need of means of hoisting the coal to the tops of the producers, a motor-driven chain hoist was added to the station equipment, and a power head the engine, owing to governor troubles and improper mixtures. All this was corrected as soon as we secured a practical gas man to take charge of the equipment. The engine is called upon to deliver about 125 horsepower during the day and upward of 250 horsepower at night until 11 p.m., when the load drops to 25 horsepower.

A marked difference was at once apparent in the coal consumption, notwithstanding the unfavorable conditions the plant operates under, running for one-third of the time at practically one-tenth load. The company is now figuring with

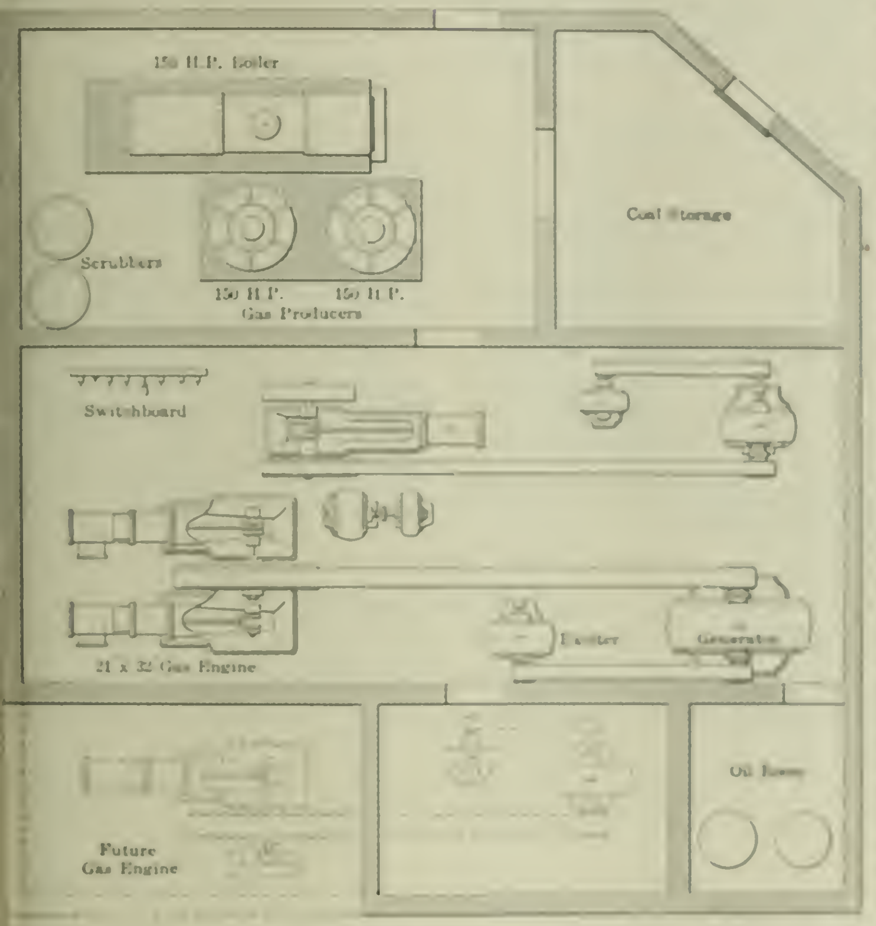

FIG. 2. THE NEW ARRANGEMENT

[d]riven by a 5-horsepower motor for the deep-well pump was put in. This latter proved a great saving, as the consumption of city water for the gas engine for cooling purposes and for the wet scrubber in the producer room was no inconsiderable item. All wires were taken from the ceiling and placed in conduits under the floor and the ceiling taken down. This additional head room afforded better light and ventilation and presented a more pleasing appearance.

In due time the new equipment arrived and was placed in position. For the first few months we were troubled somewhat by the slowing down and speeding up of the engine builders for a second engine of the same type, but of smaller size, and when this is installed and running during the lighter load periods, 1¼ pounds of coal per horsepower hour will doubtless be realized.

The dotted lines in Fig. 2 show the probable location of the next engine to which will be belted the 85-kilowatt generator. When this change is made the steam engine and remaining boiler will be removed, which will make room for one more producer of the same capacity as those now installed.

C. E. Benson.

Hoopeston, Ill.

Drum Motion Distortion

In the article on drum-motion distortion, published in the issue of January 26, I see that I made several statements which may lead to erroneous conclusions, and therefore think it well to give the following as additional to that article.

As has been previously pointed out, this cause of distortion in indicator diagrams may be analyzed by considering the variation in the force existing in the cord during a cycle of the drum motion. This force is the resultant of the spring tension and the force of acceleration of the drum, which act in the same line. Beginning at the head-end dead center, the spring tension is minimum, while the force of acceleration is negatively maximum (under the assumption of harmonic motion); that is, the drum acts as a drag. Thus, the force in the string is the numerical sum of these two forces. At the crank-end dead center, however, the force of acceleration is positively maximum; that is, the inertia of the drum here helps it onward; and therefore the active force in the cord is the numerical difference between the accelerating force and the spring tension at the crank-end dead center. If these forces in the cord are equal at the ends of the stroke (as they may be), and if the force of acceleration increases in the same way as the spring tension, there would be no deformation in the diagram. The latter condition, however, cannot ordinarily be fulfilled, as the spring tension increases uniformly throughout the stroke of the drum, while the force of acceleration increases according to another law, except under the condition of harmonic motion which is only approximately satisfied.

The following numerical example may make clear an interesting characteristic of drum-motion forces. Suppose the speed of the drum is such as to give an initial accelerating force of − 1 pound and, at the end of the stroke, a force of + 1 pound. If the corresponding spring tensions are + 2 pounds and + 4 pounds, the forces in the cord will be 2 + 1 = 3 pounds and 4 − 1 = 3 pounds, and, therefore (for harmonic motion), constant throughout the stroke. Now, if the speed is increased so that the accelerating forces are − 2 and + 2 pounds, we cannot again obtain a constant cord tension by varying that of the spring, because the range through which the two forces operate are equal only in the first case. For instance, if the spring is tightened so that the initial tension is 3 pounds, the final would be 5 pounds (the increase always being constant for the same extension of spring). The forces at the ends of the stroke would then be 3 + 2 = 5 pounds and 5 − 2 = 3 pounds. The conclusion is reached, therefore, that for any drum spring of given strength there is only one speed at which there is approximately no distortion of a diagram of a given length. At other speeds the best tension is obtained as previously described.

J. C. SMALLWOOD.

Philadelphia, Penn.

Verifying Motor Connections by a Diagram

I had just finished reading the "Catechism of Electricity" in the January 5 number, when the chief came in and asked me to reverse the rotation of a motor. We have about twenty motors and they are apparently all shunt-wound. But having the "Catechism" in mind, I looked into the motor and found it to be a compound-wound machine. I could not re-

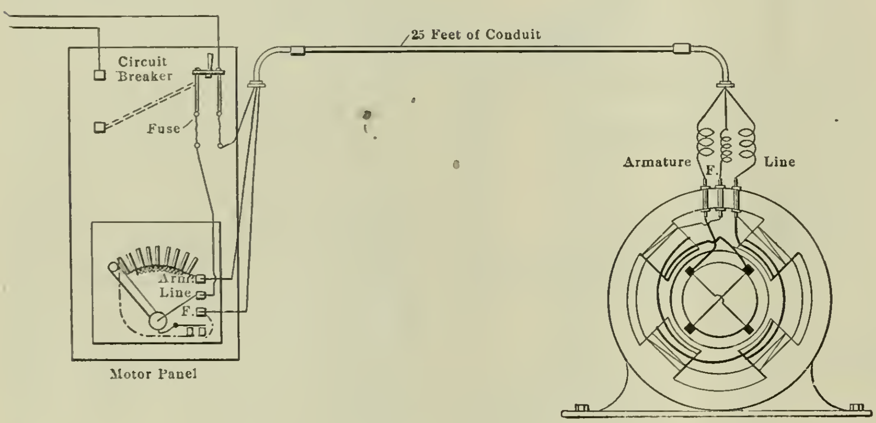

DIAGRAM FOR VERIFYING MOTOR CONNECTIONS

verse the shunt winding alone because that would make the motor differential, and the only way I could see was to reverse the current in the armature by exchanging the leads to the brushholders.

I started the motor up to find out which way it had been running and the starting lever touched the first contact on the faceplate of the starting box, and the motor started off at a furious rate; it seemed to me it turned up about 2000 revolutions per minute, when it should have run 450. I immediately pulled the switch and began looking for a break in the shunt-field circuit. Being unable to find any defect whatever in the circuit, I made a diagram of all of the connections of the motor, which is shown herewith. Owing to the conduit being so long, I had to use a test lamp to "prove" the diagram and in doing this I found that the main leads had been transposed at the motor. This showed me how the motor lost its shunt field. The shunt circuit from the starter to the field winding was all right, but the only return path was through the armature lead instead of the line lead; consequently the shunt winding was connected merely to the terminals of the starting resistance, and got practically no current.

Changing the main leads back again straightened out the trouble and I then reversed the motor by transposing the brushholder cables. I found later that the wiremen had connected the motor up to try it and it had then been disconnected and moved away from its position. When put back it was turned around and the outside leads were connected up backward, as described.

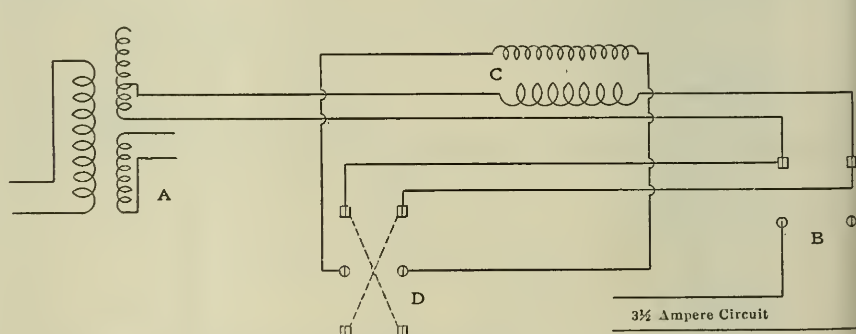
Toledo, O.

Puzzling Transformer Action

I submit herewith an electrical problem, hoping that some reader of POWER may be able to solve it. The accompanying diagram shows the wiring of one section of our switchboard which supplies current to a 3.5-ampere series incandescent



WIRING DIAGRAM OF ONE SECTION OF SWITCHBOARD

lamp circuit for street lighting. The constant-current transformer *A* has two secondary windings, one of which supplies this circuit, and the other, through an inductance regulator, supplies a 6.6-ampere circuit not shown; *B* is the circuit switch; *C* is a 20 to 1 constant-potential transformer which may be connected so as to raise or lower the voltage impressed on the line, a double-throw switch *D* being provided to control the primary current in the transformer or to cut it out altogether, as required. The idea was to produce closer regulation than that given by the steps of the transformer *A*, which are too far apart.

When the switch *D* is closed upward the voltage is boosted, but when closed downward, the transformer *C*, instead of lowering the voltage, boosts it 10 or 15 volts. The question is, why doesn't it buck?

I would esteem it a favor if some other reader would give me a correct explanation.

E. L. MASON.

Garnett, Kan.

Lifting Limitations of a Pump

In the reply to an inquiry in an issue of several months ago, it was stated that a pump will not raise water to the theoretical limit of 34 feet because of the "slippage" and the friction of the water against the pipe walls. This is correct and in the case of a pump designed as an ordinary single-action hand pump in which the bucket can be adjusted to work clear down to the valve, thus eliminating the clearance, your explanation is practically complete if the water is cool and the suction pipe air-tight.

In a pump made as a steam pump is ordinarily constructed there is another and greater reason for its failure to raise water to the theoretical hight, and that is its inability to create a perfect vacuum.

Take, for instance, a pump of such dimensions that the piston displacement is 1 cubic foot, and the cubic contents of the clearance between the piston and cylinder head and the space between the valve disks is 0.25 foot. Then when the piston is at one end of the cylinder and moves to the other the 0.25 cubic foot of air in the suction end would be expanded to 1.25 cubic feet at 3 pounds pressure if there were no suction pipe on the pump and the opening for it closed. Of course this would not be the condition in pumping, and air would be taken from the suction pipe as that in the cylinder is rarefied but under no circumstances could the air in the cylinder, and consequently in the suction pipe, become less than 3 pounds; therefore, the effective air pressure to raise the water would be but 15 — 3 = 12 pounds, enough to balance a head of about 27 feet, and the pump could not raise water by suction to exceed this distance even if all other conditions were as nearly perfect as it is possible to make them. We know 15 pounds is not exactly correct for the air pressure, but this does not affect the principle.

In many pumps the clearance is greater in proportion to the piston displacement than 1:4—the ratio we have considered here—with a consequent lowering of the pump's efficiency in raising water by suction.

Frank L. Wallis

Des Moines, Iowa.

[Mr. Wallis' argument would apply to a pump starting up with no water in the suction end of the system, but the condition on which it is based disappears when the pump is "primed," which is easily and commonly done.—Editors.]

The Surface Condenser

I noticed in your issue of February 16, page 351, an abstract of an article relating to condensing apparatus, which was published in the December 25, 1908, number of London *Engineering*. I submit herewith a copy of a letter which I have forwarded to the editor of *Engineering*, commenting upon the article in question, as follows:

"I was much astonished at the article which appeared in the issue of December 25, 1908, of London *Engineering*, in which the statements were made that the economy to be gained by the increase of vacuum from 24 inches to 28 inches was approximately 17 per cent. on steam turbines, and with the reciprocating engine the same increase of vacuum would result in a saving of only 2 per cent., and that, in order to utilize such a high vacuum, the low-pressure cylinder would have to be built rivaling Captain Ericsson's 14-foot hot-air engine cylinder, and the small economy gained by the increase in vacuum is given as an excuse why the average marine engineer regards low vacuum as justifiable. It appears to the writer that the statements made in this article are not in accordance with the facts and that the use of low vacua as mentioned in marine practice is an exception and, instead of being justified by economy, is only an excuse for badly designed condensing apparatus or a lax engineering department.

"In looking for data on existing practice regarding the best vacua to carry, I have made some investigations among the transatlantic liners, and the best ships with reciprocating engines are carrying from 26 to 28 and more inches of vacuum. Where the results are looked into, the engineers are required to keep the vacuum system tight and carry all the vacuum they can get, and while it is true that greater benefits can be derived from high vacua in a steam turbine than in a reciprocating engine, it is also true that, where primary heaters are not used, the higher the vacuum carried the greater is the [illegible] economy which can be obtained from the plant. The Allis-Chalmers Company, of Milwaukee, Wis., has built more pumping engines than any other firm in the United States and has earned large sums for producing results better than those guaranteed, and the higher vacua have played an important part in those results.

"While the writer was chief operating engineer of the Interborough Rapid Transit Company, New York City, we changed the motor-driven air pump and jet condenser for a barometric type of condenser and increased the vacuum on each of the 8000-horsepower Allis-Chalmers horizontal vertical engines at the Seventy-fourth street station from 26 inches to 28 inches, thereby increasing the power on each of the eight units approximately 272 horsepower, and the economy of the station was increased very nearly in the same ratio. This change was made about seven years ago and the plant is still operating with 28 inches of vacuum, the vacuum being measured with mercury columns connected to the exhaust pipe at a point just below the exhaust nozzle of the low-pressure cylinder.

"A careful test made on the Fifty-ninth street station of the Interborough company showed a decrease in steam consumption of 8 per cent. when the vacuum was raised from 25 to 28 inches. These engines drive 5000-kilowatt generators and the test was very carefully conducted. In view of the results obtained by the test just mentioned, the writer questions the statements made that an increase from 24 to 28 inches of vacuum results in the saving of only 2 per cent.

"The South Side Elevated Railway in South Chicago has 3000-horsepower units on which is carried 28 inches of vacuum and has been for the past three years, and we could give many other instances where high vacua are being carried on reciprocating engines with economical results, sufficient to justify the installation of the high-vacuum apparatus.

"It is true that eternal vigilance is required to keep air leaks out of the system, but the writer submits that it is cheaper to keep the system tight than it is to pump large quantities of air or, what is ordinarily done, run on low vacua.

"Operating on low vacua is due to one of three things: Either the condensing apparatus is not suitable for its work, a lax engineering department, or the policy on the part of the management which will not furnish help enough properly to maintain the plant in good operating condition.

"The remarks in the article relating to vacuum gages are unfortunately true and the writer has yet to find a vacuum gage that will stay correct for any great length of time, but in American practice in any well managed station, mercury columns are installed to check up the gages and the gages are used only as an approximate check on operating conditions. In the larger stations, mercury columns are attached to each unit so that a correct observation can be made at any time."

As to Increase of Salary

An engineer asked me not long ago if I thought it proper for him to ask his employers for an increase of salary. The question looked simple enough, but before giving him my answer I asked him why he thought he was worth more. He replied that the man they had before him received $200 per year more than they were paying him, and the "boss" took delight in telling of paying his old engineer $18 per week, although he was saving him $30 per week over the running expenses of the former engineer.

He said he always made it a point not to ask for an increase, but always tried to show his employers by his work that he was worth all they could afford to pay.

I should like to have the opinion of Power readers in regard to this question. Is it proper to ask for an increase of pay?

The Cummer Engine

The very comprehensive articles on "Setting the Valves of the Cummer Engine," in the December, 1908, and January, 1909, numbers, by Messrs. Allen, Coffine and Francis I found very interesting. To my mind there never was placed on the market an automatic engine with better material, finish and capability of withstanding hard service with the least [illegible] and less [illegible] to keep up than the old Cummer, an engine that has won much praise from those who have known its performance. The only reason I can assign for its not being more prominently known and used is its having peculiar valves and governor.

I had charge of a 100-horsepower Cummer engine for nearly ten years and have often wondered how many hours of thinking, reasoning and experimenting the inventor had put in while designing the engine.

The articles referred to are so clear and concise that no one who ever ran a Cummer engine can doubt for a moment that the advice and instruction contained in those articles alone are worth more than a year's subscription to Power.

My old Cummer has been displaced by a Corliss engine in order to provide for an increased demand for more power.

Refrigerating Plant in Steel Works

Largest Plant in Existence for Drying Air Supply to Blowing Engines; Saves $1 a Ton in Making Pig Iron and Produces More Uniform Output

BY OSBORN MONNETT

It is but recently that the subject of water vapor held in the atmosphere has had any attention with reference to its effect on the operation of blast furnaces. While it has long been realized that all air in its natural state contains water vapor in varying quantities, depending on the temperature and the opportunity which the air has had for acquiring moisture, it was for a long time considered that this was one of the insurmountable difficulties and drawbacks in furnace operation, although all the other elements which go toward the making of steel have had careful consideration for many years.

Advantages of Using Dry Air

At the late meeting of the American Society of Refrigerating Engineers, held in New York City, Bruce Walter, who has been connected with developments in this line from the beginning, brought out many interesting facts based on experience with refrigerating outfits in several different plants. It appears that there are required approximately two tons of ore, one-half ton of limestone and one and one-half tons of coke, to make a ton of iron. In addition to this, five tons of atmospheric air is required to furnish the necessary oxygen. In this enormous quantity of air it can be readily seen that the moisture will be a great disturbing factor. Irregularity in moisture content of the atmosphere under different conditions not only changes the quantity of oxygen delivered from time to time according to the humidity, but each pound of the moisture requires something like 13,000 B.t.u. to decompose it into oxygen and hydrogen. This, of course, reduces the efficiency of the furnace, requires more coke and interferes with the regularity of the output.

In 1897 the Carnegie Steel Company began experimenting under the supervision of James Gayley, who is the inventor of the Gayley dry-blast process, with a view to determining the approximate cost of removing the moisture by means of refrigeration.

Subsequently at the Isabella plant of the United States Steel Corporation, located at Etna, Penn., a large outfit for removing moisture from the air was installed and the results have been highly satisfactory to steel men. The coke saving has been shown to be about 350 pounds per ton of iron, the daily output increased about 10 per cent., the iron produced is more regular in quality, and less air is required, due to the decreased temperature and consequent smaller volume. An

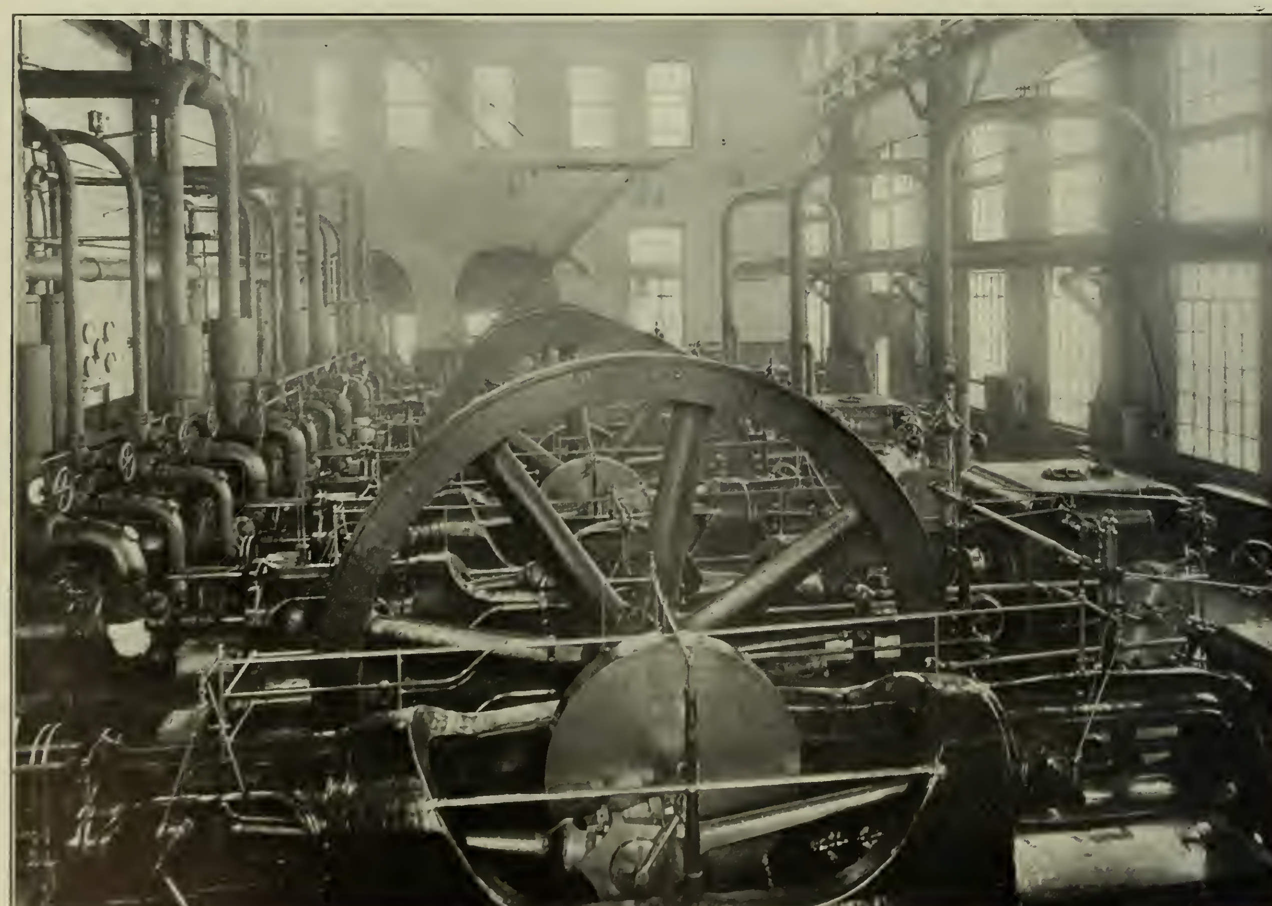

FIG. 1. GENERAL VIEW OF COMPRESSOR ROOM

interesting point in this connection is that the saving in steam used by the blowing engines has been found to exceed the amount of steam taken by the refrigerating equipment. Incidentally there is also a decrease in the quantity of limestone required owing to the fact that the reduction of the amount of coke reduces the ash, and less lime is required to take care of it.

Experience at the Isabella plant and elsewhere, both in this country and Europe, has determined that there is an average decrease of cost in the manufacture of pig iron of approximately $1 per ton, due to the application of dry air.

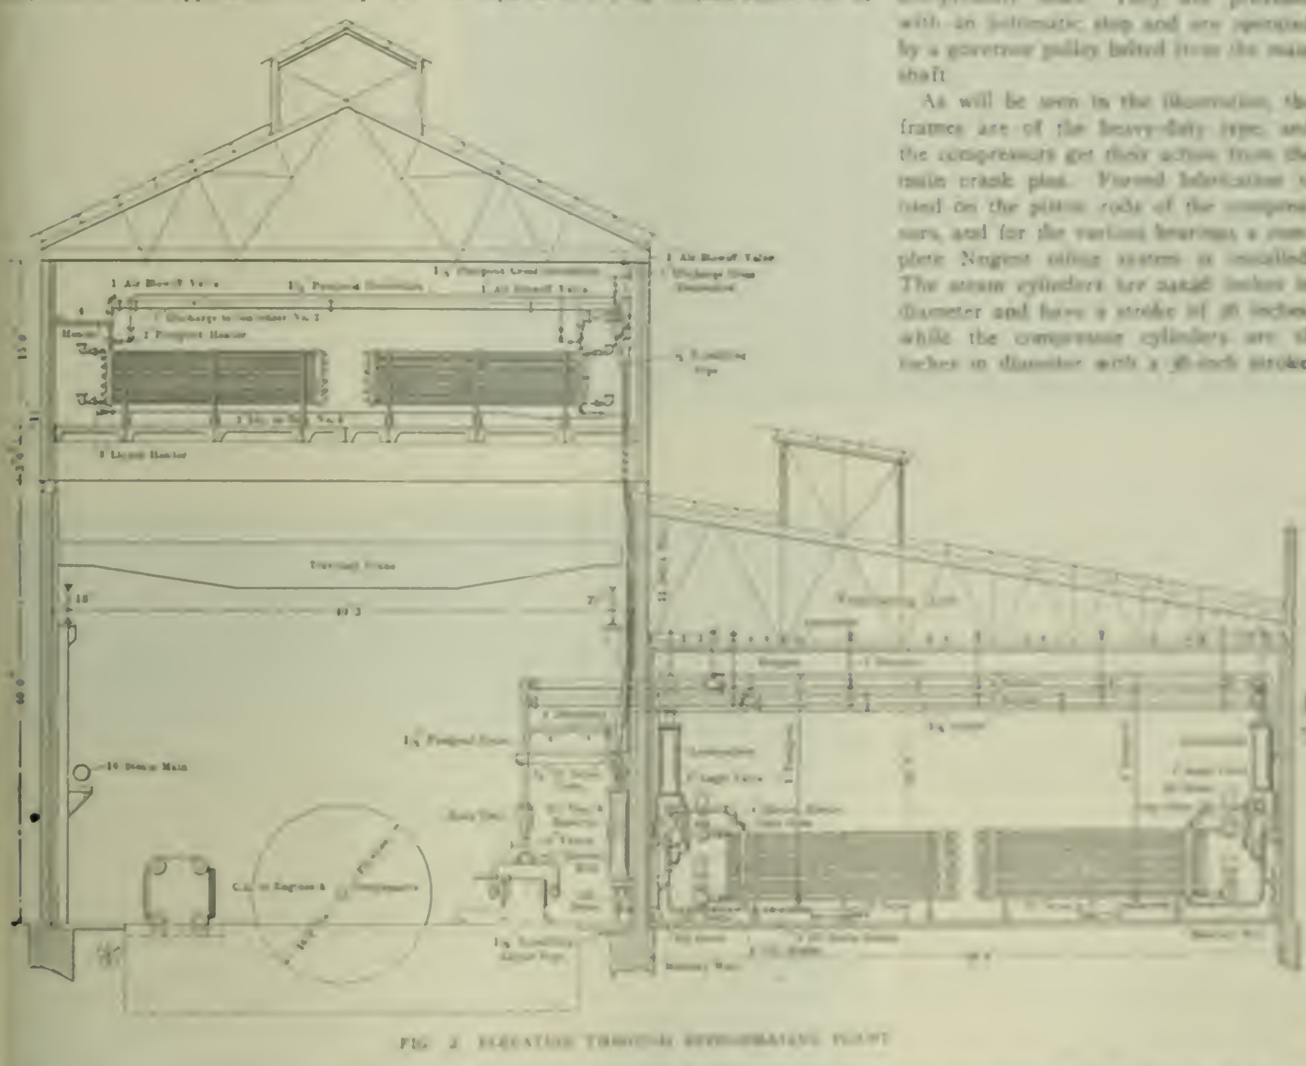

FIG. 2. ELEVATION THROUGH REFRIGERATING PLANT

Although this is a great advantage, a still greater one is the fact that the quality of the output can be depended upon to be more nearly uniform than when using natural air. The quantity of water removed from the air supplied to a blast furnace making 450 tons of iron per day is said to be 5000 or 6000 gallons in 24 hours, when the humidity is greatest.

As the amount of moisture in the air varies from 0.5 grain per cubic foot on a cold day in winter to 9.5 grains per cubic foot in mid-summer, it can be seen that the load on the refrigerating equipment will vary considerably, so that the average amount of steam required is much less than that called for by the full capacity rating of the machines. This explains why the saving in steam required by the blowing engines, which operate continuously with cold air of corresponding small volume, is more than sufficient to operate the ammonia compressors.

1200-TON REFRIGERATING PLANT

Recently there has been put in operation at the South Works of the Illinois Steel Company, at South Chicago, the large refrigerating plant shown in the accompanying illustrations. The plant which is capable of drying 122,000 cubic feet of air per minute, and is the largest that has so far been installed for this purpose, consists of four refrigerating machines of 300 tons capacity each, of the duplex horizontal type. Each machine consists of a cross-compound condensing Corliss engine and two ammonia compressors placed opposite the high- and low-pressure steam cylinders.

Fig. 1 shows a general view of the machines. They are located in a building 124 feet long and 92 feet wide, which is spanned by an electric traveling crane. A 16-inch steam main extends the length of the building at one side, resting on brackets and roller bearings to take care of expansion. From the top of this header a steam connection is made to each of the units through long-sweep bends. The compressors, together with the ammonia condensers, brine coolers and air coolers were supplied and installed by the Vilter Manufacturing Company, of Milwaukee, Wis. The steam ends of the machines consist of the Vilter standard Corliss-engine design, with a single eccentric actuating a wristplate from which the valve motion is derived. The governors, which are of the regular flyball pattern, control the cutoff on both the high- and low-pressure sides. They are provided with an automatic stop and are operated by a governor pulley belted from the main shaft.

As will be seen in the illustration, the frames are of the heavy-duty type, and the compressors get their action from the main crank pins. Forced lubrication is used on the piston rods of the compressors, and for the various bearings a complete Nugent oiling system is installed. The steam cylinders are 24 and 48 inches in diameter and have a stroke of 48 inches, while the compressor cylinders are 18 inches in diameter with a 48-inch stroke. The latter are provided with a set of two suction and two discharge valves. The compressor heads are bored to a true [illegible] and the pistons and valves [illegible] to the same [illegible], the construction [illegible] of large valve area and small clearance. Provision is made for preventing the suction valves from falling into the cylinders in case of the breaking of a valve stem. In the same [illegible] the cylinder barrels [illegible] [illegible] of [illegible] [illegible] pressed into the cylinder by hydraulic pressure and bored and finished at the same time as the [illegible] [illegible] [illegible] [illegible] the [illegible] between the cylinder jacket and cylinder proper forming the water jacket.

Double-pipe Condensing and Brine-cooling Systems

Discharging from the compressors, the gases pass through oil traps, of which one is provided for each machine, and enter the condensers, which are located on the second floor of the building, as shown in the elevation, Fig. 2. These condensers are of the double-pipe type, consisting of 2-inch pipes 18 feet long with 1¼-inch pipes passing through them for circulation of the cooling water. Twenty-five stands of such double-pipe condensers grouped 12 pipes high are provided for each machine, making in all 100 stands. Fig. 3 is a photograph of this part of the installation. Although each condenser ordinarily operates with its individual compressor, connections are so arranged as to permit the operation of two or more of them in combination on all or part of the condenser system.

Four receivers collect the liquefied gas and carry it through individual pipes to the cooling apparatus in which the liquid ammonia is expanded, thereby extracting the heat from the brine.

The double-pipe system is also used in cooling the brine and consists of four batteries of 20 stands each. Each stand has twelve 3-inch pipes with 2-inch pipes passing through them. This apparatus is installed in a building adjoining the compressor room and shown in Fig. 4, which is 68 feet 4 inches long by 58 feet 8 inches wide and 25 feet high. The floor, walls and ceiling are insulated with a double layer of 2-inch cork board. A saturated solution of calcium chloride is used as the cooling medium. This is forced through the inner pipes and transmits its heat to the liquid ammonia in the annular space on the interior of the 3-inch pipes.

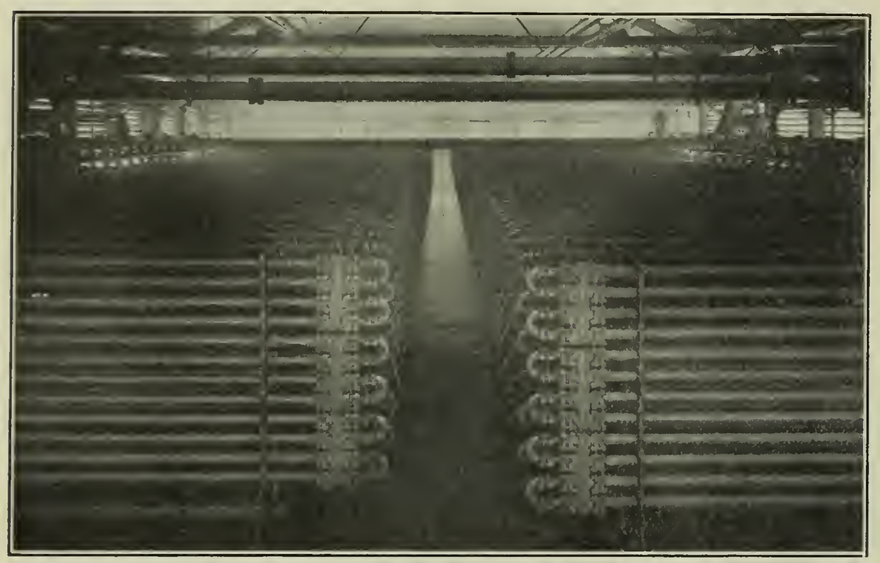

FIG. 3. AMMONIA CONDENSER ROOM

Novel Method of Introducing Refrigerant to Cooling Coils

One of the features of this part of the installation is that relating to the method by which the liquid refrigerant is introduced to the double-pipe cooling coils. In usual practice this is accomplished by needle valves or expansion cocks attached to the supply side of each double-pipe system, and the expansion is regulated as nearly as possible, so that each set of cooling stands receives its requisite amount of ammonia according to the demands on the system. Unless this regulation is very accurate, there will be some of the surface left ineffective for lack of liquid ammonia to which heat can be transmitted, or more or less of the ammonia will pass through the apparatus in a liquid state, thus materially decreasing the capacity.

In this installation there is an elevated receptacle called an accumulator for each battery of cooling coils. As shown in the drawing, Fig. 2, these accumulators are placed at such hight that liquid ammonia will flow through the cooling coils entirely by gravity. In the upper part of each accumulator is a coil through which circulates the liquid ammonia from the condensers. The cold expanded gas passes out through this part of the accumulator on its way to the compressors and cools the incoming ammonia.

After being cooled, the ammonia is liberated through a valve and allowed to run into the bottom part of the accumulator where it is subjected to suction pressure only. The success of the procedure depends upon relieving the liquid ammonia of its excess of sensible heat before it is allowed to pass to the accumulator. Therefore, there is no evaporation when the ammonia passes from the condensing pressure to that due to the suction pressure on the system.

After passing into the bottom of the accumulator the liquid ammonia flows by gravity to the double-pipe brine coolers, flooding them with liquid. The exchange of heat is then obtained by a boiling process rather than by instantaneous expansion as with other systems. As the liquid in the coils absorbs the heat from the warmer brine, it boils, the same as water would boil in a steam boiler, and the gaseous ammonia thereby formed makes its way to the outlet of the coil which, as shown in Fig. 2, connects with the accumulator at a point just above the level of the liquid. In case any liquid am-

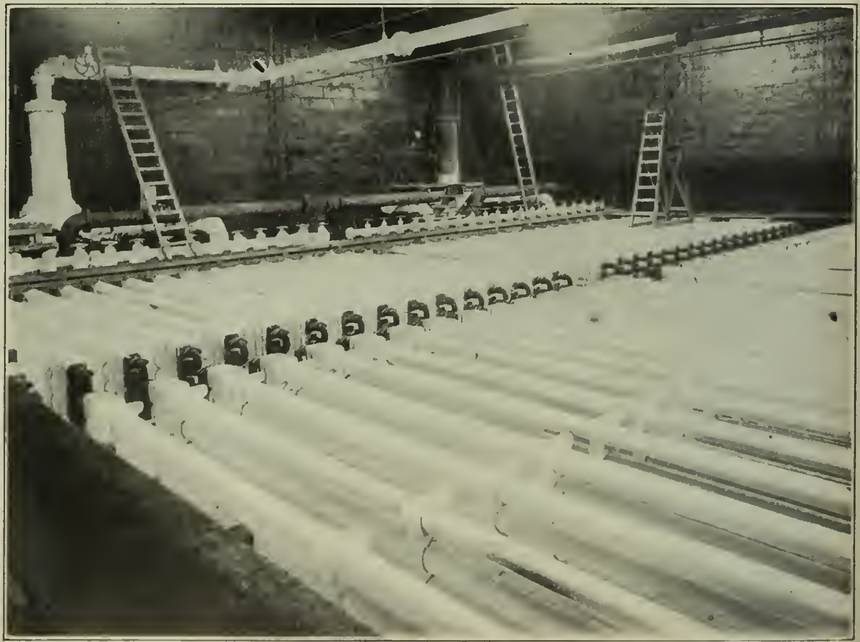

FIG. 4. DOUBLE-PIPE BRINE COOLERS

monia should pass through, it immediately drops into the bottom of the accumulator and is circulated again until it has absorbed its quota of heat and is expanded into gas. The gas then ascends into a large pipe header which terminates in a separator before returning to the compressor cylinders.

Cooling the Air

An important part of the work of this installation is circulating the cold brine through the coils where the air is cooled before going to the blowing engines. For this work there are three Prescott Corliss cross-compound, flywheel-type pumping engines installed. Each has a capacity of 1200 gallons per minute when operating with 120 pounds of steam. The pumps have steam cylinders 12½x24 inches in diameter and plungers 8¼ inches, all with a common stroke of 24 inches. These pumps were especially designed to take care of brine at the low temperature required in this plant, and particular care was taken to avoid shrinkage in the castings, considerable more metal being allowed in the pump sections than is ordinarily the case.

Each suction and discharge deck contains seven 4-inch valves with a total area of 70 square inches, which gives a velocity of 2.8 feet per second through the valve seats. A suction pressure of 15 pounds is carried on the system. The brine enters the air-cooling coils at about 16 degrees Fahrenheit and returns to the pump at 32 degrees.

A separate structure is provided in which to cool the air. This is a building 47 feet 10 inches by 66 feet 10 inches in ground plan and is divided by brick walls into seven compartments. In each compartment are numerous coils of 2-inch pipe, 40 feet long and 200 pipes high. The coils are staggered in order to bring the air into contact with all the cooling surface and are connected with brine headers on the top and bottom. Brine enters at the top and flows downward in the opposite direction to that of the air. Ducts on each side of the building in the basement distribute the air to the compartments, which are controlled by inlet gates. The air is blown into these ducts by two motor-driven fans, forced up through the cooling coils and out of the top of each compartment at a temperature of 32 degrees, where it is collected in an 8-foot conduit leading to the blowing engines.

As the moisture is removed from the air it collects on the coils in the form of frost, and it is arranged so that the compartments may be taken out of service one at a time for the purpose of thawing off this accumulation after it has reached a certain thickness. To do this the compartment is isolated by closing the top and bottom gates, the brine is drawn off into storage tanks and water is sprinkled on the coils until the frost is removed, when the compartment can again be put into service.

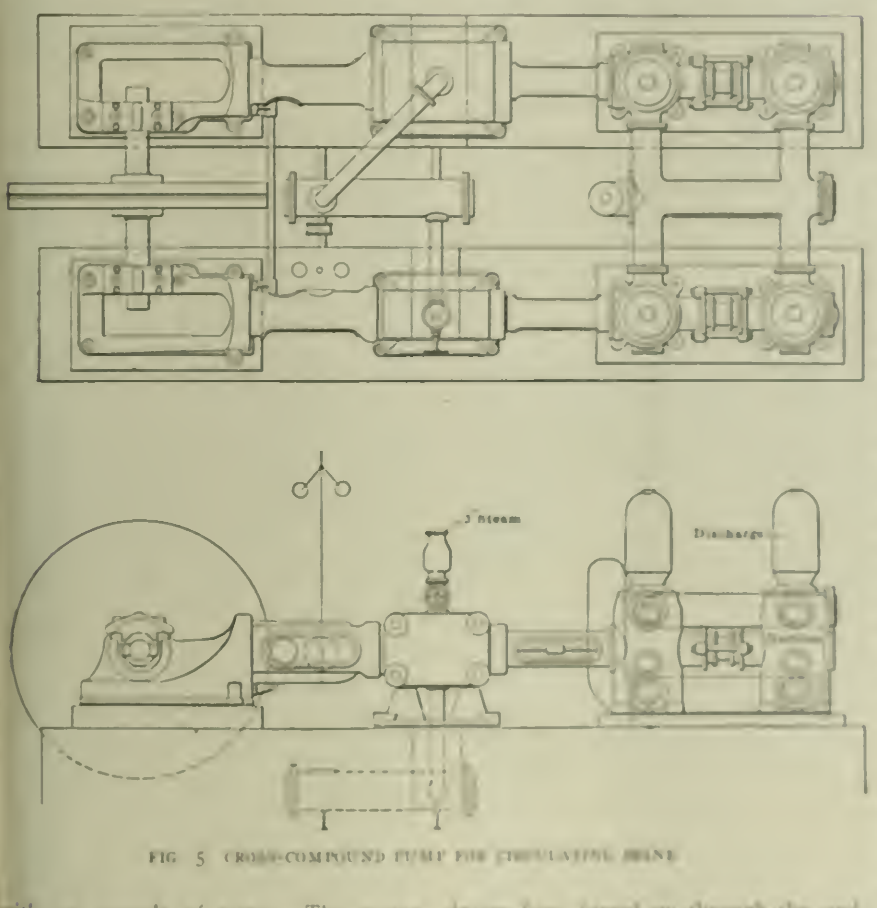

FIG. 5. CROSS-COMPOUND PUMP FOR CIRCULATING BRINE

Single- versus Four-valve Engines

Although many conditions may differ to affect the relative merits of single- and four-valve engines, the following conclusions, reached by F. W. Dean, mill engineer and architect, Boston, Mass., as the result of a series of comparative tests are certainly instructive as regards economy. The engines in the series were all simple, of the high-speed type, direct-connected to electric generators and ranging in size from 12x10 to 20x18. They had all been run under working conditions for a considerable period, with one exception, exceeding 2000 hours.

The most important conclusion reached is that the four-valve engines, which were built to be more economical than single-valve engines, utterly failed in their object. The results show that efforts to realize economy by duplication, or multiplication of parts, even if ports are shortened and clearances reduced, accomplish nothing. The duplication of valves used in the four-valve engines tested simply increased the opportunity for leakage. Mr. Dean asserts that it is doubtful if the four-valve type is tight even when new, and that it has no chance of ever being tight thereafter unless it is refitted, which is seldom done. This type of valve must take the whole responsibility of the extravagance of the four-valve engines. He does not hesitate to advise builders to abandon four valves on high-speed engines unless they are prepared to build a really high-class engine having four Corliss or gridiron valves made and fitted in the best manner. Even then it would be necessary for them to prove their case. Steam engines of whatever type should have valves that are not only tight originally, but that should become so by wear if they are not so originally. The wearing process should be a tightening process.

A bulletin has just been issued in the engineering series of the bulletins of the University of Wisconsin, under the title, "Current Practice in Steam Engine Design." The monograph was prepared under the direction of the late Storm Bull, professor of steam engineering, by O. N. Trostel. The book, which is intended for general distribution, contains forty-odd charts showing graphically the proportions, weights and dimensions of the essential parts of Corliss and high-speed automatic engines. It is the result of an investigation of considerable extent of recent practice of steam construction and covers the changes that have taken place in the last ten years. It enables comparisons to be made between plans and drawings submitted and the common averages, and maximum weights and proportions in current practice. The authors also furnish formulas for designing the essential parts of a steam engine.

Some Useful Lessons of Limewater

Practical Test for Hardness in Water; How to Soften Permanent-Hardness Water; Explanation of the Reaction in Water Softening

BY CHARLES S. PALMER

In last week's instalment we noted one test with barium solution for telling the difference between temporary-hardness water and permanent-hardness water. That is what would be called a chemical test, and it means a great deal, for it uses the insoluble white barium sulphate for finding sulphuric acid (or soluble salts of the acid, called sulphates). All that is good; but it is only an explanation of what you know already about the practical testing of hard water.

Practical Test for Hardness

You take a piece of soap to test for "hardness" in water. If the soap will not make a quick lather and, worse still, if the soap causes that greasy scum to form in and on the water, which you know is called "lime soap," then you know that the water is hard. That is the first step in testing hard water practically. The next step is to find out whether the water will become soft by simple heating and settling; if it will become soft by heating (and now you know that this is only changing the extra or bicarbonate of lime or calcium, which is soluble, to the insoluble plain carbonate), if the water does this on simple heating, then you know that the hardness is only temporary; it can be got rid of in ways that are comparatively easy. But, if the hardness of the water is not improved by heating and settling, if the soap still refuses to lather quickly, and if that greasy lime soap still comes in the water after the heating and settling, then you can be sure that you have "permanent" hardness.

This permanent hardness is harder to remove than the temporary hardness, and for several reasons. The chemical test that you gave the water at the end of the article in February 16 showed you that the permanent hardness is due to calcium sulphate, $CaSO_4$. Now the sulphates are all "salts" of sulphuric acid, oil of vitriol; and one quality of this sulphuric acid is that it is not easily volatile, as carbonic acid is; and another quality is that it is a strong and stable acid. In the case of the lime carbonate, we added extra carbonic acid from the breath; and we drove it off again by simple heating. But in the case of sulphuric acid you are dealing with a stronger, a more stable and a less volatile acid than carbonic acid; and that tells some of the reasons why temporary hardness, or "carbonate hardness," as it may be called, is so much easier to get rid of than permanent hardness, or "sulphate hardness." In both cases, you will have to do mainly with lime-like compounds for the basic part of the "hard" salts, although there are also salts of sodium, of magnesium and so on, in hard water; but the big difference between the temporary or carbonate hardness and the permanent or sulphate hardness will be found to lie in the difference between the instability of the carbonates and the stability of the sulphates. Let us get some experiments with this other kind of lime-like salts, the sulphates, which are found in permanent-hardness water.

The first thing to do is to make some of this permanent-hardness water. You can do this in several ways. One way is to shake up a little common plaster of paris in a tumbler of water, and after some minutes filter off the clear solution. Plaster of paris is nothing more than calcium sulphate (sulphate of lime), and it is thirsty for water. That is the reason why it is used for making all sorts of things where a quick-drying paste is wanted; and that is also why plaster of paris is called "anhydrous," which means "without water" but willing to unite with it. You will filter the solution of this plaster of paris to get a sample of artificial permanent-hardness water, or you can make it in another way.

Go back to that solution of plain limewater. Slip a strip of your litmus paper down the side of a tumbler and fill it half or two-thirds full of filtered limewater. You note that the litmus paper is blue; and that reminds you that the limewater is alkaline or strongly basic. Now take the bottle of sulphuric acid and carefully drop in a drop or two of sulphuric acid, not too much, stirring with a piece of the glass rod which came with your outfit. Bring the sulphuric acid and limewater to neutrality, so that it makes the litmus paper neither red by acid nor blue by the alkaline limewater, but neutral purple. You can get this point by several trials; and it is worth your while to get it and get it right. You may find that the sulphuric acid is too strong for the limewater, and that a few drops of the acid will more than neutralize a half tumbler of the limewater; in that case, your wits will tell you to pour out a few drops of the acid into another tumbler of water, and then to use this second tumbler of diluted acid to neutralize the limewater. But, when you do get the limewater and the sulphuric acid together, neutralized and filtered, you will have the same thing as the filtered solution of plaster of paris, and both will be nothing more than artificial permanent-hardness water. And if you don't believe that this kind of water is permanently hard, just try to get rid of that lime-like part quickly, easily and cheaply. It can be done, in some cases, and perhaps in all cases; but it is part of the object of these lessons to see what the difficulties are, or rather what the possibilities of help are. You know what the troubles are.

Softening Permanent-hardness Water

Well, here is your solution of permanent-hardness water, or sulphate water. Tease it with every test that you used with limewater and lime-carbonate water. You will probably get no precipitate with carbonic acid, whether taken from the breath, from the glowing coal, from the bottle of "fizz," or from the apparatus shown in the February 9 number, where you made carbonic acid from marble or soda and hydrochloric acid. The calcium sulphate which makes the scale, the hard scale, in permanent-hardness water is more soluble than the theoretically possible lime carbonate which might come down by blowing through some carbonic-acid gas; but the hard water does not give down its lime sulphate as easily as that. The reason why the carbonic-acid gas from the breath, or from any of the other sources that you used, does not throw down the lime as calcium sulphate seems to be that as the carbonic acid would take hold of the lime, the sulphuric acid would have to step out; but this same sulphuric acid would not remain free in any quantity but turn round and attack the lime carbonate formed somewhat; and so the possible reaction would work backward; at any rate it does not work to soften the water.

But this has given you an idea; if plain carbonic-acid gas will not throw down the lime from lime sulphate, why not put in something with the carbonic acid, something like a base, to take care of the sulphuric acid that will be set free? Why not try something like soda carbonate, soda ash, or the like? You will find that this will make an interesting experiment; and it will block out the way for some good thinking.

Make a pint or so of this filtered solution of plaster of paris, then add a pinch of soda ash; shake the water well, and let it settle. Do not filter this, but let it take its time to settle by itself. While the stuff is settling, you can study the following equation of the reaction:

Explanation of Reaction in Softening Water

You will notice that the "salt" lime (or calcium) sulphate has two parts, a basic part and an acid part, and a similar thing is true of the "salt" sodium carbonate, that you add to the hard water to soften it. You can straighten it out and remember it at the same time, in this way: Write out the names of the substances, underlining the base parts, and overlining the acid parts, thus:

$$\left.\begin{matrix}\underline{\textit{Calcium}}\ \overline{\textit{Sulphate}}\\ \textit{Soluble}\end{matrix}\right\} + \left\{\begin{matrix}\underline{\textit{Sodium}}\ \overline{\textit{Carbonate}}\\ \textit{Soluble}\end{matrix}\right.$$

equals

$$\left.\begin{matrix}\underline{\textit{Calcium}}\ \overline{\textit{Carbonate}}\\ \textit{Insoluble}\end{matrix}\right\} + \left\{\begin{matrix}\underline{\textit{Sodium}}\ \overline{\textit{Sulphate}}\\ \textit{Soluble}\end{matrix}\right.$$

You see that the exchange between the salts is much like dancing couples exchanging partners. Each "salt" has its acid part and its basic part, and the parts simply exchange places, with the selective affinity necessary to make one of the salts insoluble, that is, the lime carbonate. Thus you have driven the lime out of solution, and while you have done this, you have also left another soluble salt in the water, that is sodium sulphate. It is like driving out a plug by another plug; but still one plug stays in the log. But in the case of the temporary-hardness water, in changing the extra carbonate to the plain carbonate you drove out both plugs at the same time. Here, in the case of the permanent hardness, the plug which stays in the log is the soluble sodium sulphate.

But, you ask, what is the harm of leaving some of this sodium sulphate in the boiler water? Well, what is the harm of leaving such a soluble thing as sulphate of soda, which you know already as Glauber's salt, in the boiler water? Because, as you well know, such salts may cause priming, not to mention the possibility of their helping in the corrosion of the metal of the boiler and its connecting pipes. So there you are, and you begin to see what are some of the annoying problems connected with this general subject of water softeners.

Now this lime (or calcium) sulphate is soluble in water, one part to some four or five hundred parts of water, if the solution is loaded to the limit. Soda, which is sodium carbonate, is very soluble; and if you add this water softener in the comparatively cheap form of soda ash, you will still need a settling tank for the lime carbonate to settle out clear. Also, the boiling water will have to be blown off frequently, to say nothing of looking out for the foaming and priming that wait on the poor boiler man to give him his full share of trouble.

Carefulness in Experiments

There is one thing that should be mentioned here regarding the action of chemicals on each other, that is, that any description of the actual happening is and can be only approximate to what does actually happen. If you alter any of the conditions, as the quantity of the water or other solvent used, or if you change the temperature, or the quantity or purity of the chemicals used, naturally the results will vary slightly. This does not mean that nothing definite will happen, but it does mean that little things will vary the general results, and each experimenter will have to keep his own eyes open to see just what does actually happen in the case of the chemicals he is using in his laboratory. Do not misunderstand me. There is no uncertainty as to conditions or results; but there may be the greatest variety in the conditions and results, and things that one may call little or of slight importance may make things appear to change greatly. But, remember this: When you and I may differ as to what does happen, nothing is easier than for each of us to try it for himself; then we will find out without depending on the books to see for us.

Explanation of Slacking Quicklime

We have found out some interesting things about this substance, lime; and yet, there is so much to examine and to discuss that we have had to overlook many things that are both interesting and practical. One of these is the "slacking" of "quicklime." You have often seen masons getting their mortar ready, and you have seen the white, muddy mass fairly boil with heat as the lime is mixed with water. Indeed, this heat of slacking lime is so strong that, as you well know, fires may be easily caused by leaving barrels of quicklime in exposed places in or near wooden buildings; and the question comes up right here: What is the slacking of lime? What is the difference between quicklime and slacked lime?

Practically, the difference is due to the action of water. Water consists of hydrogen, two parts, and oxygen, one part; and we tell this long story in the short and curious way implied in the formula, H_2O, which is read thus: "H two O;" that is, there are two chemical units of the element hydrogen and only one part or chemical unit of the element oxygen. So you learn the formula of water as H_2O. Now you already know that quicklime is the rust of the metal calcium, and that is told in the form CaO, which is read: "C-a-O," Ca standing for the chemical unit of calcium and O standing for the chemical unit of oxygen. You can write the action of water on quicklime this way:

Quicklime and Water [illegible]

or you can write the same story with symbols in this way:

$$\left.\begin{matrix}CaO\\ \text{Calcium}\\ \text{Oxide}\end{matrix}\right\} + \left\{\begin{matrix}H_2O\\ \\ \text{Water}\end{matrix}\right\} = \left\{\begin{matrix}Ca(OH)_2\\ \text{Calcium}\\ \text{Hydroxide}\end{matrix}\right\} + \text{Heat}$$

As you look at these, there does not seem to be much difference between quicklime and slacked lime; but as you remember that the difference is enough to set a house on fire, evidently it is worth considering. The difference practically is evidently the adding of water to quicklime; but the quicklime is what is called "a base anhydride," that is, it is a base minus water; and in some curious way this takes on water, splits it into several parts, rearranges these parts with the calcium and oxygen and forms the quiet base, calcium hydroxide (or calcium hydrate) $Ca(OH)_2$. It is apparently an important difference, this between the base anhydride as quicklime and the base proper, calcium hydroxide; and you will find this same difference between some of other bases and their anhydrides. But it is interesting to know that this common quicklime is the only common, available and active base anhydride. When you dissolve some quicklime in water, it first takes on water forming the base proper, slacked lime (calcium hydroxide or hydrate), and then this dissolves in the water; so that probably it is not possible to have a solution of quicklime as such, CaO; but you will get rather a solution of the real base, slacked lime, $Ca(OH)_2$. In much the same way, you will find that some acids have the two forms, the anhydride alone on the one hand, and on the other hand the anhydride with the ingredients of water, making the real acid. This is true of sulphuric acid, of nitric acid, of phosphoric acid (which gives one a chance to get an acid anhydride as active in its way as quicklime is a base anhydride in its way) and, especially, silicic acid.

The story of silicic acid starts from common sand, which is the acid anhydride of silicic acid. You would hardly guess that clean white sand is a heavy acid anhydride from the indifference it shows to water and everything else ordinarily; and this is found out by some ingenious ways. But just think of what you have actually seen of the common brick furnace, the common laundry supply, or even your own furnace, with its [illegible] "salts" of the silicic acid [illegible] combined with such bases as [illegible] lime or [illegible], and so on. You can [illegible] a good [illegible] with this kind of sand [illegible] your boiler [illegible]. Use a big lump of lime in one corner of your [illegible]. If [illegible] it will stay there; it is [illegible]. Get a shovel of clean sand and put it in another corner of your [illegible]; it will stay there, for it is [illegible]. But [illegible] the base anhydride quicklime and the [illegible] acid anhydride, sand, and pretty soon you will see the fire fuse the two together, making a clean melt in the liquid molten slag, which is a lime or calcium silicate.

You see this tendency toward the making of slag in every shovelful of your cinder; and now you begin to see that there are several fields of chemical action: there is the water field, sometimes called the field of "wet" chemistry; and there is the field of hot molten fusion, sometimes called the field of "dry" chemistry. Most elements have special relations with both fields, and this is particularly true of the substance lime. In the first place, it is made by burning limestone, driving off the volatile carbonic acid and leaving the base anhydride, quicklime. Then you dissolved this quicklime in water forming the true base, slacked lime, in limewater, or calcium hydroxide (the word "hydroxide" means that it has some of both hydrogen and oxygen). Then by blowing in carbonic-acid gas, you drove this calcium hydroxide, or limewater, to the plain insoluble carbonate, the same thing as limestone. Then by more carbonic-acid gas you forced this plain insoluble calcium carbonate over to the soluble extra or bicarbonate of calcium. Then you drove it back to the insoluble plain carbonate, by heating and settling. You also brought back the soluble bicarbonate of calcium to the insoluble plain carbonate, by mixing it with some of the base limewater emulsion, the two averaging up as the plain carbonate of calcium, the result of water softening by Clark's process.

You also begin to get a glimpse of the permanent hardness of sulphate of calcium waters; and you found out that you can throw down the lime by the alkaline salt, common washing soda, or soda ash. By the way, you will be interested to learn that common cooking soda is the extra or bicarbonate salt of soda; and that can be changed to the plain carbonate (soda ash or washing soda) by heating dry for an hour or two at a heat considerably higher than boiling water, roughly about that of molten solder. You can do this in a saucer on your kitchen stove at home, or in the front part of your furnace. It is interesting to know that the extra or bicarbonate of sodium can be changed to the plain carbonate only by heating it in the dry way, while the similar lime bicarbonate salt can be changed to the plain carbonate by heating in the wet way, another curious illustration of the relations and differences pertaining to the fields of "dry" and "wet" chemistry.

Thus far we have had to do mainly with lime or calcium compounds in our study of hard water, although we have frequently referred to the fact that there are other substances which come in to complicate things. One of the other things which is important in hard water is the salts of magnesium, for this element is almost a chemical cousin of calcium.

There is also one other thing to which you may want to give some attention, and that is the collecting of samples of actual boiler scale from various boilers and from various waters. You will find that the scales from some of the waters can be entirely cut or dissolved in the hydrochloric (muriatic) acid; these are mostly the temporary-hardness waters; while some of the scale will not easily or completely dissolve in any of the acids which you have, these are mostly the scales of permanent-hardness waters; and this kind of testing is closely related to the test given at the close of the third paper of these lessons, in the February 16 number. And so we are gradually accumulating the familiarity with limewater that will carry us on to the clearer understanding of what hard water is and how it may be treated.

Catechism of Electricity

937. *If the thermometer readings in 936 were taken on Fahrenheit thermometers instead of on Centigrade thermometers, would the results be affected?*

They would. If, however, the Fahrenheit readings be converted into Centigrade by substitution in the formula $C° = 5 \div 9\ (F° - 32°)$, in which $C°$ represents degrees Centigrade and $F°$ denotes degrees Fahrenheit, and these new figures in the calculations, the results will be the same as before.

938. *How long does it require a motor working under full-load conditions to attain maximum temperatures in its various parts?*

Small motors attain their maximum temperatures sooner than larger motors. Ordinarily, about four hours is sufficient for small motors and from six to eight hours for large ones.

939. *Is it possible to detect abnormal heating in a motor by any method not yet mentioned?*

Yes, by the sense of smell. When the heating has reached this stage of development, the limit of safety has been far exceeded. Trouble asserting itself in this manner may usually be located in the field or armature coils as the insulation on these windings when subjected to undue heat gives forth a very pungent odor not easily mistaken. If the machine is not shut down at once, the trouble is liable to increase until smoke is visible and the damage irreparable.

940. *What are the general causes of abnormal heating at the commutator?*

Those defects which have previously been mentioned as causing sparking at the commutator will also raise its temperature. They constitute the general causes of abnormal heating at the commutator.

941. *How should these general causes of abnormal heating be removed?*

By removing the source of the sparking as previously explained.

942. *Does not the appearance of the commutator serve as a guide to the direct cause of the heating?*

It does if the trouble is with the commutator. For example, if there are burnt spots on the surface of the commutator, there is probably dirt or foreign matter on it which should be removed. If, when the current is applied, small sparks can be detected in the insulation between the commutator bars, there is either foreign matter between the bars or the insulation itself has become defective. In the former case the troublesome particles should be removed and in the latter case a new commutator will probably be necessary.

943. *Is a hot commutator sometimes caused by trouble in other parts of the motor?*

Yes.

944. *What usually causes the brushes to become abnormally heated?*

Loose connections in the brush holders or between the brush holders and the brush-holder cables, decomposition of the brushes at their contact surfaces, or carbon brushes of too high resistance.

945. *What should be done in case the brushes are of too high resistance?*

Some improvement may be noticed if the brush holders are set lower so as to make that portion of the carbon through which the current passes as short as possible. Other methods of correcting this trouble consist in providing brushes of larger cross-section, in using a greater number of brushes and brush holders on each stud, and in increasing the conductivity of the carbon brushes by using copper in one form or another in connection with them.

In case one of the carbon brushes is found to heat more than the others, a comparison between its resistance and that of one of the others will show at once if the difficulty lies in its conductivity. If its relative resistance is found to be high, advantage may be taken of any of the remedies just given for decreasing its resistance.

946. *To what cause can abnormal heating of the field coils usually be traced?*

To the passage through them of a larger current than they are designed to carry.

947. *What would be the heating effect if one of the field coils was short circuited?*

The short-circuited coil would be cooler than the others, and its pole piece would be weaker magnetically.

948. *Is there a more accurate method*

of locating a short-circuited field coil than that mentioned in 947?

Yes. To make absolutely sure whether a field coil is short-circuited, measure the resistance of each one by the drop method. This consists in passing a direct current, maintained constant by means of a rheostat and ammeter, through the field coils connected in series and measuring by aid of a voltmeter the drop in pressure across the terminals of the individual coils. If there is a variation of more than 5 or 10 per cent. between the voltmeter readings, there need be no doubt but that the coil showing the low reading is short-circuited.

949. *How may a short-circuited coil be remedied?*

If the trouble lies at the terminals of the coil it is usually easy to bend or insulate them without removing the coil from the pole piece; otherwise, it should be taken off and rewound.

950. *What are the causes for high temperature in the pole pieces?*

Either heat conveyed to them from other parts of the machine which have reached a high temperature or eddy currents in the pole pieces.

951. *Describe how eddy currents are developed.*

Changes in the magnetic condition of the pole pieces due to a variation in the field current through the magnet coil are responsible for the development of eddy currents. The eddy currents travel at right angles to the lines of force of the field. They penetrate into the interior of the pole pieces, although not to a great depth, and heat the iron cores.

952. *What harm is done if the pole pieces reach a high temperature?*

They raise the temperature of the field coils and so increase their resistance.

953. *How is it possible to tell whether hot field coils are caused by eddy currents in the pole pieces or by too large a field current?*

If eddy currents are causing the trouble, the temperature of the pole pieces will be higher than that of the field coils. A comparison of the respective temperatures of pole pieces and field coils may approximately be obtained by the sense of feeling, if due allowance is made for the difference in conductivity between the iron of the former and the insulation of the latter. A more accurate comparison of temperatures can, of course, be made by means of thermometers properly applied.

954. *What can be done to eliminate eddy currents from the pole pieces?*

The reconstruction of the pole pieces is the only practical remedy. They should be laminated by building them up of plates or disks stamped from soft sheet iron, instead of forming each core of one solid mass of iron. The plates are enameled or painted on both sides, and when dry are bolted tightly together and cast in with the frame. The enamel on the plates acts as a resistance to the eddy currents and checks their formation. It does not, however, impede the flow of the lines of magnetic force through the pole pieces, because these lines pass lengthwise along the plane of the plates.

955. *Are eddy currents ever responsible for unduly raising the temperature of the armature?*

Yes, especially when they form in the armature core. In this case there is no noticeable sparking, but there is a higher temperature in the core than in the surrounding coils. The machine also requires more than the usual amount of current to run it at no load. As in the similar case with the pole pieces relief can be obtained only by laminating the iron core.

If the motor is of large capacity, carrying heavy armature conductors, eddy currents may also develop in them. This trouble may be distinguished from that just mentioned by a higher temperature in the conductors than in the core. It will be necessary to subdivide the conductors into strands or strips, twist them about each other, and sink them into slots in the armature core in order to overcome the difficulty.

More Water Needed at Colliersville

By Thomas Wilson

That a water power plant should be designed, erected and be in actual operation for some time before it was discovered that there was not sufficient water to run it the year round even to the capacity of the smallest unit installed, would appear to be incredible. Such a plant was designed, however, and put into commission about a year ago on the Susquehanna river near Colliersville, Otsego county, N. Y. The plant was intended to furnish power for the 61-mile line of the Oneonta and Mohawk Valley railroad, also power and lighting to the adjacent towns and villages. The railroad company also has a steam plant at Hartwick, N. Y., about [illegible] miles distant, from which current was formerly supplied. It is now the intention to use it as an auxiliary to supply any deficiency in current from the water plant at Colliersville. From all indications it would appear that the steam plant must be called into service quite frequently, and during the dry summer months be depended upon entirely.

The equipment is divided into two units of 1000-kilowatt Westinghouse generators direct-connected to Holyoke horizontal turbines of [illegible] horsepower each. The Stevens-Hewitt Engineering Company, of New York, designed the plant, and in June, 1906, construction was begun by the designers acting as contractors on a percentage basis. Before the work had progressed very far, it became evident that the cost would overrun the estimate. A new contract was consequently executed by the same parties and the firm of William Barclay Parsons was appointed by the owners, Henry W. Ross and associates, as engineers to supervise the completion of the work and the testing of the machinery. This work was completed under the direction of P. S. Tunner, representing the Stevens-Hewitt Engineering Company, and tests were conducted by H. M. Brinckerhoff, mechanical and electrical associate of William Barclay Parsons.

From all available information it would appear that the capacity of the plant and the subdivision into units was based on the average minimum rather than the lowest flow of water, and that the data for this flow was taken from incomplete reports of the Geological Survey and from observations of the designing engineers which extended over a period of only two years' duration. That these observations did not extend over a long enough period even to check the accuracy of the figures obtained by the Geological Survey was evidenced last summer during the worst drought of many seasons. Ordinarily the average low flow of the Susquehanna river at this point is approximately [illegible] feet per second, but during the dry months of August and September of last year the flow dropped to [illegible] cubic feet. As a consequence the plant was entirely shut down during these months. During a normal summer it would be possible to obtain from [illegible] to [illegible] horsepower during the two dry months for at least a few hours per day. With 1000-kilowatt units this power could not be secured with efficiency, so that the installation really involves [illegible] plant averaging from [illegible] to [illegible] horsepower, the water power being readily obtained from the minimum flow which is found [illegible] per second.

For the average power during a year's operation data are wanting, but it is perfectly evident that the plant [illegible]. With the [illegible] units it is impossible to take full advantage of the low flow, and just why some smaller units, such as [illegible], were not installed in preference to one of the 1000-kilowatt machines, is a question that should be answered by the designing engineers.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

Is Water Power Cheaper than Steam?

The answer to such a question depends largely upon the size of the plant in relation to the minimum flow, its flexibility, or the power to utilize efficiently all available flow, and the nature of the load to be carried. In many instances the capacity of a plant is based upon the normal June flow, which is considered a fair average, although it is known that the amount of water available during the three dry months following will be away below this figure, and sometimes, if the flow is based on erroneous figures, or if there is an unusual drought similar to that experienced last summer, the supply of water will dwindle to such an extent that it may be necessary to shut the plant down entirely. This condition was realized at the Colliersville, N. Y., plant, as told elsewhere in this number, there being no small units to take advantage of the small supply actually available—nothing but two 1000-kilowatt machines to utilize a flow hardly sufficient to develop 250 horsepower. Fortunately, a steam plant was available to carry the load, and from all appearances it should have been allowed to carry it the year round. Of course, the extraordinarily low water of the last dry season was altogether unusual, and many other water-power installations had their troubles, but with a plant so unwieldy as that at Colliersville, a repetition of last summer's difficulties is almost sure to occur during the dry seasons of succeeding years. Imagine the economy of maintaining two plants to supply a given power: one a water plant operating ten months in the year, and then not always at full capacity; the other a steam plant kept in constant repair and readiness to supply any deficiency in current from the water power. The fixed charges on such an arrangement would be very considerable, and the aggregate cost per unit of output from the combination would in all probability be more than that from an average steam plant designed for the load.

Basing the capacity of a water plant on the minimum flow also has its objections, for during nine months in the year a large amount of water would be overflowing the dam, and there would be enough water available to develop power far in excess of the rating of the plant. Much depends on the nature of the load. A lighting load adjusts itself to some extent with the seasons, that is, it is lighter during the three dry months and heavier during the remainder of the year, when there is usually plenty of water. A motor load requires a constant supply of current with but little variation from month to month, and in such a case it is either necessary to rate the plant on the minimum flow and provide a reservoir for storage, or depend upon costly steam reserves to supply the deficit of power. In either case it is important to know accurately the real minimum as well as the average minimum flow, and no chances should be taken or guesses made as to the actual quantity of water that will be available after the plant is installed.

The Flywheel as an Element of Danger

Seven years of experience of the Fidelity and Casualty Company has shown that the loss ratio in flywheel insurance is twice as great as in boiler insurance; that is to say, the proportion of the money received as premiums to that paid out for losses is twice as great in the case of flywheels as in the case of boilers. For the year just passed it has been three times as great. Another statement warranted by the experience of the same company is that about thirty per cent. more of the flywheels in use explode than of the boilers in use.

In the regulation of speed fluctuation, the capacity of a flywheel depends upon its weight and the speed at which it is run. In a wheel of any diameter, if the speed of rotation be doubled, only one-half the weight is required, and as the cost of flywheels depends directly upon their weight, it is customary, in order to save cost, to make them as light as possible and to run them at the highest possible speed consistent with safety.

The forces tending to rupture a flywheel are in many respects similar to those which tend to bring about boiler explosions. In the boiler the steam pressure exerts a radial force on the shell tending to tear the sheet along longitudinal lines, and when this force exceeds the strength of the material of which the shell is made an explosion takes place. In the flywheel, also, the force tending to tear it apart is radial and dependent upon the speed. In the boiler the force increases directly with the pressure, while in the flywheel the force to be reckoned with increases as the square of the speed. Doubling the boiler pressure simply doubles the stress on the seam, while doubling the speed of the wheel quadruples the force acting on the rim.

In the boiler the strength may be increased by thicker sheets. If the thickness of the sheets be doubled, the boiler is twice as strong as before, but doubling the thickness of the rim of the flywheel, although it doubles its strength, also doubles its weight and the force tending to rupture it, for as the weight is increased so is the centrifugal force, and the rim is no stronger than before, however much it may appear to be so.

The point that is desired to be brought out is this: The flywheel is certainly an element of danger in power-plant operation, if placed in the hands of ignorant or incompetent men, and it is just as important that the engineer should be as familiar with formulas relating to centrifugal force as with those bearing upon the efficiency of riveted joints.

Draft and Boiler Capacity

Not many years ago an evaporation of two pounds of water per square foot of heating surface was considered good practice. This has been increased to two and one-half pounds for horizontal tubular, and in the case of the water-tube boiler to three pounds for the normal rating. Modern tendencies are to greatly increase this evaporation by burning more coal per square foot of grate area and necessarily increasing the supply of air, which in some cases has practically doubled the capacity of the boiler with but a slight drop in the efficiency. It is now proposed by the Technologic Branch of the United States Geological Survey to double or treble the capacity of a boiler by passing two or three times the usual quantity of air through the fuel bed and boiler. Numerous experiments along this line have been made by passing measured weights of air through two beds of lead shot, one always remaining the same to represent the boiler, while the other is varied as to size of shot and depth to represent the fuel bed. From the data obtained with the shot numerous charts have been plotted and a number of laws deduced bearing on the relative amounts of power required to force air through fuel beds of various thicknesses, composed of various sizes of coal, and through boilers of various lengths and areas of gas passages.

As a result of these experiments it may be possible to increase the rate of working the boiler-heating surface to three or possibly four times the present value. Such an increase would undoubtedly mean new designs of grate, stoker, furnace and boiler, especially fitted for high rates of working.

No attempt should be made to force more air through existing boilers by running the fans at a much faster rate, as the power consumed for this purpose would increase out of all proportion. New fans and engines must usually be installed, which will supply the greater volume of air at as high or even greater efficiency. Data are now being obtained as to the power required by pressure and exhausting fans to produce the desired pressure and volume of air.

One way of reducing the work required from a fan working under the new conditions is to increase the grate area, thus avoiding a high pressure drop through the fuel and insuring better combustion of the fine particles of coal. The pressure drop through the boiler would be increased materially, creating a high velocity where it is desired.

Further experimentation along this line is to be desired, and especially with hot fuel beds and boilers in actual operation. It is the intention of the Geological Survey to perform such experiments in the near future, and the results of their work, to be published in a bulletin on "Drafts," should be of exceptional interest.

Competent Engineers are Not Mere Machines

When an engineer is intrusted with the care and operation of a steam plant it would seem that if he really is competent his judgment should, to some extent, be relied upon in matters involving the spending of money for supplies and repairs.

This thought was brought to mind by the experience of an engineer who has a particularly alert mind and a fertility in resource rarely equaled.

One of the side walls of a boiler furnace needed renewal. On being informed of the need, the proprietor said:

"Get a mason and the necessary material and do the work, but do not allow the expense to run above ten dollars."

Mason and material were secured and the work started. After the wall had been stripped and the new brickwork started, the engineer said to the mason:

"You know just how much firebrick and clay are worth and you know, too, just what you charge an hour for your time. Now keep track of the time, fire-clay and brick and when these items together amount to ten dollars, stop work and come out of the furnace."

With about twenty-five more brick to lay, the mason came out and was sent home. Then the engineer notified the owner that the appropriation had been exhausted and the work was not complete. There was nothing to be done except to send for the mason to return and finish the work.

"Why did you let him go away before the work was done?" asked the employer.

"When I came here," said the engineer, "you told me that you wanted to know where every dollar that was spent on this plant went, and you have set the price on a great many things that you did not know anything at all about, thereby costing yourself a lot of money by not allowing the man you hired for what he knew about engines and boilers to use his knowledge. I have grown to be ashamed of some of the things that you have made me do and have called a halt. If I stay with you, I am going to be the engineer.

"I shall operate the plant as well as I know how and make all the repairs I can for you, but I will not be handicapped any longer by such petty restrictions as you have heretofore imposed on me. I wish to say what repairs are really necessary and where I shall buy [illegible] and firebrick and how thoroughly repair work on the apparatus under my care shall be done, with due regard for the safe and successful operation of the appliances for which I am responsible."

The owner was somewhat surprised at this and said so, adding:

"I think I can put myself in your place and see the situation from your point of view. I have always looked upon an engineer as a sort of necessary expense accompanying the engines and in need of the same supervision as other labor. I see that in this instance, at least, the engineer is a real factor in economical power production, and a factor to be reckoned with. In the future we will try to see what can be accomplished by intelligent cooperation, that is, as nearly as we may be able to arrive at it."

In this instance it was readily accomplished and today the engineer of the plant is the head of the department to which he belongs. He treats the plant as though it belonged personally to himself and he is determined that it shall be the best of its kind. He insisted that he be given an opportunity to prove his worth, and when given it he "made good."

Polytechnic Institute Student Section of the A. S. M. E.

This organization has just been formed as an adjunct to the department of mechanical engineering of the Polytechnic Institute of Brooklyn, in charge of Prof. William D. Ennis. The section is intended mainly for the undergraduates, but the movement is being enthusiastically supported by the alumni and other prominent engineers of Brooklyn, many of whom have authorized the committee on admission to present their names for membership. At present about [illegible] are enrolled and it was expected that fully a hundred would be on hand for the February meeting.

The activities of the section will take the shape of addresses by men eminent in the various branches of mechanical engineering, visits of inspection to nearby establishments and the reading and discussion of members' papers.

Regular meetings will be held on the first Saturday of each month during the college year, excepting October, usually in the evening, in the auditorium of the College of Engineering, Livingston and Court streets, adjacent to the Brooklyn City Hall.

An unusual invention for the [illegible] was recently demonstrated at the [illegible] in which a [illegible] The [illegible] that the [illegible] may be [illegible].

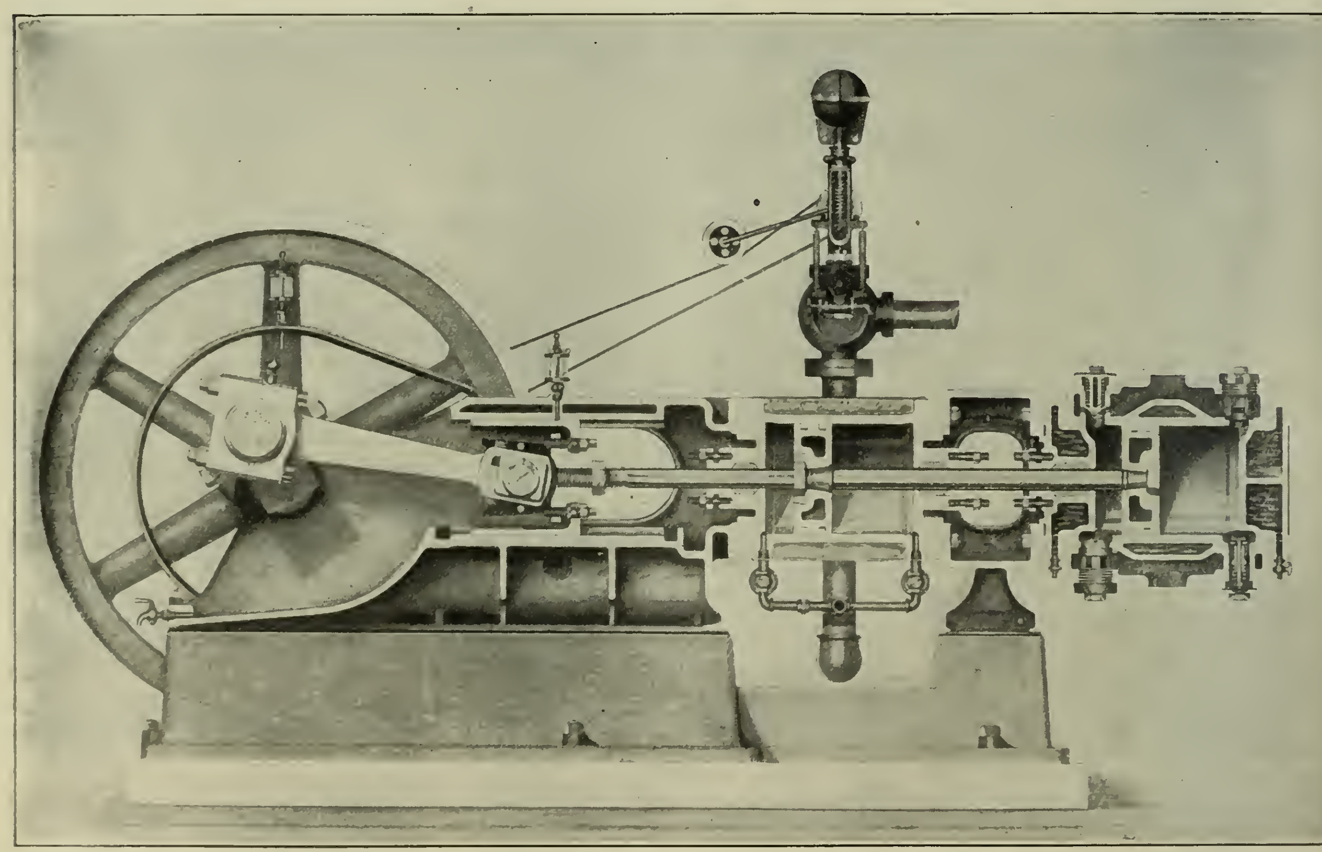
Dallett Air Compressor

The air compressor shown in sectional view herewith is built by the Thomas H. Dallett Company, York and Twenty-third streets, Philadelphia, Penn. This compressor incorporates the essential features of having all parts requiring adjustment or renewals readily accessible, and employing a liberal amount of metal, so placed as to insure rigidity in operation.



SECTIONAL VIEW OF THE DALLETT STEAM-DRIVEN AIR COMPRESSOR

The frame is of the open-fork center-crank type, designed to obtain on each size of compressor a greater range of capacity by substituting, when desired, a cylinder of the next larger size than the standard to operate at 100 pounds pressure.

The main bearings are lined with babbitt metal, which is thoroughly peened in to obviate shrinkage, and then bored and scraped to fit the crankshaft. The duplex-belt, duplex-steam and single-steam machines are supported on deep, rigid subbases, thus making the entire machine self-contained.

The steam cylinder and valve gear of the steam-driven machines are designed to give high efficiency. All steam ports are short and direct, and the clearance has been reduced to a minimum. A plain D balanced slide valve is used on the small and medium-sized machines and the Meyer balanced adjustable cutoff valve on the larger machines. To provide efficient heat insulation, all steam cylinders are lagged with mineral wool and jacketed with sheet steel.

The governor of the steam-driven machine is equipped with a safety-stop device. The governor pulley is situated on the end of the shaft outside of the flywheel on the single-steam machine, thus bringing the flywheel as close to the bearing as possible. Formerly, in the case of duplex compressors with compound steam cylinders, if the machine stopped with the high-pressure side on the dead center, it would not start automatically, due to the fact that the high-pressure side takes steam from the line. This trouble has been overcome by using a reducing valve which reduces the live-steam pressure for use in the low-pressure cylinder. The air and steam cylinders are tied together and held in position by means of an internally flanged tie or distance piece.

Mechanically operated inlet valves are supplied on any size of compressor if desired. These valves are ground to gage and the valve holes lapped to size.

The air-intake and discharge valves are special features of these compressors. The intake valve is of the automatic poppet type, contained in a malleable-iron cage. The cage is one piece, and combines both seat for the valve and guide for the valve stem. The cage is threaded and screws into the wall of the air-intake chamber only, and is simply seated in a recess on the main cylinder wall, using thin corrugated-copper gaskets to secure a tight joint. A hexagonal recess has been cast in all cages to accommodate a special cast-steel wrench for use in removing and replacing valve cages.

The valve-cage cap acts as a locknut for holding the cage in place after it has been screwed down on its seat in the cylinder. It is provided with a hexagonal projection, and the same wrench can be used here as on the valve cage. In the case of compound machines corrugated-copper gaskets are placed under the valve-cage caps on the high-pressure cylinder to insure against leakage, as the discharge pressure from the low-pressure cylinder is constantly at these joints.

The valve proper is of a special alloy hardened steel, with seat and stem ground to gage. The valve spring is of phosphor bronze and of the right proportion to give the valve an easy opening and a quick closure.

The spring holder on the valve comprises a split taper ring set in a recess on the valve stem and held tight to the stem by means of a solid taper ring slipping down over it. The hammering of the valve on its seat tends to tighten the spring holder on the stem instead of driving it off, due to the action of the taper.

The discharge valve is of the automatic poppet type contained in a valve cage of malleable iron. The method of seating in the cylinder and locking in its seat is identical with that of the intake valve. A projection or boss has been provided on the valve cap which acts as a positive stop for the valve when it has reached a lift giving a full-opening area and does away with fluttering. This same projection on the cap also acts as a spring guide for the valve spring.

Both inlet and discharge valves are simple and compact, and each valve requires not over a minute's time for complete removal.

The intercooler has a large cooling area, employing the return-flow type of water circulation, and using baffle plates to deflect the flow of air and aid in its effectual contact with the cooling tubes, which may be removed intact from the intercooler box without disturbing any of the piping, as unions are supplied to obviate this feature. The intercooler is supplied with a pop safety valve, a pressure gage and a drain valve.

Each belt-driven machine is provided with an unloading device which automatically unloads the air cylinder. When a certain determined pressure is reached in the air receiver, one or more inlet valves at both ends of the air cylinder are held open and the load is taken off the compressor, allowing it to run light until the pressure drops in the receiver, upon which the valves are released and air compression is resumed.

On the steam machines, a combined speed and pressure governor is used. This governor unloads the air cylinder exactly as on a belt-driven machine, and at the same time it controls the speed, allowing a single-steam machine to turn just over when unloaded, and bringing a duplex or compound machine to a dead stop. By this means a great saving in steam is effected and the wear and tear on the working parts, as in the case of continuous running machines, is reduced.

These compressors are built from 8-inch stroke up to and including 18-inch stroke and with a capacity range of from 79 cubic feet of free air per minute to 1200 cubic feet.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer.

Refrigeration Troubles

I wish to make a few changes in the 10-ton ice plant (can system) I run and would like to have your advice about it. The engine is an old-style compound with 12x16-inch cylinders running at from 90 to 100 revolutions per minute and exhausting into a condenser with a relief valve set at 15 pounds. When we are running more than half the exhaust blows out at the relief. The circulating water for the condenser is the overflow from the ammonia condenser flowing through by gravity. Now what I wish to do is to take the old piston out of the engine and get a new one, throw the old condenser away and put in a surface condenser, and put an oil filter between the condenser and the reboiler.

I think we can cut the coal bill enough to pay for making the changes in one season. The boiler is a horizontal tubular, 66 inches in diameter by 18 feet long, with 58 four-inch tubes, carrying 95 pounds pressure. We burn from 100 to 125 tons of coal a month. I think we burn too much coal for the amount of ice we make and the only way to cut expenses is to cut down the amount of steam the engine uses. And another thing, when we are running we cannot blow the whistle or let the safety valve blow for fear of knocking the cylinder head out. The main steam pipe and safety valve are connected to the highest point on the boiler. The engine lifts the water so you cannot tell how much you have in the boiler. If you are running with two gages in the glass and shut down, from three out of four the water will disappear from the glass. Please let me know what you think about it.

W. M. J.

From your description of the conditions existing in your plant we think that your equipment must be suffering from a complication of diseases.

We assume in consideration of what you say that the whole of the 100 to 125 tons of coal consumed per month is burned for generating steam for the ice plant only. If so, it is too much. A 10-ton plant producing 400 tons of ice per month should certainly not require over 75 tons of good coal at the outside and not over 100 tons of poor coal.

If you have steam blowing away through the back-pressure valve it certainly indicates that more water is being evaporated than is required for the ice plant. But safety and back-pressure valves are very deceptive pieces of mechanism, however, and it is almost impossible to gain any idea of the amount of steam escaping by observation alone. Try slowing down your engine until no steam passes the back-pressure valve, keeping the other conditions as nearly constant as possible. This will give you an idea of the amount of steam going to waste, since the total steam will be proportional to the original speed in revolutions per minute and the steam that the condenser will take after will be proportional to the number of revolutions per minute made by the machine after slowing down. The difference in speed in revolutions per minute divided by the original revolutions per minute will give the per cent. decrease in speed which will also be the per cent. of the total steam generated which is being lost through the back-pressure valve.

There would be no advantage in using an engine of so high an efficiency that the steam used would not supply the ice cans with water, and we do not think that it would pay to run a 10-ton plant condensing. If, however, you can improve the efficiency of your steam-consuming apparatus to such a point that it will supply only enough steam to supply the required amount of distilled water without running condensing, it should be done.

We think there is a possibility that your boiler is not evaporating as much water as it should per pound of coal. There must be reasons for your trouble with boilers other than that of the large amount of steam required.

Make sure that the tubes are not getting scaled badly. If that is not the case we would be inclined to think that there is insufficient draft or deficiency of air space through the grates. You should carefully inspect the settings and see that they are as nearly air-tight as they can be made. See that there is no short-circuit which allows the fire gases to pass directly from the combustion chamber to the stack without coming in contact with all of the boiler-heating surface.

It would be interesting to test the strength of your draft by means of a homemade gage made up out of two pieces of glass pipe and a rubber tube. It would also be interesting to determine the combustion conditions at the boiler. [illegible] per pound of coal.

Hoboken N. A. S. E. Entertainment

The seventh annual entertainment and reception of Hoboken Association No. 5, N. A. S. E., Hoboken, N. J., took place at Odd Fellows' hall on Tuesday evening, February 9. The attendance was larger than ever before. A top-notch entertainment was given, after which the floor was cleared for dancing, and in spite of the crowded condition of the hall, an enjoyable time was had. The committee of arrangements comprised W. J. Reynolds, James J. Dustin, Adolph Comens, John Platt and Henry Downes.

Newark Association Entertainment

The twenty-fourth annual entertainment and reception of Newark Association No. 3, N. A. S. E., Newark, N. J., was held on Friday evening, February 12, at the New Auditorium. The occasion attracted a large attendance, there being more than 1200 persons present, including many prominent supplymen and engineers. An entertainment of unusual excellence was followed by dancing. The address of welcome was made by A. B. Penny. Great credit is due the hustling committee.

On Saturday evening, February 6, at the Waverly hotel, Lowell, Mass., the Southwick Textile Club of the Lowell Textile School held its eighth annual meeting, at which Charles B. Burleigh gave an address on the equipment of textile mills with electric drives and the use of the steam turbine in connection therewith. The address was one of the best ever delivered before the club and Mr. Burleigh was given a vote of thanks.

Business Items

Orders received during January for "Swartwout" steam specialties made by the Ohio Blower Company, Cleveland, Ohio, include 9 steam separators, 2 oil separators and 10 cast-iron exhaust heads.

The Russell Engine Company, of Massillon, Ohio, is installing a 450-horsepower four-valve semi-Corliss engine for Samuel Bacon's Sons Company, Laurel, Del. Also a 300-horsepower tandem compound four-valve semi-Corliss engine for the Laurel Electric Light and Power Company, Laurel, Del.

A free sample of Ames alloy high-pressure sheet packing is being sent to engineers who apply for it by the U. S. Indestructible Gasket Company, 16 South William street, New York. This packing is made of a special composition and has been tested up to 6000 pounds, making it suitable for the highest pressure and for hydraulic work.

The Hoopeston Gas and Electric Company, Hoopeston, Ill., has placed an order with the Minneapolis Steel and Machinery Company for a 100-horsepower Muenzel producer-gas engine. They already have a 280-horsepower Muenzel producer plant and the small engine will be run on the light loads. In this way they will be able to run the entire plant more economically.

B. M. Knobel, who recently severed his connection with the Crandall Packing Company, has organized the Triumph Engineering and Supply Company, with headquarters at 253 La Salle street, Chicago. Here will be carried a complete line of rubber goods, packings, mats, etc. Also the "Cassco" bar metallic packing. Mr. Knobel has been prominent in steam-engineering circles in Chicago and throughout the middle West.

The G. M. Davis Regulator Company reports a recent shipment to the General Fire Extinguisher Company, of Providence, R. I., of a 30-inch pressure reducing valve to reduce pressure of 75 pounds down to 30 pounds. This valve is designed to pass twenty million gallons of water per day. The shipment weighed three tons and it is considered to be the largest pressure-reducing valve ever constructed in this country. The company also reports the receipt of an order for a 30-inch combination atmospheric relief and back-pressure valve to be used on a 5000-kilowatt Curtis turbine being installed in the 59th street station of the Interborough Rapid Transit Company, New York City. This company has nineteen 30-inch Davis relief valves installed in this plant.

New Equipment

The city of Anadarko, Okla., has voted $14,000 bonds for improvements to electric plant.

H. J. Kunkle, Wataga, Ill., has been granted franchise to construct an electric-light plant.

The Roosevelt (L. I.) Water, Light and Power Company has bought site for a pumping station.

An addition will be built to the power house of the municipal electric-light plant at Nashville, Tenn.

A municipal heating and lighting plant is to be erected in Albion, Neb. R. T. Flotres is city clerk.

The Gloucester (Mass.) Cold Storage and Warehouse Company will erect an additional cold storage warehouse.

The town council, Faundsale, Ala., contemplates installing water-works and electric lights. S. Stollenwerck, town clerk.

It is reported that about $35,000 will be spent in improvements at the water-works and electric-light plant at Opelousas, La.

The Carthage (Tex.) Ice and Electric Company has been incorporated with $20,000 capital by J. C. Whitney, M. E. Pittman and J. G. Woolworth.

The Syracuse (N. Y.) Cold Storage Company will erect a seven-story warehouse, an ice factory and five refrigerating stores at a cost of about $275,000.

The Peoples Ice Company, Wichita Falls, Tex., recently incorporated, will establish ice plant of 45 tons daily capacity. P. Marcus, president.

The Toronto (Ont.) asylum will install four new hot-water boilers, feed-water heaters, pipe, etc. W. D. Medcalf, inspector of boilers, should be addressed.

The Metropolitan Electric Company, Reading, Penn., will erect a new power house and transmission and distribution system at a cost of about $1,500,000.

It is stated that improvements will be made at the water works at Alton, Ill., including the installation of a new pump with a daily capacity of 6,000,000 gallons.

The Ft. Wayne & Wabash Valley Traction Company will remodel its power house at Lafayette, Ind. It is said between $100,000 and $200,000 will be expended.

The Board of Public Service, Cincinnati, Ohio, has been requested to have plans prepared for a new electric-light plant and a refrigerating plant for the city infirmary.

The Great Western Power Company has taken out a permit for the construction of a $50,000 building at Oakland, Cal., to be used as an auxiliary electric generating plant.

The Electric Generating Company, Fredericksburg, Va., has been incorporated with $100,000 capital. Will erect plant. R. M. Vandom, Exchange hotel, Fredericksburg, is engineer in charge.

New Catalogs

The Snee Wave Motor and Its Possibilities

A New and Apparently Overestimated Turbine Construction Designed to Utilize the Energy of Ocean Waves and Currents to Develop Power

BY FRANKLIN VAN WINKLE

Windmills and water wheels were undoubtedly the first forms of prime mover devised for the development of inanimate power, and it is not surprising that the restlessness of the seas should have suggested to ambitious inventors the possibilities of developing vast amounts of energy from the motion of the currents and waves of the ocean.

The appearance of ocean waves and the havoc wrought by their incessant action in time of storm give rise to distorted impressions of their motions and local development of energy. When the eye follows the crest of a wave as it moves over the surface of a body of water, the impression is created that the whole body of water is in rapid horizontal motion. In reality there is little more than progressive vertical displacement which is almost exclusively confined to a local rising and falling of the general surface. Floating objects, unless driven by action of winds or currents, are carried up and down nearly vertically over the same spot excepting for a small oscillation backward and forward, which occurs as the wave is passing.

FIG. 1. SNEE WAVE MOTOR BEING INSTALLED AT [illegible]

The action of surf in breaking over a beach leads many observers to believe that waves consist of an actual flow of the sea shoreward, when in fact the curling and breaking of surf are caused by the final falling down of the unsupported crest of a wave, which in falling and spreading out is rolled over and thrown up as surf by the return of waters from preceding waves that have been spread out on the beach.

Very few of the projects for utilization of wave power have attained importance beyond the experimental stage, because it has soon become apparent to experimenters that, in order to concentrate any considerable amount of energy from power of waves, extensive mechanical installations are necessary, to say nothing of difficulties attending construction and maintenance, and the uncertainty of source of energy and great cost of installation for a given output, as compared with that required for other methods of generating power.

Most of the schemes proposed for utilization of wave power were designed to take advantage of energy created only by the rise and fall of the waves, in which respect they appear to be rational. Some others have been proposed for utilizing the energy of [illegible] currents, oscillations and vertical movements of water, which according to [illegible] are supposed to be [illegible] through [illegible] of wave motion, and very few of the [illegible] of wave motors of this kind appear from their designs to take into account the fact that in order to gather energy from the movements of water, it is necessary both to arrest the motion of the water, and for continuous development of energy, the water so confined must be got out of the way of succeeding volumes of water.

A new form of wave motor has been widely advertised of late by the Snee Universal Wave Motor Company [illegible] that company. It is claimed for this motor that it will utilize the energy of ocean waves or currents, as well as that of channel and river currents, and "will revolutionize the power development of the world."

Atlantic City Plant

Two wave motors of the company are being installed at Young's new million-dollar pier, Atlantic City, N. J., for the alleged purpose of generating electric current for supplying light, heat and power. As shown in Fig. 1, the plant is being located adjacent to the pier and about 1150 feet seaward from the boardwalk. One of the motors is shown in Fig. 2. It is 14 feet high, 11 feet in diameter over all and weighs 61 tons, the inside revolving section weighing 16½ tons.

From its general appearance the motor might be taken for an elongated turbine. The main working parts of each motor consist of a vertical-shaft water wheel or runner revolving within a circular framework or cage, the latter formed of vertical parallel guide blades, a feature common to all types of inward-flow pressure turbine.

Fig. 3, which is a photograph taken of a small model exhibited at the Snee company's office, 1278 Broadway, New York City, shows the runner or wheel proper, partly removed from the cage or casing of guide blades. In Fig. 2 it will be noticed that the wheels under construction at Atlantic City have their exterior casings supported by two 24-inch I-beams, to which are bolted six steel heads, each 2½ inches in thickness and weighing 4700 pounds. Between these the outside guide blades or deflectors, made of 9/16-inch steel plate, are riveted in tiers, the hight of blade being 30 inches in each tier. The interior revolving part or wheel is to be mounted on a hollow steel shaft and hung from roller bearings, with the bottom of the shaft retained by a compartment filled with oil which is expected to rise in the hollow shaft to a hight sufficient to counterbalance the head of water on the outside. It is proposed to cover the two upright I-beam supports with concrete, and to secure the motors to a foundation resting on nine concrete piles, each containing 1050 barrels of cement and reinforced with steel rails. In addition to this piling, three steel reinforced concrete floors, weighing more than 100 tons each are introduced, making the structure a rigid mass of concrete and steel weighing over 500 tons. Constructed in this manner, it is expected that the action of salt water will not affect the supports of the motors.

Fig. 4, a top view of the motor, shows a brake wheel, by means of which it is expected to shut down on the motor when occasion demands. It is proposed to gear electric generators directly to the shafts of each wheel and operate a storage battery in conjunction with the generating plant, the battery to carry the load between the periods of power supply by the wave motors. It is reported that the exact arrangement and connection of the generators have not been definitely determined.

It is also proposed to install on the top of the foundation wind-driven wheels of the same design as the water wheels and measuring 28 feet in diameter by 50 feet high. This, of course, will increase the cost of the plant, but it is expected that by placing reliance on both wind and wave both motors will not be idle together for any considerable length of time.

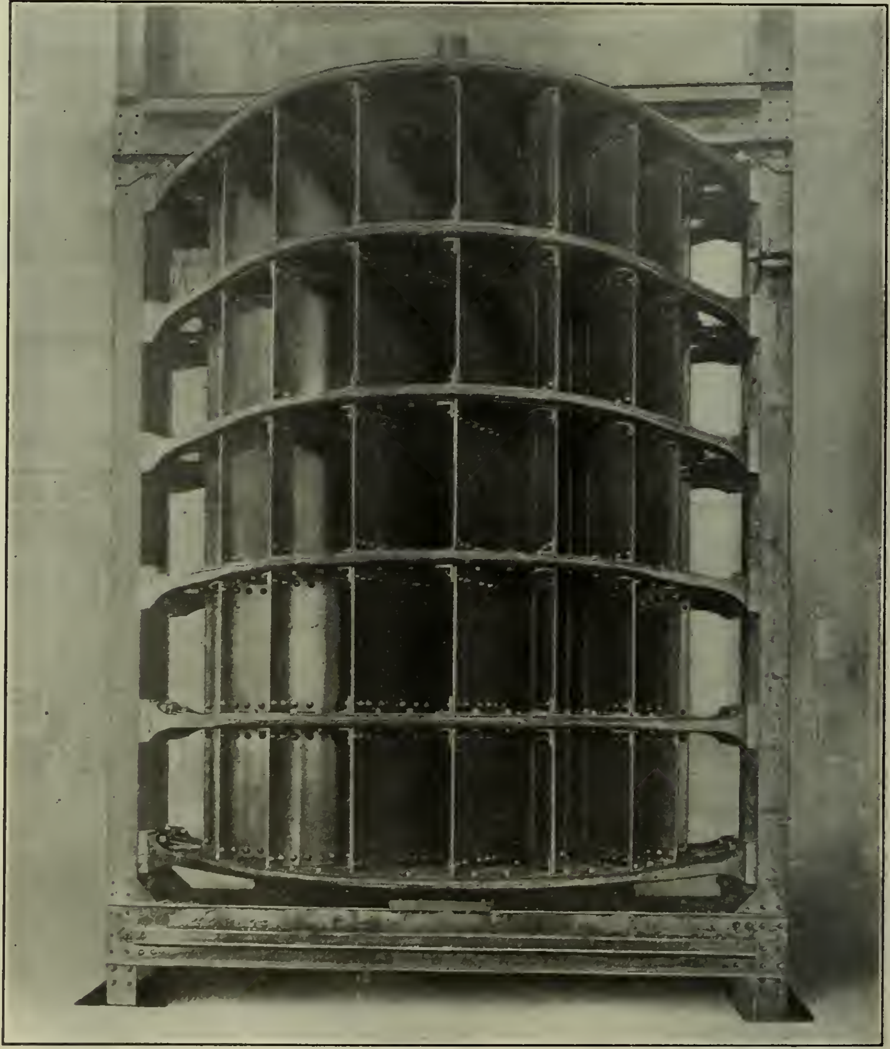

FIG. 2. SUPPORTING STRUCTURE AND ARRANGEMENT OF GUIDE VANES

No very definite data are available on the rating of these motors, only that with a current of 30 miles an hour, or 44 feet per second, each motor is expected to develop 2000 horsepower. The cost of the motors and foundation is placed at $100,000, or when figured at the rating given, $25 per horsepower. An average velocity of ocean waves at Atlantic City of 30 miles an hour is, of course far above normal, and even assuming that the whole body of water partakes of the same velocity as the movement of crests of the waves, the power for usual conditions could be only a small fraction of the rating claimed, and would undoubtedly raise the cost of installation per horsepower to such an enormous figure as to limit the use of the motors to their exhibition as novel attractions rather than as efficient and practical machines.

Operation of Motor Analyzed

That a motor of this design, if acted upon by swift currents of air or water, may be capable of developing some power is not to be doubted, for models made of galvanized sheet iron exhibited by the company demonstrate that fact. But the effective energy which motors of a given size and cost may be capable of developing will control their practical usefulness and commercial value. The installation proposed for Atlantic City has been extensively advertised by the projectors and the public is invited to purchase stock of the company upon claims of such extraordinary merit as to elicit an analysis of this wonderful invention.

Fig. 5 illustrates the general arrangement of the guide blades and the runner, shown in horizontal cross-section. In this diagram, A_1, A_2 A_3 A_4 represent the guide blades, *B* the curved buckets of the runner and *R* the radial vanes of the runner. The radial vanes and curved buckets of the runner are of the same general form as the flat, radial vanes and curved buckets of the ordinary horizontal-shaft water wheels, with the difference, however, that both kinds of float are used

FIG. 3. ARRANGEMENT OF BLADING SHOWN IN SMALL MODEL

FIG. 4. BRAKE WHEEL ON TOP OF MOTOR

for the runner of the Snee wheel. Flat radial vanes and semi-cylindrical buckets in pairs, as shown in the diagram, extend the full depth of the runner with parallel edges devoid of forward or backward curvature. The motor is in fact a current wheel intended to operate successfully with the vanes submerged during complete rotation of the wheel.

A striking feature in operation of the models of this motor is the uniformity of the direction of rotation, regardless of the direction of flow of the propelling current, and it is therefore proposed that this motor will be especially valuable for deriving power from waves and tidal currents as well as from river currents which are constant in direction of flow.

It is to be observed that in operation the Snee motor differs from that of the inward-flow turbine in one important particular, viz., that inward-flow vertical-shaft turbines are constructed for discharging the propelling fluid downward through the runner, while for operating the Snee motor the propelling current must enter through guide passages in one side of the motor, engage the buckets as it passes across the guide case and be discharged through other submerged guide passages on the down-stream side of the motor.

Placed in an open current sweeping across the motor, it would appear, as indicated by the arrow-head flow lines of Fig. 5, that not more than one-fourth of the guide passages can possibly be construed as effective in delivering water to the blades of the runner, because entrance through any more of the guide passages would only result in choking off free admission by those passages which are most effective in discharging water upon the runner. Rotation of the runner being in the direction indicated by the arrow *R*, it is to be noted that when the propelling current approaches the motor from the side *T* the effectiveness of water entering a guide passage like *A* will be seriously interfered with in the transfer of its energy to the vanes and buckets which have arrived at *D*, because there is no outlet for discharge of deflected water except by cutting across the path of other vanes, thereby causing a churning action and a breaking up of the solidity of masses of water which are in the wake of such vanes. The energy required to effect this displacement must be reserved out of the initial energy of current which may be presented to the runner, to say nothing of the effect of the breaking up of the solidity of water between vanes which have passed around to positions beyond useful effect from jets or streams impinged upon the runner.

The churning action referred to is somewhat lessened by the backward curvature of the outer ends of the series of curved buckets, but this feature cannot possibly compensate for energy lost in the formation of swirls and eddies between the vanes. While it may be said that energy rejected by the first vane or bucket will then be gathered by vanes on the opposite side, it is readily seen that a very large portion of such residual energy is not thus available for that purpose, and besides, as any energy which may be so available is to be derived only from irregular streams of water flowing at irregular velocities, the gathering of this residual energy is evidently incompatible with a well established principle of turbine water-wheel practice, viz., that in order to realize the best effect, either by impingement or pressure on a vane, there must be a fixed ratio between the velocity of the water and that of the vane. Analysis of this motor under principles of turbine water-wheel practice would, therefore, appear to be entirely out of place.

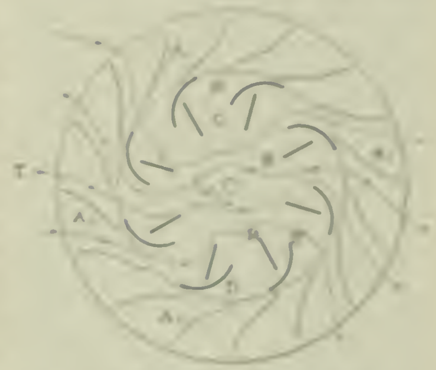

FIG. 5. INSTANTANEOUS FLOW IN THE MOTOR

Assuming the course of the current across the wheel to be constant in direction and velocity, the effective energy transmissible to the vanes and buckets of the runner cannot be construed as equal to the energy derivable from direct action of the main current, because there is counter action of deflected currents. The efficiency of vanes receiving direct and uninterrupted action of currents has been clearly established by Smeaton and other experimenters, and more particularly by Poncelet in testing the efficiency of ordinary current wheels.

In nearly all countries, and for many centuries, crude float wheels, with horizontal axes and driven directly by swift currents of rivers or tides, have been in use for raising water and for other mechanical purposes. Water wheels of that kind were undoubtedly the earliest form of rotary hydraulic motors, see Figs. 6 and 7. Carried on boats moored in a rapid current, they have been quite ex-

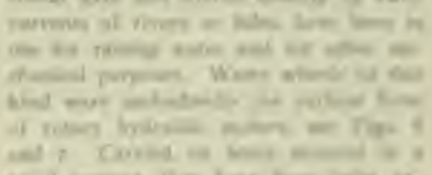

FIG. 6. VERTICAL SECTION [illegible]

tensively used in European countries in driving pumps for small flouring grist mills.

These water wheels are usually provided with flat radial vanes or floats placed around the periphery of the wheel like those of an ordinary steamboat paddle wheel, the floats or paddles being placed apart a distance equal to their radial length, which is usually about one-fourth the greatest radius of the wheel.

It has been demonstrated that for the best effect from these wheels, only so much of the wheel should be lowered down into the water as to insure complete submergence of each float as it passes under the axis of rotation of the wheel. The vanes dip into the unconfined current and receive motion from the passing water, accompanied by a heading-up of the impeded current. Much of the main body of the current passes to either side of the wheel, and in order to receive any energy from that portion of the current which does present itself to the floats, the floats must have less velocity than the current. These wheels cannot, therefore, be made to utilize more than a small proportion of the total energy of a current, and Poncelet found that they could develop only 40 per cent. of the energy of that portion of the current which had cross-sectional area equal to the projected area of one vane.

The maximum energy that can be imparted by a jet to a flat vane, normal to an unimpeded jet or stream of water which is free to glide from the vane, is one-half of the energy of the jet. But in operation of current wheels, such portion of volume of the jet or stream acting on the vanes as may be in excess of the quantity which can follow the vane in its path is impeded in its escape by a surrounding body of water which offers more resistance than if the excess discharged itself into the atmosphere.

Where any considerable amount of power is required, the employment of water wheels of this kind is usually prohibitive on account of the extensiveness of installation necessary for a given capacity, and also their great cost as compared with installation of other forms of prime mover.

The old horizontal float wheels possess the advantage over the Snee motor of retaining the dead water between the floats undisturbed by discharge from the surface of the vanes, and it would therefore seem physically impossible for the Snee motor to realize equal benefit from a given amount of energy of current from the time of its induction upon the runner to the time of its exit from the guide case, even though the directions of discharge chanced in all instances to be favorable to forward propulsion of the runner.

In the Snee motor retarding resistance will be offered by sweeping water between the vanes around the side *C*, Fig. 5, whether the water is thus carried as dead water or is made up of water deflected from vanes, and the proportion of back-water effect thus introduced will be considerably in excess of the proportion of total energy wasted in back-water effect by the old horizontal wheels with flat radial floats, as back-water resistance in the latter is only such as may be due to lifting the vanes gradually out of dead water moving with nearly the same direction and velocity.

The backward curvature of the curved buckets and "ventilation" afforded by the arrangement of curved buckets; as combined in pairs with radial vanes, have the effect of attracting outflow to the side *C*. Though the direction of such outflow may

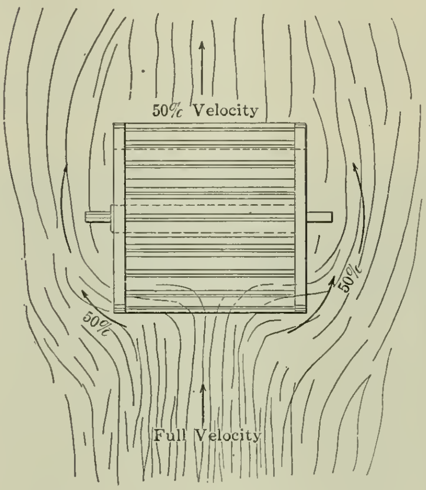

FIG. 7. PLAN OF CRUDE CURRENT WHEEL

chance to be favorable to the direction of rotation of the runner, there must be a sweeping around of dead water immediately in advance of the vanes on the side *C* with the final presentation of a solid body of water to all guide passages at which admission occurs. Neglecting any centrifugal tendency, and assuming that the dead water describes a circular path with half the velocity of current striving for entrance from tangential guide passages, the current cannot enter the space occupied by the runner without being checked in its velocity by the presence of dead water accompanied by a heading up of current which will fall to waste in passing to both sides of the motor. Any water which may enter and pass across the inner compartment has its velocity further reduced by the presence of dead

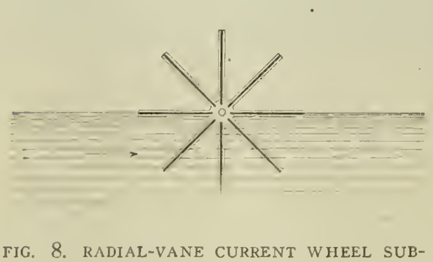

FIG. 8. RADIAL-VANE CURRENT WHEEL SUBMERGED FULL DEPTH

water and is constantly hindered in transfer of energy to the vanes or buckets of the runner by interception of dead water in its course and is halted in its velocity by the increasing presence of dead water. Whether or not it is so intercepted by all the dead water, a considerable amount of the energy so developed under such conditions is absorbed in sweeping dead water around the interior of the guide case.

It would therefore appear that the motor would operate more efficiently if turned on its side, with the axis of rotation horizontal, and were to be charged only with energy of current having a cross-sectional area equal to the projected area of a vane.

The tangential arrangement of guide blades can be considered of advantage only in better directing the current on the vanes of the runner. Their employment results, if anything, in a waste of initial energy of current by changing its direction. The greatest advantage that can be claimed for them is that the gradual reduction of the guide passages results in the reduction of waste of head incidental to changing the direction of current tangential to the path described by the vanes. However, no more energy is recoverable than the tangential deflection is responsible for, and it is extremely doubtful whether the presence of rivet heads and other sources of roughness of the surface of the guide blades can be compensated for in this manner, either when the passages are considered as only mouthpieces for admission of water to the runner or as gradually enlarged ajutages for final discharge of water from the space occupied by the runner.

Probable Efficiency

Whether or not the disadvantages pointed out do attend induction of initial current upon the blades of the runner, the total energy and effectiveness must be materially less than though the wheel were composed only of straight radial vanes extending from the center to the periphery as though the impingement of current were directed upon one-half of the wheel, employed as a horizontal-current wheel, as shown in Fig. 8. In such a case, the energy of current chargeable to the motor would be that portion of the current whose sectional area would be equal to the radius of the wheel, multiplied by its length, and the center of effective pressure would be at the center of the area of the vane. As, for best results, the velocity of the center of the vane should be one-half the velocity of the current, the velocity of the periphery of the runner would have to be equal to the velocity of the current, receiving no energy from the water. The total effective energy would be only one-half as great as though directed on the periphery with appropriate velocity of periphery.

The arrangement of guide passages of the Snee motor can hardly be construed as effecting direct delivery of current on more than one-half the full radial size of the runner wheel, and an estimate of capacity and efficiency based upon that of a current wheel receiving an area of current equal to one-fourth the projected area of the runner wheel and acting on radial vanes of the same area and in the same manner as in crude float wheels would accord to this motor as high power and efficiency as it is capable of developing, if not higher.

Speed of current, diameter, length and weight of runner, depth of submergence, velocity of runner and form and roughness of guide passages, buckets and vanes will all have material influence on the effectiveness of the wheel, but the assumption of maximum capacity and efficiency as given are based on all of these conditions being in most favorable combination.

Possible Power Development

The motors proposed for installation at Atlantic City have runners about 14 feet long and the diameter of the runners would appear from Fig. 4 to be something under 5 feet. Assuming these dimensions for the runners and the effective current area chargeable to the motors to be one-fourth the projected area of the space occupied by the runner, then the sectional area of initial water current operating on one of these motors would be one-fourth of 70, or 17.5 square feet.

Calling f the gross energy capable of being exerted by a current of water expressed in foot pounds per second, then

$$f = A\,v \times W \times \frac{v^2}{2g}, \qquad (1)$$

in which

A = Cross-sectional area of current in square feet,

v = Velocity of current in feet per second,

W = 62½ pounds, being the weight of 1 cubic foot of water, and

g = 32.2, the acceleration of gravity.

Substituting these values equation (1) may be written

$$f = 0.97\,A\,v^3. \qquad (2)$$

From equation (2) it is to be observed that the foot-pounds per second vary directly as the cube of the velocity of current. Substituting for A, equation (2), the quantity 17.5 square feet, the cross-sectional area of effective current assumed for one of the Snee motors gives

$$f = 0.97 \times 17.5 \times v^3 = 16.975\,v^3$$

foot-pounds per second. The gross horsepower of current acting on the motor would be

$$\frac{16.975 \times v^3}{550} = 0.03086 \times v^3$$

gross horsepower in the water.

For reasons which have been pointed out, it would appear impossible for the Snee motor to realize as high per cent. of efficiency as Poncelet found for crude current wheels which, as stated, was found by him to be 40 per cent. The interference and cross-currents encountered by the water in passing through the runner of the Snee motor cannot but detract from the transfer of its energy to the vanes of the runner, and the retarding effect must necessarily place its efficiency below that of the crude current wheels, varying with the velocity of the current presented and the speed of rotation of the runner. But for purposes of commercial comparison of this motor with other methods of generating power, if the same percentage of efficiency is accorded to these motors as ordinary current wheels, viz., 40 per cent., then the net horsepower of one of these motors would be

$$0.40 \times 0.03086 \times v^3 = 0.01234 \times v^3.$$

One of the principal claims for these motors is that they have certainty in developing power from ocean waves. This must be on the assumption that wave motion is accompanied by horizontal flow, i.e., current sweeping through the motor. Should a wave dash upon and spill over the motor it could only result in spasmodic bursts of energy, only momentary in effect and so weak as to be worthless of storage from the time of one wave to another. The horizontal velocity of current incident to wave motion is practically nothing, except in the case of surf waves, and then there is velocity only by the wave falling down and spreading out. If a place can be found for setting up one of these motors where surf waves fall down at all stages of the tide, then the current or spilling-over action of surf waves might be availed of. When it is considered that two surf waves rarely break in the same spot, the impracticability of dependence upon the action of surf waves can be understood.

It is a fact, however, that ocean currents exist and that surface currents are augmented by the travel of crests of waves in the same direction, but there are few, if any, ocean currents which ever attain a velocity of 5 miles per hour, and tidal currents of channels and rivers which empty into the ocean rarely attain that velocity. A velocity of 5 miles per hour would be equal to 7.33 feet per second. If such an ocean current could be found for installation of one of these motors, then its development of power, if accorded 40 per cent. efficiency would be

$$0.01234 \times (7.33)^3 = 4.86 \text{ horsepower.}$$

The U. S. Coast Survey reports the average flood-tide velocity through Hell Gate channel as 4.7 knots per hour and average ebb tide as 4.8 knots per hour. The average of these, 4.75 knots per hour, would be equal to 8.02 feet per second. This channel is about the swiftest tidal water in the vicinity of New York City. If one of the Snee motors of the size of those being installed at Atlantic City were to be placed in Hell Gate channel, then, on the same assumption of 40 per cent. efficiency of current, its power would be

$$0.01234 \times (8.02)^3 = 6.36 \text{ horsepower.}$$

The results to be attained by placing these motors on a beach like that at Atlantic City are hard to conjecture, but the power obtainable can scarcely be assumed as equal to that obtainable in the swift channel of Hell Gate, and this amount certainly would not warrant a very serious investment.

Placing the annual value of a horsepower at $40 and regarding this value per horsepower as worthy of capitalization on a basis of 5 per cent., each horsepower might be regarded as worthy of an investment of $800. Taking for granted that the cost of installation per motor would be only $25,000, i.e., only half as much as quoted for the installation of those at Atlantic City, it can be seen that in order to make a paying investment on the assumed basis of horsepower values, the $25,000 motor plant would have to be capable of developing 31¼ horsepower at $800 per horsepower. In order to develop 31¼ horsepower, the motor would have to be employed in a current of sufficient velocity to fulfil the equation

$$0.01234 \times v^3 = 31\tfrac{1}{4} \text{ horsepower,}$$

i.e., v^3 must equal 2,532.4, showing that a velocity of initial current of 13.6 feet per second would be required. This would be in a current having a speed of from 9 to 10 miles per hour.

Even though such an ocean current were to be found the difficulties of installation would undoubtedly increase the cost far beyond the assumed figure, $25,000. There may be a few isolated locations where river currents attain the maximum velocity of 9 to 10 miles per hour, but the difficulties due to choking up the motor from silt and debris would unquestionably make such installation [illegible] impracticable.

As for the Atlantic City experiment, it will be surprising to learn that it has accomplished anything worthy of consideration [illegible] exhibitional purposes.

Civil Service Examination

The United States Civil Service Commission announces an examination on March 17 at the usual places to secure eligibles to fill a vacancy in the position of mechanical and electrical engineer, $[illegible] per annum, Quartermaster's Department at Large, Fort Bayard, N. M., and similar vacancies as they may occur in any branch of the service.

Applicants who have not had at least two years' practical experience in mechanical and electrical engineering will not be admitted to this examination. Graduates in mechanical or electrical engineering will be considered as equivalent to [illegible] of this period. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application form [illegible].

Central Heating Plant for Lebanon, Ind.

By Byron T. Gifford

The Central Station Engineering Company, of Chicago, Ill., has just completed a central-station hot-water heating system for the Lebanon Heating Company, of Lebanon, Ind. The system covers the best residence district, as well as the business district of the city. Nearly all the mains are located in alleys, which are used wherever practical. In the initial installation, that is, the mains which were laid last year, there are approximately three miles of pipe lines, ranging in size from 12 to 3 inches. The sizes of these mains and laterals were determined by making a careful survey of the territory to be served, and ample capacity has been reserved for future extensions from the original installation.

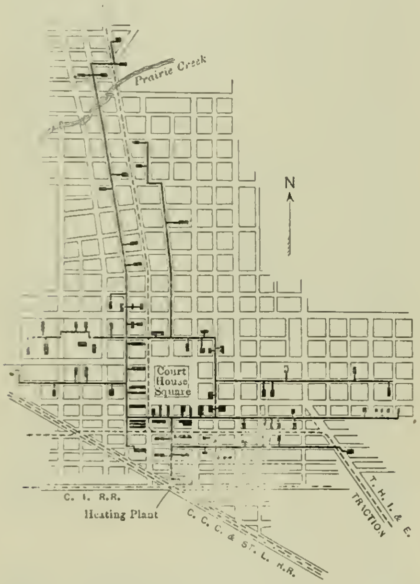

FIG. 2. INITIAL INSTALLATION OF STREET MAINS

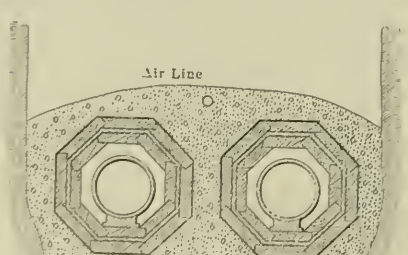

FIG. 3. CROSS-SECTION OF CONDUIT FOR WATER LINE

The pipe line leaving the station is 12 inches in diameter, and continues that size up to the first alley south of the public square; there the line branches two ways with 8-inch pipe which circles the square in the alleys and ties together on the north side, forming a belt which acts as a center of distribution and equalizes the pressure on the lateral lines. Gate valves are placed on all laterals, and also on both sides of the branches in the belt line, in order that any part of the distributing system may be closed off at any time without interfering with the service on the balance of the system.

The system is arranged on the two-pipe pressure-differential plan, and the pipe sizes are based upon a maximum velocity of 5 feet per second. The amount of water to be handled is determined by the number of square feet of radiation to be served, nine pounds per square foot of radiation per hour being the maximum amount used during the coldest weather. The insulation used around the mains is Wyckoff patent steam-pipe covering, which was put in place after the pipes had been tested and made tight under 80 pounds cold-water pressure. After the covering was in place and the joints thoroughly waterproofed with asphaltum, the entire covering was surrounded with from 2 to 3 inches of concrete of 1-2-5 mixture. This was applied comparatively wet and was thoroughly tamped so as to fill completely all spaces around the covering. The concrete envelop acts as a physical protection to the covering, as well as a foundation for the pipe line, and is not considered an insulator.

FIG. 1. STATION OF LEBANON HEATING COMPANY

The air line, which is used as a conductor of compressed air for the operation of the temperature-controlling devices placed on each job, is also embedded in the concrete, as shown in Fig. 3. The expansion joints, shown in Fig. 4, are of the slip-joint type with a brass sleeve sliding into a cast-iron body. These joints have extra-large packing boxes and are of the removable-gland pattern to insure easy access to the joint for the purpose of repacking.

The pipe rests on rollers which travel in metal guide plates, placed approximately 6 feet apart. The anchors, used to hold the pipe in place securely and control their expansion and contraction, are of the beaver-tail type, as shown in Fig. 5. These anchors are placed around the pipe at a coupling in the line, and are embedded there in an enlargement of the concrete envelop. Large roomy double-lidded manholes are built around each set of expansion joints and valves, the extra lid serving as a dirt catcher. The entire line is buried at least 3 feet under the surface of the ground. Detail of the entire line, showing all possible conditions between two anchor points, is shown in Fig. 6. Water leaving the heating station at 200 degrees Fahrenheit will reach a consumer 7/8 of a mile away from the station at 197 degrees Fahrenheit.

Boiler Installation

The station is located at a junction of the Big Four railroad and the Central Indiana railroad, the latter being the direct road from the Indiana coalfields. Coal is unloaded directly in front of the boilers from a side track connecting both of the above-mentioned railroads. The coal goes into a large bin, which is made as nearly dustproof as possible, being lined with paper and built of matched lumber. The boilers in the initial installation are four in number, viz., two 80-horsepower return-tubular boilers, and two 347-horsepower circulating boilers. The steam boilers are used to generate steam for the circulating pumps and other steam-driven apparatus in the station. The circulating boilers, built by the Rust Boiler Company, of Pittsburg, Penn., are composed of three banks of tubes connected to six drums, three at the top and three at the bottom. The circulating water enters the top drum at the rear of the boiler, passing down a bank of tubes to the lower rear drum, then over to the lower middle drum through a row of tubes, rising to the middle drum at the

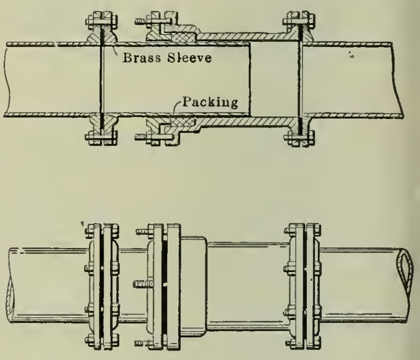

FIG. 4. TYPE OF EXPANSION JOINT IN USE

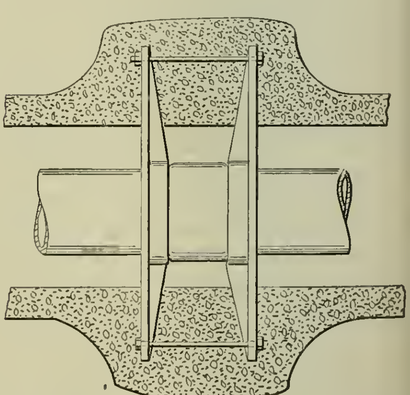

FIG. 5. BEAVER-TAIL ANCHOR

top and passing over to the front drum at the top, then down to the lower drum at the front and from there into the flow main and out into the pipe line. The gases in these boilers pass from the lower front drum to the upper front, down the middle bank of tubes and up the rear bank. With this arrangement the hottest gases come in contact with the hottest water, and the coldest gases with the coldest water. All four boilers are equipped with Green chain-grate stokers. Mechanical draft is used because of the low temperature of the gases under the circulating boilers, which would have necessitated a very high stack had natural draft been used.

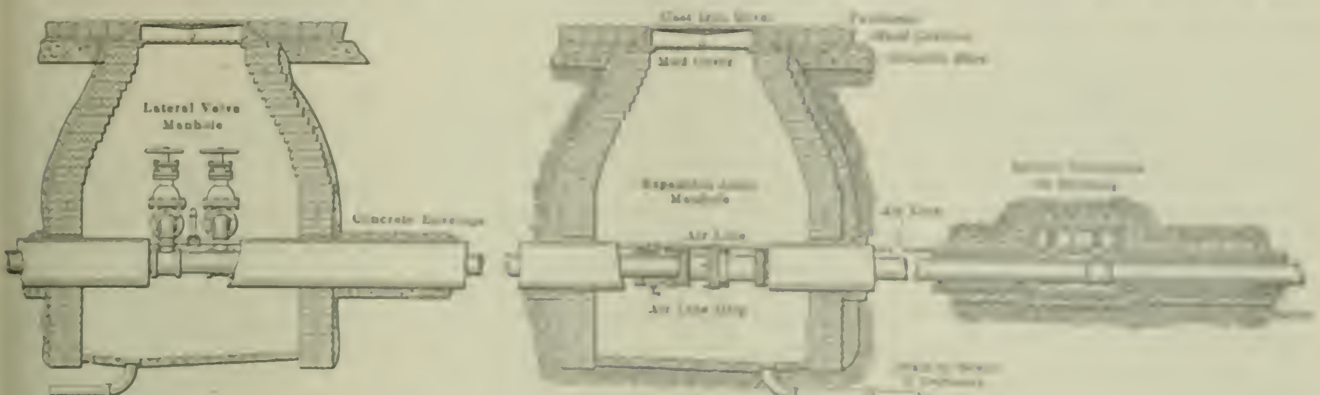

FIG. 6. COMPLETE SECTION OF PIPE LINE BETWEEN ANCHOR POINTS

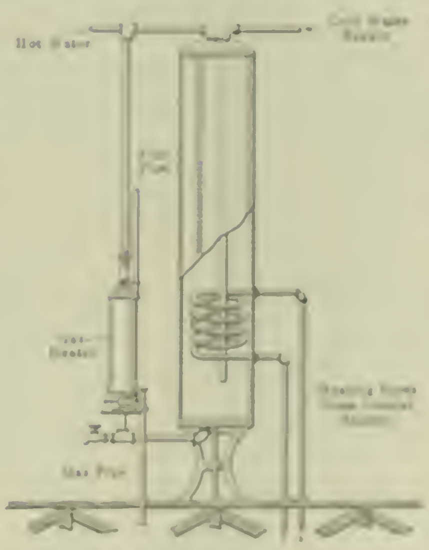

FIG. 7. HEATING WATER FOR DOMESTIC PURPOSES

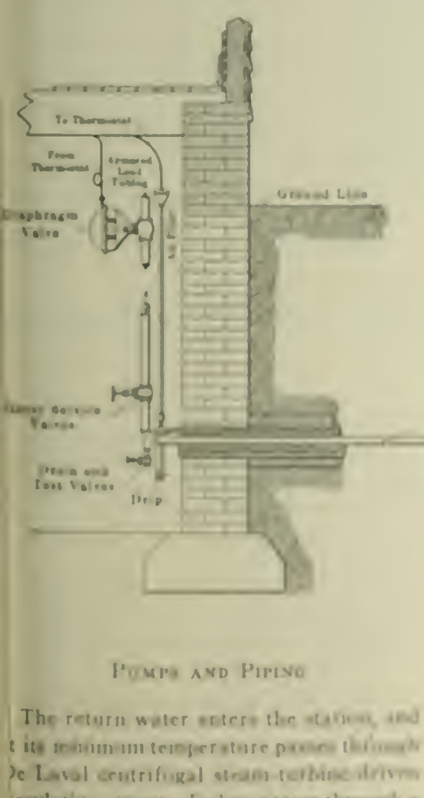

FIG. 8. TYPICAL SERVICE CONNECTION

Pumps and Piping

The return water enters the station, and at its minimum temperature passes through De Laval centrifugal steam-turbine-driven circulating pumps. It then passes through a surface condenser, in which is utilized all of the exhaust steam from the different pumps and other steam apparatus in the station, the condenser being so designed as to pull at least a 1-inch vacuum under all conditions. After the water leaves the condenser it goes to the circulating boilers, and there absorbs the amount of heat necessary to raise the temperature to the schedule then prevailing, before it is again sent around the heating mains. All the necessary auxiliaries, such as boiler feed pumps, low-pressure pumps, governors for the same, condensation pumps, duty well pumps, etc., are installed. A gage board equipped with thermometers, gages, etc., shows at all times just what the entire plant is doing.

At the present time the load connected to the plant is [illegible] square feet of radiation. Of this amount about [illegible] square feet consists of gravity equipment, which was installed in the different buildings before the central plant was built. The balance, or [illegible] square feet, is equipped for central-station heating, with no pipes smaller than 1 inch. The temperature of each building is controlled by a thermostat operated by compressed air supplied from a Westinghouse air compressor at the station. If desired, the company allows circulating water to pass through a coil in a range boiler, as shown in Fig. 7, in which water is heated for bath, lavatory, laundry or kitchen purposes, giving the consumer at all times hot water ranging from [illegible] to [illegible] degrees temperature.

Service Lines

The service lines running from the mains to the different buildings are installed in practically the same way as the mains. Where the service leaves the main, a swing joint is put in to take up the contraction and expansion. A curb box with shutoff valves is placed just inside the curb line or just outside of the property line on each service. The construction and other features are the same as in the mains. A longitudinal cross-section of this is shown in Fig. 8.

Duplicate apparatus consisting of pumps, boilers, [illegible], have been installed and space is provided for future installation in order that there may be no [illegible] of service by power-house equipment [illegible] an uninterrupted period.

Flanged Pipe Joints for High Pressure

Types of Screwed Joint, Peened, Shrunk and Riveted; Variations in the Van Stone or Lap Joint, and the Autogenous Welding of Flanges

BY WILLIAM F. FISCHER

One of the problems confronting the engineer in the installation of a system of high-pressure steam piping for the modern power station is the selection of a flanged pipe joint suitable to the work, pressure carried on the boilers and temperature of the steam if superheated. The failure of a flanged pipe joint, if properly made, is seldom attributed to the steam pressure alone, but can nearly always be traced to other causes such as careless erection, improper support of the piping, valves, fittings, separators, etc., or to the combined stresses caused by expansion, contraction, vibration and water hammer.

Screwed Joints

Although the old-fashioned screwed joint has proved entirely satisfactory in the majority of cases, when used in connection with saturated steam for pressures up to 160 pounds and in many cases even greater with a moderate degree of superheat, it is generally acknowledged, however, that the screwed, shrunk, shrunk and peened, or riveted joints are not altogether suitable for steam mains carrying the high steam pressures of today, or for highly superheated steam, due to the fact that these joints, when strained to any extent, have a tendency to develop a leak through the threads or between the pipe and the flange.

In many cases leakage or failure of a screwed joint when under pressure is due as much to imperfect and careless workmanship in the cutting of the threads and the fitting of the flanges, as to careless erection or poor design of the piping system. It is important that the threads be perfectly cut to standard sizes with tools of the best quality and in good condition. The pipe should be screwed completely through the flange to guard against leakage, and also to make the threads metal-tight against the oxidizing action of leaking steam and water. All grit, dirt, iron chips, etc., should be thoroughly removed from the pipe and flange threads before screwing on the flange, otherwise the friction of the parts may be so great as to prevent the joint being made up steam-tight. Occasionally in the larger sizes the pipe to be threaded is not perfectly round, having been flattened in handling or during transportation, and the threads cut deeper on one side than on the other. In a case of this kind the steam is apt to leak through the threads, no matter how tight the flange.

Several methods have been devised for making screwed joints to guard against leakage through the threads. One method in use is to cut a calking recess in the hub of the flange, as shown at *A* in Fig. 1. The pipe is screwed into the flange steam-tight, and the recess *A* is filled with soft copper which is calked in firmly. All flanges fitted with this recess should be ½ inch higher on the hub than the regular flanges to give sufficient bearing for the threads. The dimensions of the recess, as given in the figure, were furnished by the Crane Company.

Screwed and Peened Joints

Another method is to peen or roll the end of the pipe into a peening recess at the face of the flange, after making the flange up tight on the pipe. Such a joint is shown in Fig. 2. The pipe and flange are carefully threaded, and the pipe is screwed completely through the flange, leaving the end projecting slightly beyond its face. The pipe is then pounded down around its inner circumference with a peening hammer, or is sometimes rolled by special machinery, until the end completely fills the recess *A*, making a steam-tight joint between the pipe and the flange. The pipe is then put into a lathe and the joint faced off true to insure the face of the flange being perpendicular to the axis of the pipe.

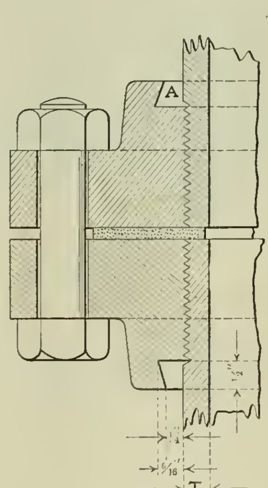

FIG. 1. SCREWED FLANGES WITH CALKING RECESS

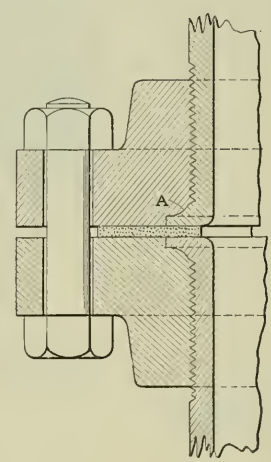

FIG. 2. SCREWED AND PEENED JOINT

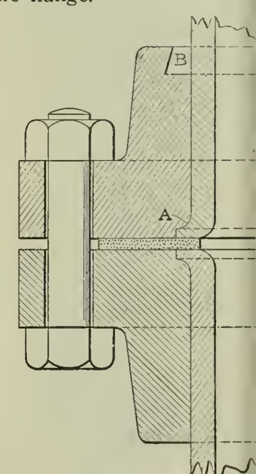

FIG. 3. SHRUNK AN PEENED JOINT

Shrunk, Peened and Riveted Joints

As pipe over 18 inches in diameter cannot be easily threaded, the flanges ar riveted, shrunk, shrunk and peene riveted and peened, or both shrunk an riveted on and then peened, all accordi to the judgment of the engineer. Th also applies to smaller pipe.

Shrunk Joints—In making the shrun joint the flange is accurately bored out t a diameter slightly less than the finishe outside diameter of the pipe. Whe heated to the proper temperature, th flange expands and is forced over the en of the pipe. In cooling, the flange co tracts and hugs the pipe all around i outer circumference with tremendo force. This, however, does not alwa insure a tight joint, and in most cases th outside of the pipe is turned true befo shrinking on the flange.

Shrunk and Peened Joints—An ord nary joint of this type is shown in Fig. The flange is shrunk on the pipe, as prev ously described, leaving a short length pipe projecting beyond the face of t flange. The end of the pipe is th peened or rolled into the recess *A* in manner similar to the screwed and peen joint. If so desired, the joint can also made with a calking recess in the hub the flange, as shown at *B*. Then shou a leak develop between the flange and t pipe, the recess *B* can be calked with so copper, as described for Fig. 1.

Riveted Joints—It is difficult to ma a plain riveted joint that will remain tig for any length of time after it is und pressure, especially where cast-iron flang e used. For work of this kind the nges should preferably be of rolled steel pressed steel. Riveted joints are more ten used for exhaust steam mains in the rger sizes than for high-pressure work. It was a custom among several of the ominent manufacturers, before welding

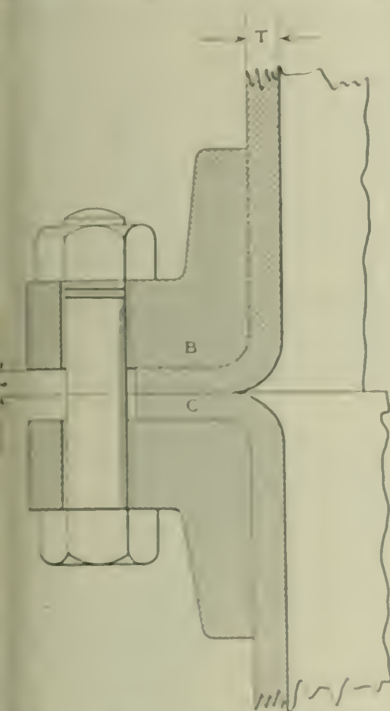

FIG. 4. ORIGINAL VAN STONE JOINT

There are many other joints in use, both in America and Europe, similar in many respects to the above, for which space is not available.

Van Stone or Lap Joints

Since the introduction of superheated steam more attention has been devoted to the details of piping systems. Valves have changed considerably. All cast-iron valves and fittings are rapidly being replaced by those made of cast steel, and in a like manner the joints previously described are being replaced by the Van Stone or lap joint.

Fig. 4 shows the Van Stone joint, of which the Lumsden & Van Stone Company, of Boston, Mass., was the originator. With joints of this type there is no possibility of a leak occurring between the pipe and the flange. In making this joint the flange is bored out to fit loosely over the pipe. The end of the pipe is then heated to the proper temperature and rolled or lapped over the face of the flange, as shown at *B*, the outer edge of the lapped portion coming just inside of the bolt holes. The faces of the laps at *C* are then turned off true in a lathe perpendicular to the axis of the pipe, and the joint is either made up metal to metal by grinding both faces of the lap, thus making a ground joint, or both faces are finished and a suitable gasket placed between them. Any good metallic or vulcanized gasket

finished lap is considerably less than that of the pipe itself. This is illustrated in Fig. 5, which shows a Van Stone joint before and after facing perpendicular to the axis of the pipe. The drawing is exaggerated for clearness. The original thickness of the pipe is shown at *T*, and

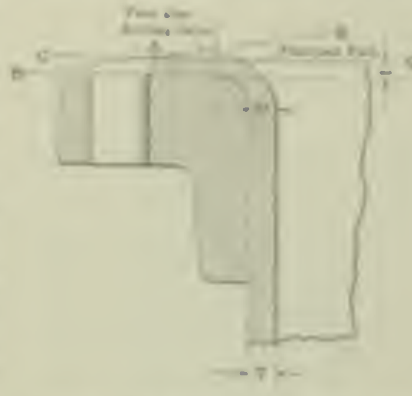

FIG. 5. VAN STONE JOINT BEFORE AND AFTER FACING

the thickness of the lap after facing front and back at *t*. Line *B B*, exaggerated also for clearness, shows the outward bevel of the face of the lap after rolling, due to the gradual thinning down of the metal, from the point *D* to the outer edge of the lap at *A*.

The method of constructing the joints

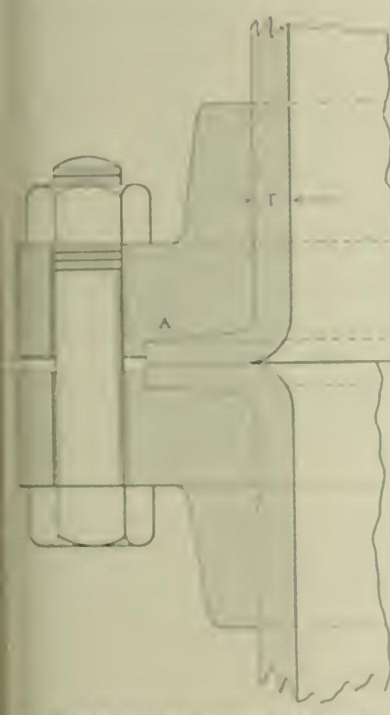

FIG. 6. IMPROVED [illegible] LAP JOINT

FIG. 7. LANGLAP JOINT

FIG. 8. IMPROVED LANGLAP JOINT

came as popular as it is today, to rivet nozzles to openings cut in the side of another pipe, making what is known as the riveted header. These nozzles in most cases are now welded on, making a more efficient joint in all respects for high-pressure work.

suitable for high-pressure superheated steam may be used.

By the ordinary method of flanging or lapping the pipe over the face of the flange the metal is thinned down considerably, so that when faced off front and back, *B* and *C*, the thickness of the

shown in Figs. 6, 7 and 8 is to bevel the face of the flange to the width of the lap to compensate for the difference in the thickness of the pipe between the inside and outside portions of the lap. The outward bevel of the face of the flange is shown at *A*. This brings the face of the joint almost true after rolling, only a light cut over the face being necessary in finishing.

Fig. 6 shows the improved recessed joint made by W. K. Mitchell & Co., of Philadelphia, Penn. The pipe is turned over on the face of the flange to within ¼ inch of the bolt holes. The flange is

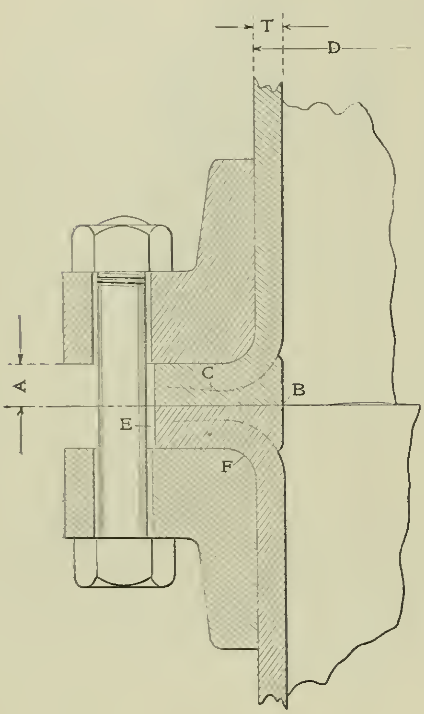

FIG. 9. THE WHITLOCK JOINT

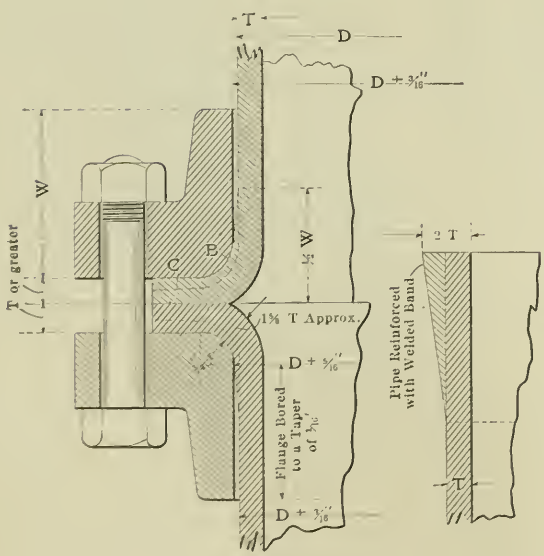

FIG. 10. IMPROVED VAN STONE JOINT

recessed on its face to receive the lapped-over portion of the pipe, but the lap is allowed to extend about 1/32 inch above the face of the flange to give a good bearing for the gasket.

Fig. 7 is the Cranelap joint, and Fig. 8 an improved type of this joint. The improvement consists in upsetting and rolling the joint flat and square at the inside edge, as shown at *B*, giving a much wider bearing for the gasket. These joints are made by the Crane Company, of Chicago.

Fig. 9 shows the Whitlock joint, made by the Whitlock Coil Pipe Company, of Hartford, Conn. This might be called a double-lap joint. In making it the end of the pipe is heated and doubled back on itself, as it were, when rolling or lapping the pipe over the face of the flange. This is shown by the dotted line *C*. The pipe is upset slightly at the inner edge *B* and outer edge *E* to square up the face of the joint before finishing. The joint is then faced off true in a lathe perpendicular to the axis of the pipe. The thickness *A* of the metal after facing is equal to, or greater than, the original thickness of the pipe *T*. This method also gives a wide bearing for the gasket, as shown at *B*, and the pipe is strengthened at the corner *F*, where the lap joins the main body of the pipe.

In Fig. 10 is shown the improved Van Stone joint made by the M. W. Kellogg Company, Jersey City, N. J. After facing, the flange is bored to a taper of 1/16 inch. In the drawing, *D* represents the outside diameter of the pipe, *T* the original thickness of the pipe, and *W* the hight of the flange from the face to the end of the hub. The flange fits loosely over the end of the pipe. In making the joint, the pipe is first reinforced by securely welding a wedge-shaped band on the end of the pipe all around the outer circumfer-

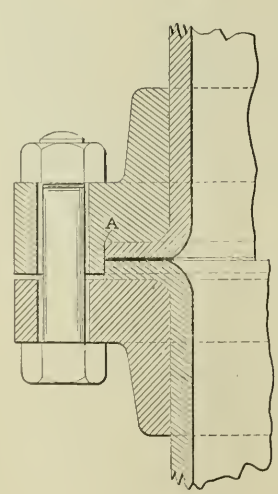

FIG. 11. VAN STONE HYDRAULIC JOINT

ence, doubling the thickness of the pipe at the extreme end. The dotted line *C* shows the position of the band after lapping or rolling the end of the pipe over the face of the flange, and finishing the joint on the front and back. The thickness of the pipe at *B*, where the lap joins the main body of the pipe, is approximately 1⅝ *T* or greater. The thicknes of the lap is equal to or greater than in all cases after finishing.

Fig. 11 shows a Van Stone hydrauli joint, also made by the Kellogg compan The upper flange is recessed at *A*, thu covering the edge of the joint to pr vent the gasket from blowing out at th

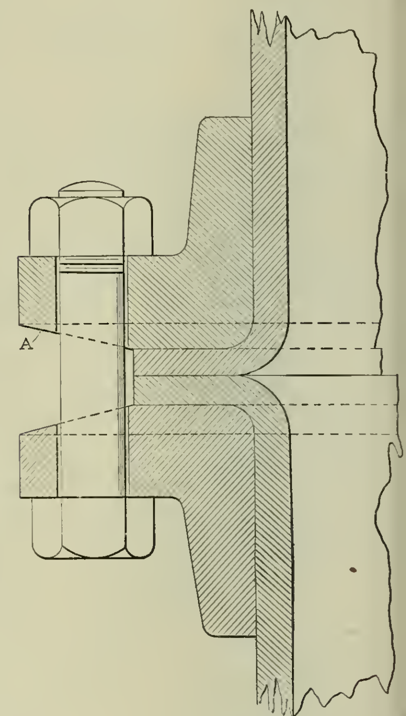

FIG. 12. VAN STONE JOINT WITH BEVEL FLANGES

higher pressures. This recessed flange also used in connection with the in proved Van Stone joint shown in Fig. 1 the joint being the same in all other r spects.

Fig. 12 shows a Van Stone or lapp joint sometimes used in connection wi a flange having the face beveled at making the gasket more accessible for r moving or renewing.

The flanges on the Van Stone join just described are loose and swivel, a fa appreciated by erecting engineers, as becomes necessary at times to change th position of the flanges to bring the bo holes into line when erecting. The flang can be revolved to the desired positio These flanges may be of cast iron, ca steel or rolled steel. The rolled-ste flange is to be preferred where the ext cost is not prohibitive.

Joints of the Van Stone type should faced off on the back of the lap, as we as on the front, in order to insure a tig joint, as scale is formed on the back whe the pipe is put through the process heating and flanging. This scale, unle removed, falls off in spots, leaving a r cess between the pipe and the flange ar allowing the flange to settle uneven against the turned-over portion of th pipe. Although the joint may be tig vhen first erected in the line, in time the cale is likely to crumble and fall away, llowing the flange to settle closer against he back of the lap, which will lessen the ension of the bolts and cause the joint o leak.

Another method has been tried for reinforcing the metal at the face of the ap. It consists in upsetting the end of he pipe before flanging. This does not give the increased thickness and strength t the place where most required; namely, t the corner where the lap joins the main ody of the pipe. It is also known that xcessive upsetting has a tendency to rystalize and consequently weaken the bers of the material.

Van Stone or lapped joints are made sizes from 4 inches up. For smaller izes, as a general rule, the screwed oint is used, and where properly made

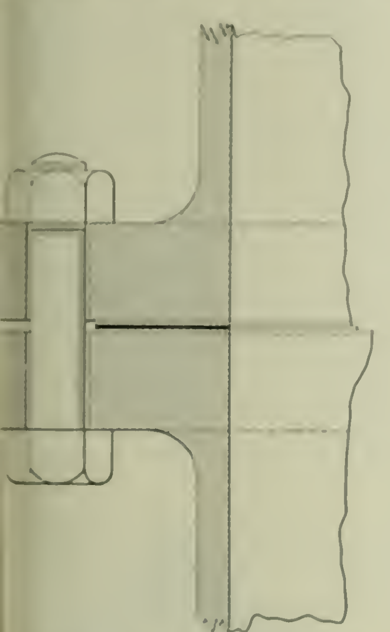

FIG. 13 FLANGE WELDED TO PIPE

ves excellent results. Or, if so desired, e flanges can be welded directly to the pe, both in the small and large sizes.

Welded Flanges

The practice of welding flanges to pipe by no means new, having been accomished satisfactorily in Europe for some years or more, especially in Germany d England. Many firms in America are w doing this work, to meet the ever ineasing demand for a metal-to-metal int of the welded type. The ordinary ethod of welding by mechanical means, ch as hammering or rolling, is not used extensively as in the past, due to the ct that the strength of a weld made in is manner is uncertain. There has retly come into use a system known as togenous welding, in which the metal self is raised to a temperature sufficiently gh to cause it to be its own joining material; that is, the parts to be welded are joined together by the fusion of their own substances without mechanical aid. By this method pipes are welded together, making any required length in one piece, and even separators and other steam appliances are welded up in the same manner, forming a homogeneous mass of uniform quality throughout.

A welded flanged joint is shown in Fig. 13. As will be noted, the flanges do not swivel on the pipe. For this reason the Van Stone joint is often preferred for erection purposes. Fig. 14 illustrates a type of welded joint much used on the Continent and to some extent in America. The flange *B* is either upset or welded to the pipe and beveled off at 45 degrees, as shown at *A*, to match the bevel on the loose-ring flange *C* directly above it. With this arrangement the bolt holes can

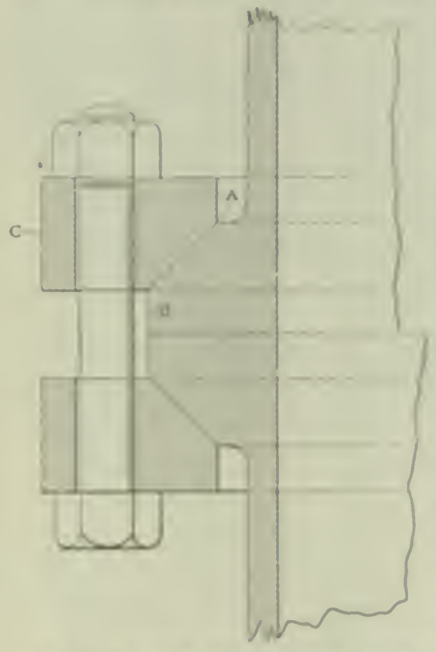

FIG. 14 WELDED OR UPSET ENDS WITH LOOSE TAPERED RING FLANGE

be brought into line when erecting by turning the flange C to the desired position. The welded flanged joint makes the most perfect and workmanlike joint in use at the present time if properly made.

In a number of tests recently made to determine the strength of welded joints, the metal showed an average loss in tensile strength of about 10 per cent. at the weld for equal areas. These welds were made by skilled workmen using modern methods. It is good practice to reinforce the metal at this point to insure the weld being as strong as or stronger than the pipe itself.

The Pennsylvania railroad commission recently issued a circular to every steam railroad company in the State of Pennsylvania which is being done to prevent [illegible] and other accidents to [illegible]

Electrolysis and Superheat

By Thomas Sawyer

I have seen a great deal in the technical press lately about the destruction of condenser tubes, but I have seen nothing at all, so far as I can remember, about the corrosion, erosion or electrolysis of pump cylinders. I was once employed for a long time in a power plant where the eating away of portions of pumps by what looked to me like electrolysis or galvanic action was a matter for serious consideration. Surface condensers with salt-water circulation were used, and every cylinder in which salt water was used suffered. In one cylinder it would be the back head, in another it would be the front head, and in still another it would be the valve deck or some part of the cylinder at or near the end of the brass cylinder lining.

The engineer always claimed that there was from some source an electric current passing into or through the pump to the water, and that where it left the pump for the water it took some of the iron along with it. He searched for "grounds" inside the plant and succeeded in getting all that could be found transferred outside of the system, but that did not appear to help matters much, so he settled down to the practice of keeping circulating-pump parts in stock, ready for instant use whenever a replacement was necessary. He got all sorts of advice from all sources and tried some of the remedies suggested.

One friend told him that the devouring element, whatever it was, was caused by acid in the water and that acid must have something to eat. It ate the cast-iron pump cylinder because that was [illegible] but zinc, being more easily dissolved in acid than iron, if it could be introduced into the water space of the pump, where it would be eaten instead of the higher-priced pump cylinder. This was tried with no change in the rate of decomposition of the pump cylinder that could be noted, and absolutely no effect on the zinc except to brighten the surface slightly where it rubbed on the iron.

There was one pump in the plant where the corrosion was confined to the valve deck, and in a few months the valve seats would become loose and drop out. It was decided to put in a brass cylinder in place of the cast-iron one, it being hoped that the current would not eat brass, and if there were no cast iron for the current to eat it would leave the pump for the water without doing any damage. The life of a cast-iron cylinder had been from a year to [illegible] months. The brass cylinder ran [illegible] three months, when the valve deck began to [illegible] at a rate [illegible] for the iron cylinder in its [illegible]

It seems that the electric current had [illegible] as effective on the brass valve [illegible] and stem that it would not leave for the water without taking along quite a bit of the material with which it had been associating. Here is a photograph (Fig. 1) of a valve stem and also a valve seat, which will give you some idea of how the wasting of the material is going on. It would seem that the outside of the valve stem is softened by the passage of the current, and in its soft state is rapidly worn away by the friction of the rubber valve. At one end there is quite a pit, about ¼ inch deep, and the pit has a copper-colored appearance, as though the zinc had been eaten out of the composition of which the stem is made, leaving the copper to be washed away by the water; from the photograph of the valve seat it can easily be seen how the wasting process has attacked both the face of the seat ring and the radial ribs. These radial ribs were originally about ¼ inch thick. Some of them are wasted away to a knife edge and considerably below the face of the valve seat. On the opposite side of the valve seat the face of the valve is depressed nearly ¼ inch where the rubber valve has worn the top surface material away.

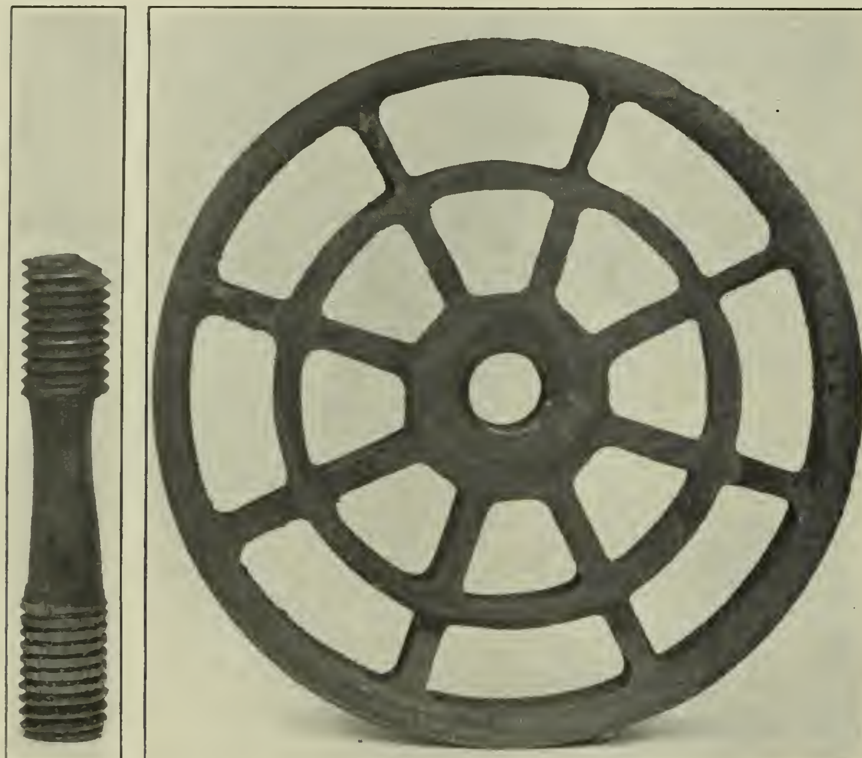

FIG. 1. VALVE STEM AND SEAT, SHOWING THE DEGREE OF WASTING AWAY

This matter is particularly interesting to me because in no other plant that I have visited have I seen the destruction of pump cylinders, valve decks, valve stems, valve seats, etc., carried on to such an extent, and I am at a loss to account for it. At certain portions of the day some sewage which possibly might contain nitrates is carried through the different pumps in the condensing system, but the greater part of the wasting away takes place entirely in this single pump cylinder.

The usual brass valve guards on the upper end of the valve stems are being replaced with cast-iron ones, in the hope that in the escape of the current from the pump to the water it will take iron along instead of brass. These small guards are cheap and if the action can be confined to them it will in a measure solve one engineer's problem. Of course, everyone knows that the proper way to cure any ill is to remove the cause, but in this case it seems that the cause is undiscoverable. It may come from the electric-car line half a mile away, or it may come from some cause in the plant itself. Anyway the problem is an interesting one and I shall watch developments with interest.

FIG. 2. WHAT WAS LEFT OF THE BRONZE VALVE SEAT

At this same plant a change was made from horizontal return-tubular boilers to water-tube boilers with superheaters, and no end of annoyance has followed the change. I know editors say that there is or need be no trouble in using superheated steam if the pipe and fittings used are o the right kind. That may be true as regards pipe and fittings, but we did no learn it soon enough. These boilers were installed under a guarantee to give 100 degrees superheat to the steam whe working at their rated horsepower, which guarantee I think was met, for I found 120 degrees superheat at a turbine throttle 120 feet from the boiler.

An amusing incident occurred one day when I started to take the temperature of the steam. We were using a steam pressure of 115 pounds and as I took the cover from the thermometer well, I looked around for something to clean out what dirt might have got in before the cover was put on. I saw what looked like a short piece of wire lying on a tool box nearby. I took the wire and, winding a little wad of waste around it to catch the dirt, pushed it down into the well. For an instant I thought the well had no bottom, for the wire went right along down When I pulled it out I had only about 2 inches left of what proved to be a piece of 30-ampere fuse wire. The well was nearly full of melted metal in which the thermometer was inserted when the temperature readings were wanted.

But I started to say something about superheat. The boilers and the new pipe line had all been equipped with special superheat valves which were all right until it was desired to close them. The first set was of the automatic nonreturn type. In less than six months they had all failed and were replaced by ordinary heavyweight valves. These answered a little better, but one day there came a glib-tongued salesman, with confidence in his goods written all over his face and showing in every word and action. He had the real superheat-proof valve. It had been discovered, he said, that all the trouble with valves in the use of superheated steam came from the difference of expansion between the cast-iron body and the bronze seats. So the company chemist had set himself the task of creating a bronze for valves and seats which should have the same coefficient of expansion as the cast iron from which the body of the valve was made, and he had succeeded.

And here was a guaranteed valve ready for use in which the bronze parts would always retain their proper relation to the iron body because the bronze parts would always expand and contract with the iron and to the same extent with the same temperature.

No argument nor "jollying" seemed to shake the confidence of this salesman in the quality of his wares and a set of stop valves for the boilers was ordered.

One day not long ago one of the valves was closed, but the closing of the valve did not shut the boiler off and other valves were shut one after another until the faulty valve, the valve with a guarantee of a live salesman and a responsible company behind it, the valve with a new coefficient of expansion, could be examined. It was found to be seatless. Here is a photograph (Fig. 2) of that part of the seat which could be found. The missing segment from the ring must have evaporated in the intense heat of the superheated steam, for no trace of it has been discovered. It will be noticed from the photograph that the seat must have become quite loose in the body of the valve and that it had danced about considerably, wearing away the threads which at first held it in position.

Annual Dinner of the A. I. E. E.

The annual dinner of the American Institute of Electrical Engineers will be held on March 11 at the Hotel Astor, New York City, and will celebrate the completion of the first quarter of a century of the institute's existence. The historical significance of the gathering is receiving special consideration by the committee of arrangements appointed by President Louis A. Ferguson, which consists of T. C. Martin, chairman; G. H. Guy, secretary; T. Beran, M. Coster, M. M. Davis, H. A. Foster, G. A. Hamilton, R. T. Lozier, W. McClellan, F. A. Muschenheim, H. W. Pope, C. W. Price, F. A. Scheffler, E. A. Sperry, A. Spies and A. Williams.

Steam and Electrical Equipment of the Ambrose Channel Lightship

By Warren O. Rogers

When an engineer passes a civil-service examination he is eligible for various engineering positions in the sundry departments of the United States Government. Among these is that of engineer and electrician on board a Government lightship. In order that a clear idea may be obtained as to what type of apparatus comprises the steam and electrical equipment of a modern lightship, a short description of the Ambrose Channel lightship, formerly known as the Sandy Hook lightship, off the entrance to New York harbor, is given herewith.

The new Ambrose channel lightship is equipped with two Scotch boilers having [illegible]

two [illegible] each, one boiler being shown in Fig. 1. These boilers generate steam for the different apparatus throughout the ship which are used for illuminating signal lights, etc. Steam is also used for blowing the huge fog whistle in thick and stormy weather. The coal bunkers are placed along the sides of the ship, and hold a supply sufficient to last from four to five months.

In Fig. 2 is shown a vertical compound engine, with cylinders of [illegible] and [illegible] inches in diameter and a stroke of [illegible] inches. It is direct-connected to a propeller shaft, the propeller being [illegible] feet [illegible] inches in diameter, with a [illegible] pitch. This engine [illegible] will enable the lightship to proceed [illegible] in case it should break away from its moorings [illegible]. The engine runs condensing, as do the auxiliary engines throughout the ship. [illegible] The condensing system is [illegible]

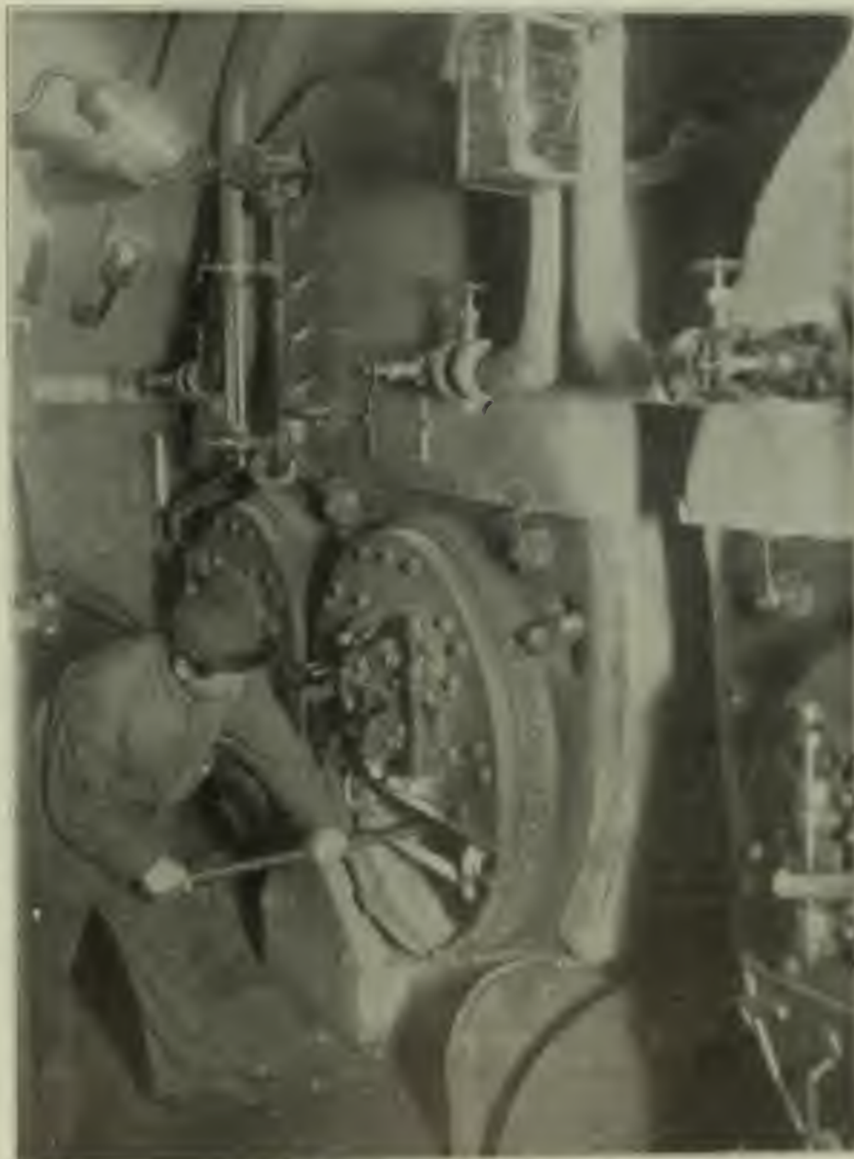

FIG. 1. SCOTCH BOILER [illegible] LIGHTSHIP

is used for all purposes. The ship is equipped with an evaporating and distilling plant with a capacity of 2500 gallons per twenty-four hours.

In Fig. 3 are shown the two generating sets used for illuminating the ship throughout and also the masthead signal lights. The generating units are in duplicate, direct-connected to a marine-type vertical engine and have a capacity of 7 kilowatts. They are of the multipolar type with a working range in electromotive force of from 110 volts no load to 115 volts full load. The armatures are of the iron-clad, bar-wound ventilated type, the cores being built up of thin, double sheet-steel laminations, in the slots of which are carried interchangeable coils separately insulated. The brushes are designed with a means of independent or collective adjustment. The circuit switches feed their respective circuits directly, and connections are made so as to operate all lights from either generator set, or both.

The vessel is wired with a two-wire feed system to which are connected fifty-five 16-candlepower 110-volt incandescent lamps. Each circuit is placed in an iron-pipe conduit with a socket so designed as to make it absolutely steam- and water-tight.

The switchboard shown between the two generator sets controls the entire electric-lighting system of the ship. It will be seen that double-throw switches are arranged so that in case of accident to one generating set, the other can be put into service. The distributing switches are also of the double-throw type and so arranged that different circuits can be carried by one engine, or any combination can be made so that one engine or both engines may be used at once on any or all circuits. The engines operate either condensing or noncondensing.

The masthead signal lights consist of three 250-candlepower 100-volt tungsten lamps suspended 55 feet above the water level. They can be seen in clear weather for 13 miles. These lamps, which are carried on the fore and main masts, are also arranged so that each can be switched onto either generator, which prevents any discontinuance of the light in case of accident to either one of the generating units. In the rear of the switchboard is the device for flashing the masthead lights, by which arrangement the lights are flashed for a certain interval and then remain dark for a certain interval, the current being automatically cut in and out. This timing device can be changed so that the period of lighting and the period of lamp extinction can be varied to suit any desired timing.

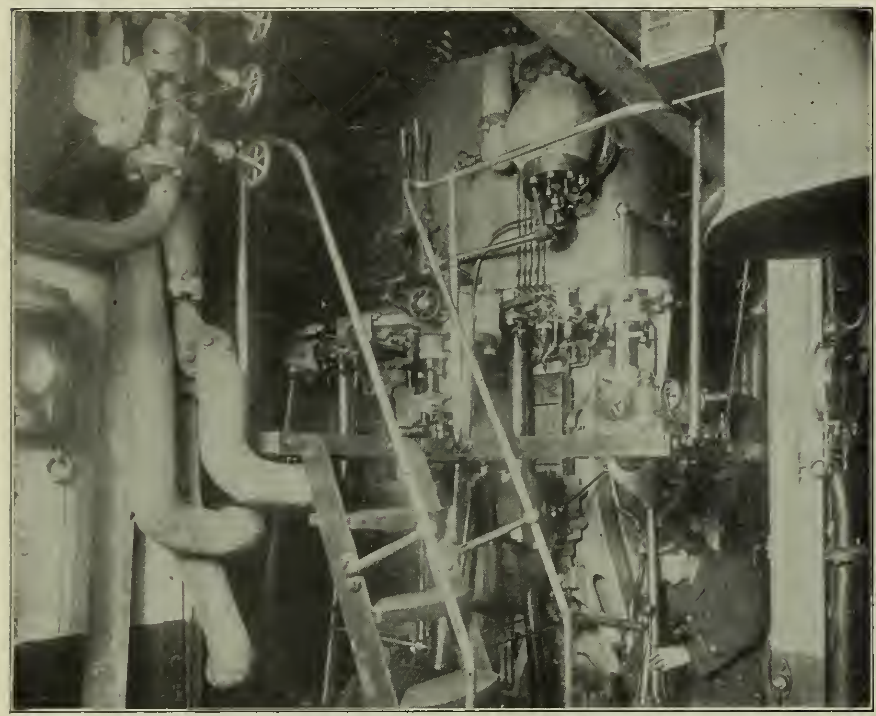

FIG. 2. VERTICAL COMPOUND ENGINE ON LIGHTSHIP

In Fig. 4 is shown a section of the upper-deck engine room which is directly over the grating of the main engine. In the corner shown will be seen a boiler-feed pump and also a small vertical engine used when operating the large fog whistle. This whistle obtains steam from a 4x12-foot wrought-iron steam drum which is connected to the boilers by short pipe connections. The steam drum was found to be necessary in order to get dry steam, as without it water would be drawn from the boilers. The whistle is so arranged that it blows for a definite period and then is silent for a definite period. The whistle blast is timed by means of blocks, the blast of the whistle representing the time it requires for the whistle lever to pass over a block and drop to its lowest position, when the whistle remains silent. When the whistle lever is again lifted by a block, its motion opens the valve in the whistle pipe and the whistle blows until the lever reaches the end of the block and drops to its lowest position again. These blocks are placed in a revolving plate and can be spaced as desired.

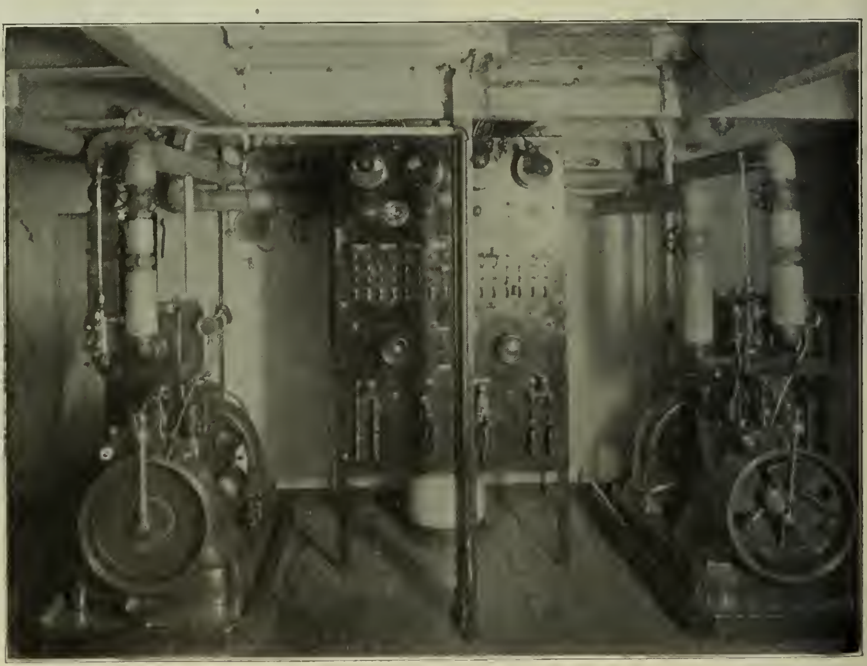

FIG. 3. GENERATING SETS ON LIGHTSHIP

On the other side of this upper-deck engine room is arranged a small vertical engine direct-connected to an air compressor. This air compressor furnishes air to the deep-sea bell of the same type which figured as an important factor in the recent collision of the steamships

"Republic" and "Florida," the bell being the means of guiding the rescuing steamship to the disabled steamer.

The operation of this bell is as follows: The bell, connected to a water-tight casing at the top, in which is a diaphragm, is suspended over the side of the ship and submerged in the water. To the top of the bell containing the diaphragm are connected two rubber pipes, which are in turn attached to the receiver of the air compressor. This bell is arranged to operate automatically by a timing device striking the number of the ship, which in this case is 22. As the air is admitted to the diaphragm and released it operates the bell clapper, which, striking the bell, sends its tone through the water for about 10 miles in all directions from the ship. The officers of a ship within that zone, if equipped with a receiving apparatus, are enabled to estimate the distance they may be from the lightship. There are usually two receivers on ships equipped with this device, and in order to determine the exact position of the warning signal, the ear is applied first to one and then the other, the one giving out the loudest tone indicating upon which side of the ship the lightship is located. In this way, the officers are enabled to determine their exact position.

The Ambrose channel lightship is said to be the best equipped lightship in the world, modern in every particular and built to withstand the heaviest sea. The writer is indebted to A. B. [illegible], superintendent of the lighthouse department, Tompkinsville, S. I., for data, etc., pertaining to this lightship.

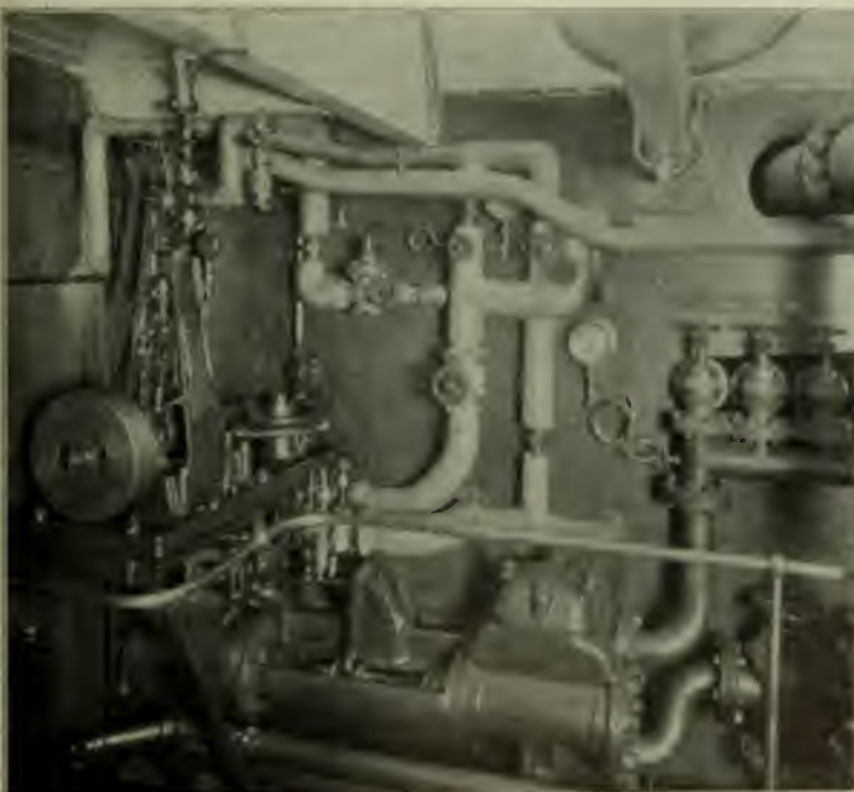

FIG. 4. PART OF THE UPPER-DECK ENGINE ROOM

Proposed Mammoth Testing Machine for the Government

On January 28, Senator [illegible] introduced into the United States Senate a bill for the purchase of an Emery testing machine of large proportions, this machine to be designed by A. H. Emery, builder of the famous testing machine at the Watertown arsenal, which was tested for acceptance in [illegible]. The proposed machine is to be able to give and weigh loads of tension up to [illegible] pounds, and loads of compression up to [illegible] pounds, on specimens up to 100 feet or more in length. The main loading platforms for testing bridge compression members, columns, etc., are to be not less than 8 feet wide and 12 feet long and are to be adapted to receive auxiliary holders and platforms. The machine, if built, will have tension holders to [illegible] and test to destruction round, square and rectangular bars with loads up to [illegible] pounds on lengths up to 100 feet or more; a pair of holders together with their pins and bushings for testing bridge links [illegible] feet or more in length under all loads up to [illegible] pounds; an auxiliary pair of compression platforms with hardened faces for testing [illegible], with all loads up to [illegible] pounds, and a pair of auxiliary platforms with pins [illegible] in diameter and [illegible] feet long for testing [illegible] with loads up to [illegible] pounds. A pair of [illegible] and the ways for these [illegible] are proposed for the erection and use of the testing machine, also the necessary hydraulic pumps and their electric motors for the operation of the presses.

The contract price for the machine complete with its foundations erected in place, together with its accessories, is to be [illegible] and the bill provides for an additional sum of [illegible] for a building in which to place the testing outfit. As designed, the main part of the machine is about [illegible] feet long, while the concrete foundation is about [illegible] feet long, [illegible] feet wide and 15 feet deep, and the metal work in these foundations is about [illegible] feet long; the width of the machine is to be about [illegible] feet. The weight of the metal work, including that in the accessories, cranes, and the metal work of their ways, will be approximately [illegible] net tons, mostly of steel, and a large part of the machine will have to be of unusually good workmanship and generally much better and more accurate than has been put in any large machine of any kind whatever.

It is to be hoped that the bill will pass.

National Gas and Gasolene Engine Trades Association

There was a meeting of the National Gas and Gasolene Engine Trades Association at the [illegible] hotel, Chicago, on Tuesday, February [illegible]. After routine business at the morning session there was a general discussion of the possibilities and the lines along which future effort should be directed. This discussion was very [illegible] and the officers and executive committee received a number of suggestions which will be incorporated in the future work. J. A. Williams, of the [illegible] Ignition Company, Cleveland, O., then read a very interesting paper on ignition, bringing out new points of the ignition of stationary, marine and automobile engines.

At the afternoon session, C. [illegible], of the [illegible] Gas Engine Company, [illegible], O., opened a discussion on the "Proper Horsepower Rating of Gas and Gasolene Engines."

A. L. [illegible], of the National Carbon Company, talked on "Multiple Series Wiring of Dry Batteries." Following this, George M. [illegible], Jr., of the [illegible] Engine Works, read a paper on "[illegible]."

Following Mr. [illegible]'s paper there was an announcement by the president of a number of committees which are to take up special subjects with reference to general investigation for future benefit of the association. It was also announced that the next meeting of the association would be held at [illegible], Ind., on [illegible] and [illegible].

Impurities Causing Scale and Corrosion*

General Characteristics of Salts, Gases and Acids Which Cause Scale or Corrosion in Boilers. Density of Water and Its Purification

BY J. C. WILLIAM GRETH

The chemist has shown the way in which to prevent scale and corrosion in boilers and also how to prevent losses in the industrial arts. His method is to remove from the water the objectionable salts which it contains by changing the soluble salts into insoluble precipitates, which can then be removed by sedimentation and filtration before the water is used. This process is rational in application, the results certain, and the cost in every case is but a small fraction of the advantage gained.

Natural water supplies furnish the water converted into steam; these supplies are rarely, if ever, pure, for water in its descent to the earth as rain absorbs carbonic acid, some air and other impurities. The carbonic acid absorbed enables it to dissolve certain salts of lime and magnesia. Other substances will be dissolved, depending upon the nature of the rocks, soil, vegetation, sewage and industrial waste with which it may come into contact.

Steam generation is a continuous process, fresh feed water being supplied to the boiler as the water evaporated into steam leaves it; this results in a continual concentration in the boiler of the impurities introduced with the feed water, since none but volatile impurities pass out with the steam. The nonvolatile impurities collecting in the boiler manifest themselves as suspended matter, scale, corrosion, or by an increased density of the boiler water.

The suspended matter may be carried in with the feed, or may be due to substances forced out of solution as a result of either heat or concentration, or both. Scale formation in the boiler is due to the action of heat, pressure, and concentration on the impurities in solution and suspension in the feed water. Corrosion of the boiler is due to the introduction of gases and acids, or their formation from some of the impurities in solution in the feed water, by the reactions resulting from heat, pressure and concentration. The increased density of the boiler water is due to the concentration of the sodium salts and of the scale-forming salts, to the limit of solubility.

Scale is the great bugbear which steam users, as a rule, fear, and make more or less of an effort to combat, and with good reason. Scale is one of the crucial items entering into boiler-operating costs. Scale can nearly always be attributed to the lime and magnesia salts in solution in the water. The character of the scale depends on the acids combined with the lime and magnesia; on the type of boiler in use, and on the rate, temperature and pressure at which the boiler is operated. For instance, the carbonates of lime and magnesia, when present alone, usually form a soft scale. The presence of calcium sulphate sometimes increases its hardness. A calcium-sulphate scale is generally quite hard.

The following are a few of the items which, from an economic standpoint, make it almost imperative to prevent scale formation, or at least to remove it periodically:

First. Reduced evaporation due to the insulating effect of the scale on the heating surfaces of the boiler.

Second. Cost of labor required for cleaning the boilers and auxiliaries.

Third. Cost of repairs to boilers, necessitated by their being subjected to overheating on account of the heating surfaces being scaled.

Fourth. Loss of efficiency and earning power of improved furnaces and stokers installed to increase evaporation, which correspondingly increases the concentration of impurities, thus forming a greater deposit of scale, and hence a greater reduction in the efficiency and life of the boilers.

Fifth. Cost of tube-cleaning machines, repairs to them, interest and depreciation on money invested, and labor and power required for operating them.

Sixth. Cost of boiler compounds, or any substances introduced into the boiler to prevent the adherence of the scale-forming matter to the shells and tubes.

Seventh. Loss due to the investment in spare boilers to be put into commission when it is necessary to take boilers out of service for cleaning or repairs.

Eighth. Waste of fuel due to heat lost in cooling a boiler for cleaning or repairs, and that required to bring it to steam again.

Ninth. Loss due to reduced efficiency of boiler auxiliaries, especially in the feed-water heaters and economizers, resulting in lower temperatures of feed water, thus materially increasing fuel consumption.

Salts Which Enter Into Scale Formation

Calcium Carbonate—This salt is in solution in natural waters as the bicarbonate. On heating the water, carbonic acid is driven off and the normal carbonate is precipitated to the limit of its solubility, which in distilled water is about two grains per U. S. gallon, but in waters containing other salts at boiler temperatures and pressures it varies from about one to five grains per U. S. gallon. This limit of solubility remains almost constant for a particular water under boiler-operating conditions. The precipitation of calcium carbonate by heat is practically complete at about 300 degrees Fahrenheit. The precipitation, however, starts as soon as the temperature of the water is raised and continues until the limit is reached. The precipitation therefore occurs, not instantaneously, but gradually, and with a diminution of precipitate as the limit of solubility is approached. This is true of all scale-forming salts that are precipitated by heat alone.

The amount of calcium carbonate left in solution in the water depends upon the other salts in solution. Heat alone will effect the removal of both the free and the half-bound carbonic acid; therefore calcium carbonate will be precipitated, and the precipitate may eventually deposit as scale. The formation of scale from precipitated calcium carbonate depends upon the other substances in solution and the conditions under which the boiler is operated. For instance, if the water contains sodium carbonate, the chances are that the calcium carbonate will be precipitated as sludge. If, on the other hand, the water contains calcium sulphate, the cementing action of the calcium sulphate will tend to form a hard scale, the hardness of which will depend upon the amount of calcium sulphate in solution in the water, and the rate, temperature and pressure under which the boiler operates.

Magnesium Carbonate—This substance has the same general characteristics as calcium carbonate, being held in solution as the bicarbonate. The normal magnesium carbonate, however, is more soluble than the normal calcium carbonate. Further, magnesium carbonate is quite easily dissociated as a result of heat, liberating carbonic acid and precipitating magnesium hydrate, which, at all temperatures, is very insoluble, rarely over one-half grain per U. S. gallon. The analysis of boiler blowoff waters will usually show both magnesium carbonate and magnesium hydrate in solution, while the scale will generally show magnesium hydrate.

Calcium Sulphate—This sulphate is solu-

*Abstract of paper read before the American Institute of Chemical Engineers.

ble in natural waters to over 100 grains per U. S. gallon, and under boiler temperatures and pressures to approximately 25 grains per U. S. gallon, depending upon the other salts in solution. It is quite generally stated that calcium sulphate is insoluble at 300 degrees Fahrenheit; this may be the case in a solution of calcium sulphate in distilled water, but it is not the case with natural water supplies or those containing other salts in solution. The analyses of hundreds of samples of blowoff waters show calcium sulphate present to the extent of 25 grains, where temperatures far above 300 degrees Fahrenheit are maintained. The amount held in solution at boiler temperatures depends upon the amount of other substances in solution, and also upon the rate of concentration of those impurities. Calcium sulphate generally gives a hard scale, deposited in layers. This is probably explained as follows:

In the boiler the calcium sulphate concentrates until it forms a supersaturated solution, from which, on agitation of some sort, it quickly deposits a mass of densely interlacing hard crystals of gypsum, until its concentration drops to the point of saturation. Further, concentration in the boiler again forms the supersaturated solution, from which later another crystallization occurs. These repeated periodic crystallizations of white gypsum, separated by the slow, constant and regular deposition of other scale, would give the laminated appearance generally seen in a calcium-sulphate scale.

Magnesium Sulphate—This substance at boiler temperatures is quite soluble, and when present alone is not likely to form scale, but in the presence of calcium carbonate will react with it, forming magnesium carbonate and calcium sulphate. Magnesium sulphate is also objectionable because it reacts with sodium chloride, forming the very soluble sodium sulphate and magnesium chloride. This reaction is the result of heat and concentration in the boiler.

Calcium Chloride—This lime salt is very soluble at all temperatures, its solubility increasing with the temperature. It is, however, a fact that with the increase of calcium chloride as a result of concentration, a point is reached where the calcium chloride begins to be dissociated, forming calcium hydrate and hydrochloric acid. The calcium hydrate is quite insoluble at boiler temperatures. Analyses of scale and sludge from boilers fed with water containing much calcium chloride show calcium hydrate, and evidences of corrosion, no doubt due to hydrochloric acid, are usually found. The calcium hydrate formed as a result of this reaction may combine with carbonic acid, either introduced with the feed water or that liberated as a result of heat, and form calcium carbonate.

Magnesium Chloride—This chloride has the same general characteristics as calcium chloride, except that it is more easily dissociated, and whenever present, scale and corrosion result. The scale is due to the magnesium hydrate precipitated and the corrosion, to the hydrochloric acid liberated. In waters containing calcium carbonate, the hydrochloric acid thus formed may be neutralized by the calcium carbonate, forming the calcium chloride and liberating carbonic acid.

Calcium and Magnesium Nitrates—These salts have the same general characteristics as the calcium and magnesium chlorides, but the quantities present in most feed waters are usually so small that not much consideration is given to them. However, there are some water supplies in which these salts are present to such an extent as to cause both scale and corrosion.

Silica—The silica in solution in a water usually does not exceed two or three grains per U. S. gallon, and by itself will not form scale, but it is always found in the scale when present in the feed water. Silica under boiler temperatures may react with sodium chloride, forming a sodium silicate and liberating hydrochloric acid.

Oxides of Iron and Alumina—These are not usually present to any great extent, but by concentration enter into the formation of scale.

Organic Matter—The substances included under this general term play an important part in the formation of scale, and in many cases when present cause the formation of a hard scale which otherwise might be quite soft. The reverse is also true with some forms of organic matter. Then again, some organic matter may prevent the formation of scale by increasing the solubility of some of the lime and magnesia salts.

Sodium Salts—These are present in nearly all water supplies and cannot be classed as scale-forming matter, although present to a slight extent in nearly all scale; this is due to their being present in solution in the water mechanically held by the scale, rather than from being forced out of solution, for long before such saturation is reached, it becomes impossible to operate the boiler.

Corrosion—Corrosion is the most dangerous of the various troubles due to impure feed water, and the one in many cases the most difficult to overcome. It is usually due to the acids introduced into the boiler in the feed water, or those formed as a result of reactions between various substances in solution, caused by heat and concentration; in some cases it is due to the oxygen of dissolved air. The different acids cause different kinds of corrosion, and it occurs in different parts of the boiler, depending upon the nature of the acid.

GASES AND ACIDS ENTERING BOILER AND CAUSING CORROSION

Oxygen—Nearly all waters contain more or less oxygen dissolved from the air. The oxygen of the air is more soluble than the nitrogen, and is frequently the cause of pitting and grooving, especially in those parts of the boiler where the temperature is low and the circulation slow, such as, for instance, in the mud drums of those types of boiler in which the mud drum is not in the direct path of circulation. The corrosion by oxygen is the direct formation of the various oxides of iron. It is next to impossible to overcome this form of corrosion, as there is no practical way of removing the dissolved oxygen from the water. The corrosion, however, is of a mild form, and does not, except in rare cases, cause much trouble. The cases where trouble from this source is experienced can almost always be charged to the design of the boiler, for if the circulation is as rapid as it should be and all of the boiler water moving, the oxygen will go off with the steam, possibly causing some corrosion at or above the water line, but not generally to an appreciable extent.

Carbonic Acid—This acid, which is mixed with the air to the extent of about [illegible] of 1 per cent., is present in all natural water supplies. It is absorbed by the water, in which it is quite soluble, from the air. The corrosion caused by carbonic acid is usually indicated by pitting and grooving, and it is shown not only in the water space of the boiler, but also above the water line and in steam lines. Its corrosive action is much greater when oxygen is present with it.

Hydrochloric Acid—This acid is rarely if ever present in natural waters, but is formed as a result of the decomposition of some of the chlorides, and reactions between such substances as magnesium sulphate and sodium chloride, and similar mixtures exposed to steam. Hydrochloric acid is volatile, also very soluble, therefore corrosion is shown both above and below the water line. This acid attacks the iron, forming the [illegible] iron chloride which, at boiler temperatures, is dissociated, the iron being precipitated as the oxide, or hydrate, and the acid thus liberated combines with more iron from the boiler, and is in turn again set free. In this way the corrosion goes on indefinitely, constantly increasing in its action on account of the continued increase in the total acidity of the water by the acid that is liberated from the dissociation of the water being added to the acid formed by the decomposition of the iron chloride. The concentration of the acid does not take place above the water line, but the heat there is sufficient to dissociate the iron chloride. Corrosion from this acid is usually shown by pitting and grooving rather than over the entire surface.

Sulphuric Acid—When this acid is present in a natural water supply it is due to drainage from coal mines or chemical plants. It is not volatile and its effects show only below the water line. Its action on the iron of the boiler is similar to that of hydrochloric acid, except that it forms the iron sulphate, which in turn is dissociated into sulphuric acid and the iron oxide or hydrate. This iron oxide usually forms a part of the scale, or is present in the water as suspended matter, giving to the water the characteristic red color of iron rust. A feed water containing only a small amount of sulphuric acid will produce active corrosion, resulting in the destruction of the boiler, on account of the continual formation of iron sulphate and its dissociation into sulphuric acid and iron oxide or hydrate. Many water supplies, especially those contaminated with the waste from galvanizing plants, contain iron sulphate, which, under boiler temperatures, is immediately dissociated.

Organic Acids—Under this head are included acids such as tannic and acetic. They are usually the result of contamination from vegetable or organic matter. The corrosion from organic acids is comparatively mild, but occurs to a greater or less extent, and is very similar to that from the other acids. However, the amount of such acids present in most waters is usually so small that little attention need be paid to it.

Density of Water in Boilers

The increase in density of the water in the boiler cannot be prevented, for the evaporation of water into steam leaves the sodium salts in solution; and there is no means by which these salts can be removed from the water, either before or after it enters the boiler. By frequent blowing off the concentration of the sodium salts in the water in the boiler can be reduced, but not entirely prevented.

That portion of the scale-forming salts soluble at boiler temperatures and pressures also increases the density of the water, but these salts are constantly concentrating and precipitating, so that after a certain point is reached for uniform pressure and rate of operation, the analysis of boiler water will remain practically the same, with the exception of a variation in the calcium sulphate and an increase in the sodium salts.

Scale and corrosion are closely related, because of the number of salts which, as a result of heat and concentration, either decompose or react, forming salts and liberating acids; the precipitated salts forming scale and the acids causing corrosion.

The analysis of the water is of undoubted value in determining the substances in solution. There is, however, among chemists a wide difference of opinion as to the proper method of making combinations from the determinations of the various substances in solution. Experience enables a chemist to formulate certain rules, and by careful observation during the course of the analysis, to note the salts present in a particular water. But in reporting the nature of the possible scale formed by a certain water, or the corrosion which might result from its use, not only the analysis of the water must be taken into consideration, but the reactions between the various salts in solution; these reactions, however, do not take place to the same extent in all waters. The amount of scale-forming impurity in the feed water rarely if ever bears a direct relation to the substances in solution in the water after concentration in the boiler, but it does to the amount of scale or sludge formed. However, there is a close relation between the amount of sodium salts introduced with the feed water and the amount found in the boiler water after concentration; this ratio indicating approximately the number of concentrations.

It cannot be definitely foretold that in a certain water containing both magnesium sulphate and sodium chloride there will be a reaction between these salts, yet hundreds of blowoff analyses show the results of these reactions, and the boilers show corrosion resulting from the liberated hydrochloric acid.

It therefore means a careful study of the water and the conditions under which the boiler operates, to determine whether scale or corrosion would result from the use of a certain water. It is almost impossible to predetermine the nature of scale from the analysis of the water. The only safe way is to feed water into the boilers, free from those substances which scale and corrode. Such general statements that waters containing only the carbonates of lime and magnesia will form a comparatively soft scale, and that the calcium sulphate will form a hard scale, and further, that it will increase the hardness of the carbonate scale, should be made with caution, for there are hundreds of instances where a hard scale is formed from waters containing only the carbonates of lime and magnesia, and also where the scale is quite soft in the presence of considerable calcium sulphate.

The nature and amount of scale formed in a boiler depend largely on the rate at which the boiler operates. For instance, in some boiler plants operating considerably below their rating, and fed with water containing as high as 30 grains of both carbonate and sulphate scale-forming salts, in a given time comparatively little scale is formed, and that quite soft; while in others, where the water contains only about 10 grains of these same salts, and the boilers are worked above rating for the same time, a considerable deposit of hard, tenacious scale is formed. The type of boiler also has a bearing on the hardness of the scale. The scale in the water-tube boiler is generally harder from the same water than that formed in the return-tubular boiler, or in the old two-flue boiler.

Softening and Purifying Water

To soften and purify a water properly means, primarily, a properly designed apparatus in which are met the requirements for complete chemical reaction. These may be summed up as follows:

1. An accurate chemical treatment, accomplished by the introduction of the proper reagents in exact quantities to react with the impurities in a definite quantity of water.
2. Thorough mixture of the reagents with the water to insure complete chemical reaction.
3. An accelerated chemical reaction, brought about by a thorough mixture of reagents and water, and by mixing the sludge of previous softening with the new finely divided precipitate. Heat will hasten the reactions, but is not essential.
4. A complete chemical reaction, brought about by a thorough mixture of the reagents with the water and by having the apparatus large enough to allow sufficient time for all the reactions to take place, and the apparatus so designed that every part of it is effective.
5. A rapid sedimentation, by having the new finely divided precipitate weighted by the sludge of previous precipitation, to cause it to settle more rapidly and perfectly.
6. A perfect clarification, by allowing time for sedimentation and final clarification by perfect filtration.

The proper softening and purification of water is, in a sense, a delicate operation, notwithstanding the large quantity of water usually handled. It is not merely a matter of lime and soda ash, but the intelligent use of the proper reagents to bring about softening and purification for a particular water supply, with neither an insufficiency of reagents nor too great an excess. A water containing 30 grains per U. S. gallon of scale-forming matter is harder than the average, yet in percentage this means only 0.05 of 1 per cent. of scale-forming impurity. Such a water completely softened should not contain more than three grains of scale-forming matter, or in percentage only 0.005 of 1 per cent. When these facts are considered, some idea is obtained of the accuracy of the treatment required for completely softening water. Of course, any reduction of the scale-forming salts is an advantage, but the maximum reduction can usually be obtained for very little extra expense with a properly designed apparatus, when such apparatus is given the necessary attention.

If a water supply contains less than four grains of lime and magnesia salts, but contains suspended matter, it should be clarified by sedimentation and filtration. If the water contains more than four grains of scale-forming salts, it should be softened and purified, that is, the reduction of the soluble impurities (not including the sodium salts, which cannot be removed) to a point where an analysis will show quantities about as follows: Volatile and organic matter, one grain; silica, one-half grain; oxides of iron and alumina, trace; calcium carbonate, two grains; magnesium hydrate, one-half grain; but no other compounds of lime and magnesia. Suspended matter should never be more than a trace. Such a water will not form scale nor cause corrosion. It will not form scale because the amount of scale-forming salts left in solution is too small, even with concentration, to form anything but a light sludge. This sludge can be kept at a minimum by proper blowing off, and the boiler, no matter how long it is in operation, will on being opened have the appearance of having been whitewashed; the iron of the boiler can be exposed anywhere by rubbing with the finger or washing out with a good pressure. Corrosion cannot take place because the water is slightly alkaline and does not contain either corrosive acids or salts which, by dissociation or reaction, will form corrosive acids.

Catechism of Electricity

956. *What other causes are sometimes responsible for excessive heating of the armature?*

Heat may be developed in some other part of the machine and be transmitted to the armature by conduction. Then, too, the motor may be overloaded and carry too much current in the armature.

If there are one or more reversed coils on one side of the armature winding, conditions will be favorable for the development of heat, because probably there will then be a local current in addition to the operating current flowing through the reversed coils.

957. *How may a reversed armature coil causing a high temperature in the armature be located and remedied?*

Stop the motor and pass a direct current through each of the armature coils in succession. Connect the source of the testing current with adjacent commutator bars and notice the deflection of a compass needle placed over the coil undergoing test. When the reversed coil or coils are reached, the deflection will be opposite to that obtained from the other coils. In order properly to adjust matters the connections of the defective coils must be reversed.

958. *What effect has dampness upon raising the temperature of armature coils?*

If the armature coils become damp their insulation is lowered, but their temperature will not be increased.

959. *How should damp armature coils be dried?*

By passing a moderate current through the coils for a considerable length of time, or by baking the armature in an oven. In either case the drying process should be continued until the insulation resistance of the windings measures over 1 megohm.

Care must be taken in applying this remedy not to overdo it, else the shellac will melt and run and the insulation will be charred or burned.

960. *If the bearings become too warm, what may be the cause of the trouble?*

The bearings may fit too closely around the armature shaft; in a new motor they may be out of line; there may be foreign matter in the bearings.

961. *How may trouble in the bearings be tested?*

By slowly turning the armature around by hand to see if it sticks, or when shutting off the power noticing if the armature comes freely to rest.

962. *What are the remedies for troublesome bearings?*

Bearings which fit too tightly must be reamed out or scraped, or the armature shaft placed in a lathe and turned down or filed.

If the bearings are out of line with each other the motor should be shut down and the bolts holding the bearings in place partially unscrewed to allow the bearings to find their proper position. When they have done so, and the clearance between the armature and pole pieces is the same on all sides, the necessary adjustments must be made for maintaining the bearings in this position. If the motor is provided with self-alining bearings which, as their name implies, are automatic in action, and which are now commonly used on all high-grade machines, little or no trouble need be anticipated from this cause.

Dirt or other foreign matter in the bearings is liable to result from unfiltered oil being used or when the room is not kept free from dust and dirt. A careful examination of the shaft will show whether this trouble exists, as there will be scratches on it when such foreign matter is present. To improve conditions the shaft or bearings must be taken out and cleaned.

963. *What is, perhaps, the most common of all causes for abnormal heating in the bearings?*

Deficiency of oil in the bearings is the most common of all causes of hot bearings. The deficiency may be due to a defect in the oiling rings on the shaft, to a stoppage or leak in the oil passages, or to empty oil cups. Usually this defect is easily made right, the nature of the trouble suggesting the remedy to apply.

964. *Could a belt too tight cause the pulley bearing to heat up?*

It would.

965. *How may the trouble referred to in 964 be detected and remedied?*

It may be detected by the unequal temperatures of the commutator and pulley bearings, the latter being the warmer. If the belt has not been run tight very long the bearing will probably not have become worn sufficiently to require rebabbitting, but in any case the tension of the belt should be lessened either by employing larger pulleys and a lighter belt or by decreasing the load on the motor.

966. *If the bearings are very warm and the armature shaft turns more easily at one point of a revolution than at another, what is probably wrong?*

The armature shaft is probably bent.

967. *What is the remedy for a bent armature shaft?*

The easiest, cheapest and, in fact, the only satisfactory way to correct this trouble is to replace the defective shaft with a new one properly turned.

968. *Are there any other shaft troubles that may produce hot bearings?*

Yes, the shaft may not have sufficient end play or it may be cut or roughened.

969. *Why is end play of the shaft necessary to keep the temperature of the bearings low?*

If there be no end play, or free movement back and forth, of the armature shaft in the bearings while the motor is in operation, the collar, shoulder, or pulley on the shaft is apt to press continually against the bearings and cause them to become heated.

970. *What should be done to correct end-play trouble?*

If, upon pressing a stick against the end of the armature shaft while in motion, there is a tendency for the shoulder or the collar on the shaft to come in contact with the bearing, a slight change in the leveling of the belt may improve matters. It may, however, be necessary to file the contact surface of the bearing or change the position of the pulley or collar along the shaft to secure satisfactory results.

971. *In case the shaft is cut or roughened, what should be done?*

The shaft should be placed in a lathe and turned smoothly. Care must be taken, however, not to remove more metal than is absolutely necessary, else the bearings will not fit and they will have to be renewed. In any case it is necessary to have them perfectly smooth before the repaired shaft is placed in position.

972. *Is a bearing liable to become hot by conduction of heat from some other part of the motor?*

It is. If the bearing on the commutator side of the machine is becoming heated from no apparent cause an inspection of the commutator and armature should be made; or if the bearing on the pulley side of the machine is hot, the pulley may be suspected. When it is found that some part has a higher temperature than the bearing on that side of the motor, the proper remedy applied to the defective part will generally lower the temperature of the heated bearing.

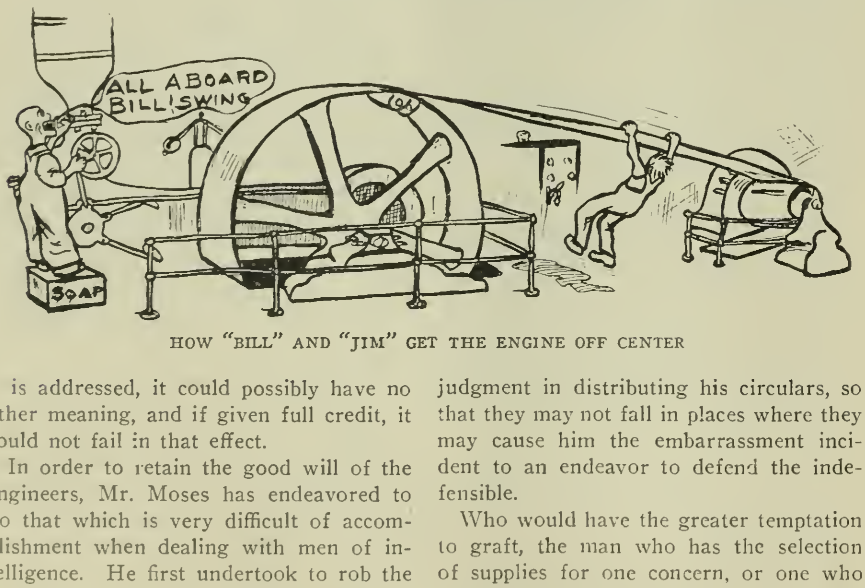
Extraneous Supervision of Power Plants

I have noticed with interest the matter appearing in recent issues under the above caption. I observe that the only difference between the article appearing over the name of P. R. Moses, in the issue of January 19, and the circular, a copy of which was printed two weeks previously, is that the former is addressed to the engineers, while the last was addressed to the employer. In effect the matter stands just this way: Mr. Moses cannot deny but that the circular in question had for its obvious object the undermining of the engineer's position in the esteem and confidence of the employer. If it is accepted seriously at all by those to whom it is addressed, it could possibly have no other meaning, and if given full credit, it could not fail in that effect.



HOW "BILL" AND "JIM" GET THE ENGINE OFF CENTER

In order to retain the good will of the engineers, Mr. Moses has endeavored to do that which is very difficult of accomplishment when dealing with men of intelligence. He first undertook to rob the engineer of his standing with the employer, assuming, it would seem, that this was the surest way of securing it for himself and his company. In order to get business for his concern he has assailed the engineer as the one most in his way, and since he has been caught in the act, and realizes that he has "stirred up a hornets' nest," he adopts the idea of patting the engineer on the back with a wink, and in effect saying aside, "I didn't mean it."

In his letter he virtually admits that neither he nor his company can do anything except through the engineer. That is so, but it is also a fact that the best engineers prefer to work under conditions where they will get credit for what they do, rather than where they will see it go to others. It is a virtual admission that all the advantage that the supervision company can offer over the engineer is that it can by concentration of purchases secure lower prices on supplies. What he can save in a plant of moderate capacity in this manner would not pay for the time the employer would have to spend in consultation with the representatives of the company.

Besides that, let us consider this matter of graft. This is the excuse put forward more strongly than any other for the existence of this company. This is a rather ugly compliment, but Mr. Moses began it and if, like the boomerang, it recoils and strikes him, he can blame only himself. He can also gain wisdom from the experience and hereafter use better judgment in distributing his circulars, so that they may not fall in places where they may cause him the embarrassment incident to an endeavor to defend the indefensible.

Who would have the greater temptation to graft, the man who has the selection of supplies for one concern, or one who has the same privilege with many? Is Mr. Moses so simon pure that he can withstand unspotted and unsullied tenfold, nay a hundredfold greater temptations than can we poor engineers? After all, we poor weak ones, who are incapable of dealing rightly with a case of itching palm, should rejoice that one has come forth and announced himself as willing to take from us this awful burden of temptation. If I were a grafter, I would endeavor to start an engineering supervision company of my own. I can see no shorter cut to successful and remunerative grafting. What is the use of fooling along with a few paltry quarters and fifty-cent pieces in one plant, when we can get in the supervising business so easily and have a neat income right along? Pshaw!

Grafting arises from certain causes, opportunity and a desire to get money faster than it can be secured in a legitimate way. The result of these causes will depend upon two things, the character of the man and the greatness of the opportunity to graft. When one man accuses a great number of a thing like this he is, to say the least, straining a point. Can any one man assume that he is so much better than so many others, that he is beyond temptation? And yet, business will come to this concern, as "a sucker is born every minute."

The capable engineer will get the results, but without him the engineering suvervision company cannot. The engineers who belong to the result-getting class will not work under conditions where they are obliterated. Hence the men who can get results will get out about as fast as the engineering supervision company gets in.

WILLIAM WESTERFIELD.

Improving Firemen's Conditions

I read with interest the letter by W. Auld, on page 168 of the January 19 number, referring to the conditions under which firemen have to work. Firemen can improve their condition themselves if they would go at it in the right manner, but the engineers would do well to assist them. No one can do more for the engineer than the firemen, and for this reason the engineer should not be afraid to stand by his firemen. Large-minded men, and the majority of employers are large minded, like to see character in their engineers, and instead of weakening his position by standing by his firemen an engineer will strengthen it.

The firemen are not alone, however, in failing to have all that they should have in the way of conveniences in the power plant. I have known many good-sized plants where the chief engineers had no conveniences. Conditions will become better only as the importance of the operating force becomes better known and recognized by the owners. This will come through the efforts of the men themselves by bringing their work and efforts to the attention of their employers.

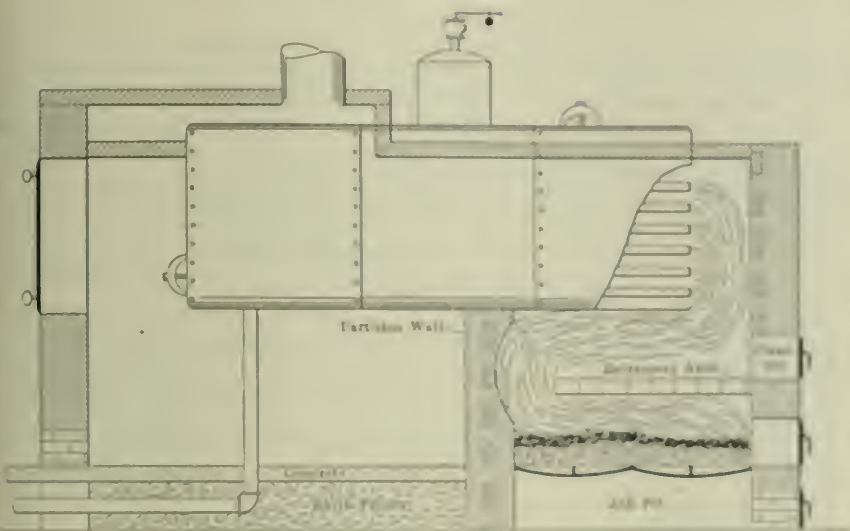
WILLIAM WESTERFIELD.

Lincoln, Neb.

An Improved Boiler Setting

The accompanying sketch shows what, in my opinion, would be an improvement on Mr. Kirlin's boiler setting, illustrated in a comparatively recent issue.

Instead of placing the fire doors on the side of the boiler, I would put them in front, where they belong, and construct a



BOILER SETTING PROPOSED BY MR. GARTMANN

fire arch, as shown, to produce proper combustion and a practically smokeless furnace.

FRANK GARTMANN.

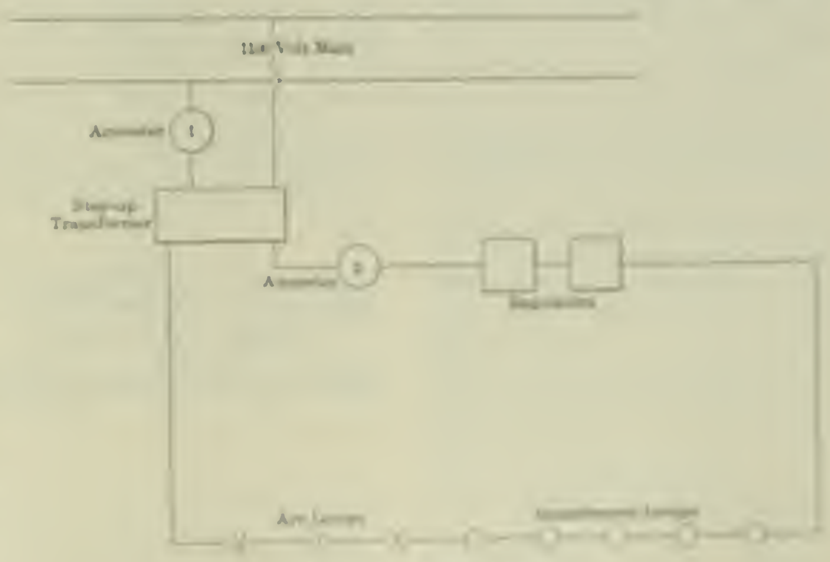
Sheboygan, Wis.

Series Circuit Supplied from Constant Potential Circuit

In one of your recent numbers you published my wiring diagram and asked the question, "Would there be any decrease in the current taken by the regulators and step-up transformer," after tungsten lamps had replaced the carbon-filament lamps?

Of the several who have made replies to the article, none has given the facts just as they have taken place since the system was changed from the carbon to the tungsten lamps. As this has been a question of some interest, particular attention has been paid to the reading of the meters during and since the change, and I will relate the facts as they have happened since the change was started.

As stated in the former letter, there were 10 inclosed arcs and 80 carbon-filament lamps in series, and operated from two 25-light regulators in series (connected together mechanically) and a step-up transformer with the secondary delivering 3000 volts. The connections were made as shown in the accompanying sketch. The ammeter connected in the primary line to transformer (No. 1) registered 20 amperes and the regulators were supplied with two extra weights in order to keep the current in the series circuit at the desired value, 5.5 amperes, when the carbon-filament lamps were in use. These were displaced a few at a time (from three to ten a day) by the tungsten lamps and the primary ammeter registered a little less after each change was made. When about 90 per cent. of the



MR. GROVE'S WIRING DIAGRAM

old lamps had been replaced with the new ones it was necessary to add six extra weights to the regulators in order to keep the current at the proper value, and the ammeter in the primary circuit registered only about 16 amperes.

Now another difficulty was encountered. The 10 arc lamps acted as if they were not supplied with enough current to close, give the magnets and the carbons burned to a point, as though the [illegible] [illegible] [illegible]; consequently the lamps would not give their rated candle power. The [illegible] [illegible] [illegible] [illegible] [illegible] the secondary connections on the step-up transformer. (This transformer is equipped with six secondary leads and connections can be made to give any of the following voltages: 4200, 4000, 3400, 3600, 3200, 3000, 2700, 2400, 1800, 1200, 600, 300.) The connections were changed from the 3400-volt connection to the 1800-volt, but this was found to be too low to give the desired current of 5.5 amperes, so the 3400-volt connection was tried and with two extra weights on the regulators it was found to be just right. After this change was made the arc lamps burned as well as they ever did, giving a nice clear light, and the primary ammeter now registers from 8 to 10 amperes.

Can anyone explain why the arcs acted so mysteriously when the transformer was connected to give the higher voltage? The candle power of the incandescent lamps was not visibly affected.

D. W. GROVE.

Covington, Va.

Knock in the Engine

I am operating a plant consisting of [illegible] simple Corliss engines, running at 90 revolutions per minute, and belted to an alternator. The engine has a peculiar sort of knock as the crank passes the centers. It can be heard more distinctly on the crank end on the gallery side and gives a clicking sound. It is heard [illegible] [illegible] [illegible] revolutions and then stops for about the same number.

Everybody in the plant has tried to locate the knock but without success. The end bearings of the crank shaft have been taken [illegible] [illegible], and the knock does not seem to be in it. All other bearings seem to be all right and are cool.

[illegible]

[illegible]

Gas Engine Valve and Ignition Timing

My experience with gas engines has led me to different conclusions from those expressed by Mr. Hollman, on page 167 of the January 19 issue. He says, near the close of his letter: "Thus the inlet valve should close when the piston has started back a certain distance, and the exhaust should open when the piston is at a certain distance from the end of its stroke."

From the language used, the four-stroke-cycle engine is being considered, in which case the theory advanced seems to be erroneous. In order to grasp the operating sequence of this type of engine it should be borne in mind that we are dealing with a gas pump during the exhaust and suction strokes, and as any adjustment that advances or retards the time of opening a valve must produce the same change in the time of closing, is it not obvious that something less than a cylinderful of mixture will be trapped whenever the valves are closed at any other time than when the crank is exactly on the center?

The fact that the gas mixture is burned in the cylinder has nothing whatever to do with the question of proper valve setting, in which case is it not apparent that in order to get the best results from our "gas pump" we must open and close the valves on the centers just as all other pumps do, or should?

The efficiency of a gas engine depends on its getting a cylinderful of a proper mixture of gas and air, compressing it to the best point and then firing at the proper time relative to the crank or piston position. All of these questions except the first one are best determined by local conditions, but the importance of starting out with a *cylinderful* of mixture is hardly open to discussion, and the only way to secure that result is to open and close the valves exactly on the dead-center points.

If the gas-engine operator will vary the quality of the mixture and the compression and the time of igniting, it will be found that the efficiency of the engine varies with these changes and that a compromise or happy medium may be arrived at where, for instance, the spark may be advanced to a point giving the highest initial pressure, the best burning conditions, etc., without going so far that the initial pressure or compression is high enough not only to overcome the inertia of the moving parts, but actually to exert pressure on the wrong side of the crank pin. In one case an engine using natural gas, compressing to 75 pounds absolute and running at 250 revolutions per minute, did its best work when the spark was set 22 degrees ahead of the dead point; that is, the crank lacked 22 degrees of having reached the dead center when the charge was ignited.

Downers Grove, Ill.

Keeping Motor Records on Index Cards

In large establishments where there are many motors in use, some system of keeping records is desirable to enable the man in charge to ascertain quickly any desired data about the equipment under his charge. The best method available, within the writer's knowledge, is the card index. The accompanying engravings are reproductions of the two sides of a card taken from the file of the plant in the writer's charge. In the system used here, alternating-current motors are numbered below 1000 and direct-current motors above 1000; the cards for alternating-current motors are salmon-colored and the others light blue. A group of numbers is reserved for each size of motor (for instance, 200 to 250 for 3-horsepower motors) and a guide card bearing this size on an extended tab is inserted between the groups of cards to facilitate the location of any card desired.

When a new motor is purchased a card is filled out with all the information except the rewinding data, and placed in the index, where it remains until the motor is brought to the shop for repairs. The card is then taken from the index file and the necessary winding data entered on it, an account of the repairs being also entered, but on the back, and the card returned to the file.

FIG. 2. REAR SIDE OF A MOTOR-DATA INDEX CARD

This card system has proved a great convenience to the writer; it makes a complete record of every motor in the plant instantly available. This letter is written with the hope that the system may prove of value to others similarly situated.

R. H. Fenkhausen.

San Francisco, Cal.

What Caused the Valve to Break ?

Following is an account of an accident that has twice happened since installing a drip-return pump and new feed line. The first accident was the cracking of a flange at the end of the feed line and the breaking of the body of a 6-inch valve. The second time a joint blew out at a flanged ell and the bonnet of the stop valve cracked.

The discharge from the drip pump enters the feed line at about its center. The feed line is of 6-inch pipe, 150 feet long and feeds water to twenty 318 horsepower water-tube boilers. Four duplex pumps, 10 and 6 by 12-inch, take water from two open heaters at a temperature of 190 degrees Fahrenheit. This feed line is supplied with a 4-inch release valve, set at 140 pounds. It is well braced and has an expansion bend in it.

The drip pump takes its water from six separators, large and small, situated on the main steam lines leading to the engines. The steam pressure is 115 pounds, and the pump is located 25 feet below the feed line. At the time when the accidents happened there were twelve boilers in operation and the head fireman reported everything as usual. All fittings and pipe are extra heavy.

FRANK J. [illegible]

New Aberdeen, C. B.

Homemade Condenser

The accompanying sketch represents a condenser such as may help Mr. Casper out. The return pipes are fitted to the

MR. [illegible]'S HOMEMADE CONDENSER

header, with a connection for the exhaust steam, and return to the side of the bottom piece, which shows the connection for the condensed water coming out of each end and flowing to the receiver, from which it may be handled by a pump.

The return pipes may be made any length, depending on the size of condenser required. The condenser is submerged in a tank, the water running in and out all the time, so as to furnish cool water for the condenser.

THOMAS [illegible]

Chemawa, Ore.

Connecting Steam Boilers

Referring to the letters by Frank Eastman and M. Kennett in the December [illegible] number, I would say that both describe a very faulty method of connecting up steam boilers, which is more or less in vogue.

It seems to be the idea of some engineers that the valves must be placed as close as possible to the boiler. This practice is wrong, as it leaves more or less

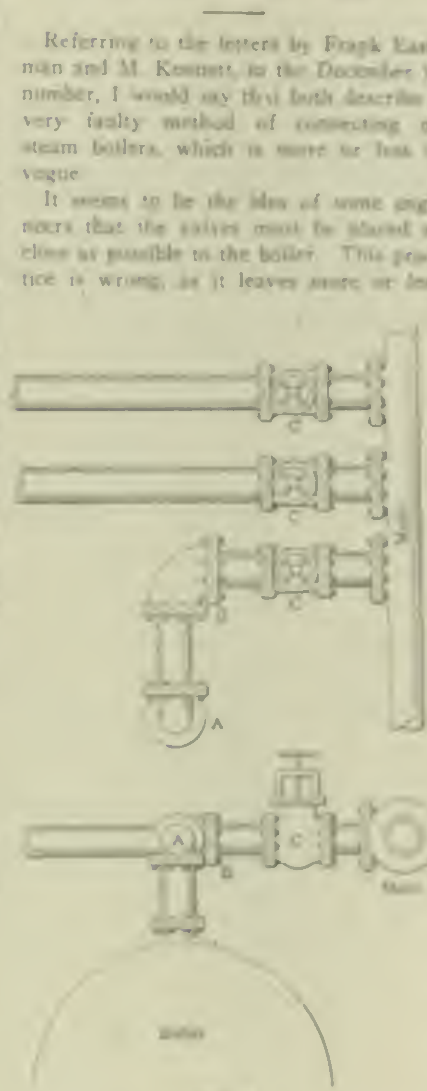

FIG. 1

pipe in which there is no circulation when the boiler is idle, causing condensation of steam, which is apt to form a dangerous slug when the boiler is put in operation.

A better plan is to put the stop valve as close to the header or point of distribution as possible, as there will presumably be steam in the header at all times when one or more boilers may be idle.

A still better plan is to put a nonreturn valve or automatic stop valve, working both ways, near the header and a plain valve near the boiler. This is according to the latest practice for high-pressure work. The valves, however, should be kept at the highest point, so that there will be no chance for water of condensation to accumulate.

Referring to Mr. Eastman's arrangement, if stop valves only were used, I should recommend placing them at C, Fig. 1, herewith, or if both stop valves and nonreturn valve were used, I should place the nonreturn valve at C, and the stop valves at either A or B, but to be placed on the vertical pipe down near the boiler.

In reference to Mr. Kennett's plan, the nonreturn valve should be placed at B, Fig. 2, herewith, and the stop valve at A.

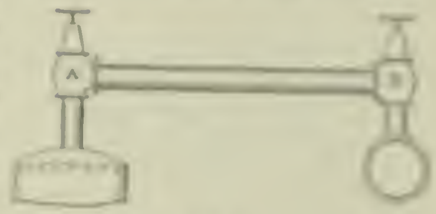

FIG. 2

Regarding the matter of draining headers, it is not a good idea to drain back into a boiler, where a number of boilers are used, as each boiler should be positively and completely cut out by one valve only. This lessens the chance of turning steam onto a man who might be inside the boiler for cleaning or inspection. A good, reliable steam trap will drain a header very satisfactorily. [illegible] headers are drained satisfactorily by using steam to run the boiler-feed pumps from the bottom of the header.

G. [illegible]

Los Angeles, Cal.

Cooling a Prony Brake Wheel

In the steam-engine laboratory of a certain school there is a small [illegible] engine, used for testing the brake horsepower developed at different valve settings.

For a long time I had trouble on account of the heat generated by the friction of the brake on the surface of the

[illegible] COOLING A PRONY BRAKE WHEEL

wheel. The plan used to overcome the difficulty was as follows: I had some [illegible] angle iron bent to a circle with a flat face out and made to fit snugly the inside of the wheel. After making two of these I bolted one on each side of the wheel, with a flat face outside, so as to form a [illegible] flange all around the inside of the wheel, as shown at A in the sketch. Water is kept in the trough thus formed, and when the wheel is revolved all parts of the inside face of the wheel are bathed, thus keeping the temperature from getting too high for some time. At B is shown the brake as it is used on the pulley wheel of an engine.

E. S. Rodney.

Baton Rouge, La.

Determination of the Calorific Value of Low-grade Fuel

In reading F. H. Neely's very interesting and valuable article in a recent number of Power, I was reminded of a modification (if it may be called such) of the well-known Dulong formula for calculating the heat value of a coal, adapting it to lignite and peat. The Dulong formula given by the American Society of Mechanical Engineers in its "Rules for Conducting Boiler Trials" is as follows:

$$14{,}600\ C + 62{,}000 \left\{ H - \frac{O}{8} \right\} + 4000\ S,$$

in which C, H, O and S are the percentages of carbon, hydrogen, oxygen and sulphur in the coal, by the true analysis. The number 14,600 represents the number of B.t.u. in one pound of carbon; 62,000 that for hydrogen and 4000 for sulphur. The ratio $\frac{O}{8}$ takes into account the oxygen which would combine with the hydrogen to form moisture and is, therefore, subtracted from the total hydrogen.

For those unfamiliar with this formula, the following analysis will clearly show its use: Carbon, 74.79 per cent.; hydrogen, 4.98 per cent.; oxygen, 6.42 per cent.; nitrogen, 1.20 per cent.; sulphur, 3.24 per cent.; moisture, 1.55 per cent.; ash, 7.82 per cent.

Substituting, we get:

$$14{,}600 \times 0.7479 + 62{,}000 \left\{ 0.0498 - \frac{0.0642}{8} \right\} + 4000 \times 0.0324 = 13{,}650\ B.t.u.$$

A calorimeter test showed 13,480 B.t.u. for this coal.

To apply the Dulong formula to lignite or peat, instead of taking the true analysis, use the analysis corrected for moisture, and to this result add the heat carried away by the moisture in the fuel.

As an illustration, take the North Dakota lignite given in a bulletin of the United States Geological Survey: Hydrogen, 5.22 per cent.; carbon, 52.66 per cent.; nitrogen, 0.71 per cent.; oxygen, 27.15 per cent.; sulphur, 2.02 per cent.; ash, 12.24 per cent. The moisture equals 15.42 per cent.

Substituting in the Dulong formula, the following is obtained:

$$14{,}600 \times 0.5266 + 62{,}000 \left\{ 0.0522 - \frac{0.2715}{8} \right\} + 4000 \times 0.0071 = 8862.9\ B.t.u.,$$

the heat carried away by the moisture.

Assuming the lignite to be at 62 degrees Fahrenheit when fired and the gases to be at 420 degrees Fahrenheit on entering the breeching, we have 150 B.t.u. to head one pound of water from 62 to 212 degrees Fahrenheit; 966 B.t.u. to evaporate one pound of water from 212 degrees Fahrenheit to steam at 212 degrees Fahrenheit; 210 B.t.u. to raise the steam to 420 degrees Fahrenheit; and 1324 B.t.u. total heat carried away by one pound of water.

$$1324\ \text{B.t.u.} \times 0.1542 = 204\ B.t.u.$$

Adding the two values gives

$$8862.9 + 204 = 9066.9\ B.t.u.$$

per pound of lignite. The fuel actually gave in the calorimeter 9061 B.t.u.

The assumption as to fuel and breeching temperatures is very close to average practice and can vary several degrees and not make an appreciable difference in the results.

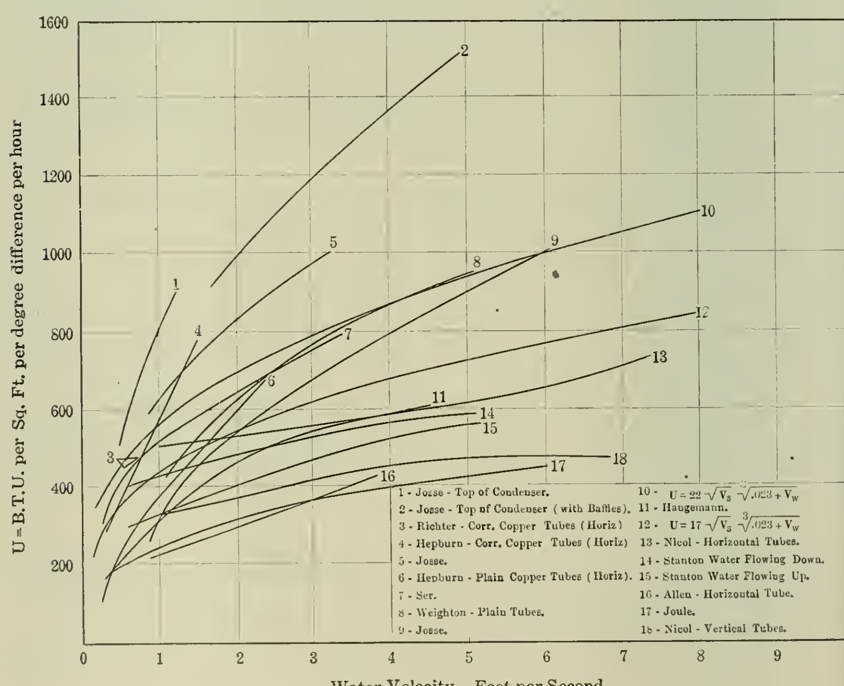
I discovered this relation while preparing a course of lectures on "Fuel Technology," which was given at the University of Wisconsin in 1906, and have applied this modification to a large number of lignites and peats and find it always gives very close results. I have never applied it to wood, but believe it would work equally well.

W. A. Richards.

Chicago, Ill.

Surface Condensation for Steam Turbines

I note with pleasure that you have published an abstract of Professor Josse's paper on surface condensers, referred to by Mr. Mueller in his criticism of my article on the same subject. Professor Josse's paper is of great value, supplementing as it does the work of Weighton and Morison. The curves given in Fig. 2, page 234 of the February 2 number, are particularly interesting and I have plotted them on the set of curves you reproduced before. The curves representing the value of U when "baffle strips" were used in the tubes are not applicable to ordinary condenser conditions, as the increase of head and power for the circulating pumps must have been quite marked. The other curves are even bet-



HEAT TRANSFERENCE THROUGH TUBES

ter than Weighton's and more nearly agree with the theoretical formula, although with a slightly different constant. It is not strange that Josse should have fallen into the error of considering that U varied with the square root of the velocity of the cooling water when it is understood that he used the metric system and all his velocities are near one meter per second; the differences between the square root and the cube root at that point would not probably be larger than the error in the value of U. With the English system, however, the numerical values of the velocity are higher and the differences much more marked. It will be seen that the values given by Ser conform more nearly to the cube-root curve than to the square-root curve.

It is also interesting to learn that Professor Josse has developed the formula for surface

$$S = \frac{Q}{U} \log_e \frac{t_1 - t_2}{t_1 - t},$$

which has been in use in this country for some time, and found it better to represent actual conditions than Weiss' old formulas so often quoted in foreign works. Hermann Wilda in his "Marine Engineering" (Hanover, 1906), gave a formula similar in form, but the further possible simplification was apparently not seen.

The experiments showing the transmission of heat to air are interesting and of value. Josse's air pump is known in this country as the Bailey pump, and has been installed in a number of naval vessels. The only new thing in it is the additional air inlet above the piston, making the pump somewhat similar in action to the new Bedmer pump of the Allis-Chalmers Company.

Professor Josse's remarks on the contraflow principle are very well taken and represent American practice fairly well, except that we find it usually advisable to use the contraflow principle. The fact that every condenser tube must necessarily be filled with water at all times with this system is sufficient reason for its adoption.

Babbitting a Main Bearing

On one occasion when babbitting a main bearing of a medium-sized engine I had trouble with seams in the babbitt.

At first it was thought the babbitt would have to be taken out and repoured. The following idea was carried out, however, and its success was well worth the small amount of trouble it caused.

Where the seam showed, the metal seemed to have run smoothly enough, but close to the edge of the box the outer edge was loose. A 7/16-inch drill was used to bore a string of holes down the seam, so as to catch a portion of the solid and loose metal. The holes were quite close together so there were very thin bridges between. After melting the babbitt as much as it would stand, a hot iron was used on the string of holes, melting down the bridges and thoroughly heating the metal. While this was being done the hot babbitt was poured in, forming the whole in one solid piece.

It is a good plan, when using the iron to warm the metal, to put in a little powdered rosin. These seams, flaws and holes, so annoying in babbitting, are mostly caused by not having the shaft, arbor, or whatever is used to cast around, hot enough. Then, too, it is sometimes difficult to get the metal in the bearing hot, but this should be done at all odds. A good material for preventing the metal from leaking while pouring is composed of flour and common engine oil, mixed to a dough. This is far better than clay or such material, as the moisture causes steam and blowouts are likely to occur.

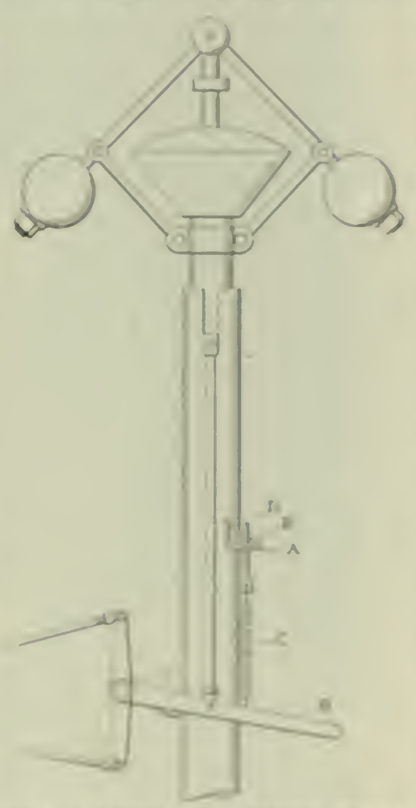
Prevents the Governor Dropping

The accompanying sketch is of an attachment we recently installed on the governor of a 150-horsepower Corliss engine driving a two-phase generator. For some time we had been troubled with the governor dropping to its lowest position when the engine was carrying full load or



DEVICE TO PREVENT THE GOVERNOR DROPPING

was slightly overloaded and the steam was a little low.

This engine was designed to run at [illegible] revolutions per minute, and in case of a heavy load would lose from six to eight revolutions per minute, thereby allowing the governor to drop, causing the safety device to prevent the latch catching the valve, thus stopping the engine. To obviate this difficulty we bolted an angle iron A to the governor post with two [illegible]-inch machine screws, and through the upper end of the angle iron drilled a [illegible]-inch hole. Through the governor lever B, and directly in line with the [illegible]-inch hole in the angle iron, a [illegible]-inch hole was drilled. In this hole was fastened the lower end of a [illegible]-inch steel coil spring C, and to the upper end was fastened a [illegible]-inch bolt D, extending through the [illegible]-inch hole in the angle iron. A butterfly nut E was placed on the upper end of the bolt.

Increasing the tension of the spring prevents the governor from dropping quickly under variable steam pressure, but the tension must be varied with different loads. The spring, however, will not prevent the governor's dropping and cutting the steam off in case the governor belt should break or fly off for any reason.

The Sense of Proportion

Most inventors lack that sense of proportion which helps a man to keep himself from looking the ass, as many of us really are. The same inventors are constantly bobbing up to the top, but there is a new inventor and a new one of genius, a new man with a fur coat. I wouldn't give a red cent for any invention unless at least one man, as the [illegible] [illegible] [illegible] [illegible], at the demonstration, wears a fur coat, or at least has fur collar and cuffs to his overcoat. He adds that we [illegible] that makes the inventor so sure he has fallen among [illegible] [illegible] [illegible] [illegible] of [illegible]. At one time it is a rotary engine. Now, of late years, there has sprung up a new development of rotary engines. Some of your [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] valves, has [illegible] [illegible] and [illegible] mechanical [illegible] [illegible] [illegible] [illegible] the [illegible] and make it [illegible] [illegible] for the benefit of the [illegible]. Some of these are [illegible] [illegible] [illegible] and [illegible] [illegible] there are new rotary engines that will work [illegible] [illegible]. And the hopeful inventor [illegible] up his little [illegible] [illegible], [illegible], [illegible] and [illegible], and in a few [illegible] he has shown you that you [illegible] the "[illegible]" it would knock [illegible] off the [illegible] [illegible] [illegible] [illegible].

Most of the men connected with these affairs are [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of [illegible] and [illegible]. They [illegible] to me [illegible] the "[illegible]." A [illegible] [illegible] [illegible] [illegible] [illegible] when I [illegible] them a [illegible] of [illegible] and [illegible] [illegible] [illegible] [illegible] [illegible].

Then there is the [illegible] [illegible] [illegible], "in a peculiar adaptation of a [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]." At [illegible] [illegible] [illegible] [illegible] the [illegible] of [illegible] [illegible] that is [illegible] on my mind [illegible] [illegible] [illegible] of the [illegible]. [illegible] [illegible] [illegible] think of hiring myself out to some honorable promoter as a writer of prospectus catch sentences. Why should such a gift of language lie fallow? I think it a beautiful sentence. As a rule if one succumbs to the temptation to go and see the wonderful invention at work there is much to be learned.

This is a great city. I have been in it for twenty years and before we had so many tubes it was often better to walk when one was in a hurry, better even than a cab, for a cab always runs its head into a block and one is held ten minutes for the block to melt away. Of course, if you are a promoter you take a cab anyhow. Well, as I was saying, I have done much walking to save time, and as I carried the map in my head and a compass in my pocket, I could usually steer a direct course from point to point. Needless to say I thereby became acquainted with strange labyrinths. But for out-of-the-way concealed curiosities there is nothing so weird as the dens into which one penetrates in finding the home of the invention which is to revolutionize all our existing ideas and wreck so many prosperous manufacturers who have but little longer to palm their obsolete productions on a too confiding public.

It reminds me of when I was a child and had a toy consisting of a house and a sort of turntable with animals on it. The table revolved and a constant stream of animals went into what I suppose must have been a model ark. One hid from one's understanding the fact that the same animals recurred like a decimal; and so now when childhood No. 1 has gone away into the dawn of nothing the old turntable turns again, but in place of animals it carries rotary engines, and boilers and new types of all manner of furnaces and smoke devices, which are usually perfect but for the one essential without which none can be. There are water circulators and occasionally a perpetual-motion device cleverly cloaking its features behind some such beautiful veil of words as I have outlined.

A story is told of an absent-minded but learned man who bumped into a cow and raised his hat in apology. The true facts gradually sank into his mind and in a bit he ran down a lady. But now he was fully aware of the enormity of his previous folly and rapped out: "Is that you again, you brute?" And so with the stream of epoch-making inventions. You don't quite know whether to raise the hat to them or treat them as brutes, and the worst is that when the real lady invention trips along she receives the welcome of a brute, and unless the idealist inventor is of tougher material than most of his kind he usually gets no better treatment by the world than the inventor of the perpetual-motion crankiness.

Leak in Belt Driven Air Compressor

In the plant where I am employed we have a small belt-driven air compressor, supplying air at 80 pounds pressure to molding machines. The capacity of the compressor is about 35 cubic feet per minute. It has an automatic governing device which holds the pressure at any predetermined point within its capacity.

While on my vacation this machine refused to deliver the quantity of air needed and no amount of coaxing on the part of my assistant, who was in charge, would get it to do so. A machinist was called in, who stripped the machine and on using his caliper found the cylinder to be out of round about 0.005 or 0.006 of an inch. This he claimed was the cause of the trouble, and wanted the cylinder bored and a new piston fitted.

Upon my return a few days later I overhauled the machine, but could find no reason for the failure to do the work, as the cylinder, piston and rings were in good condition. I concluded that air was being wasted somewhere about the plant, and looked for leaks for several days. At times the pressure would go to 65 or 70 pounds and at others down to 25 pounds. Finally a search resulted in locating the trouble. It was in a beautifully arranged ventilating system using a sort of spray jet, having a head with nine 1/16-inch holes and was supplied by a 3/8-inch pipe with a valve to regulate the amount of draft. This device was not used all the time, which accounts for the fact that at times we could get our air pressure about up to normal.

The ventilating scheme was put in without my knowledge, or I should have known that it was the cause of the many hard names I had to stand for from the foundry foreman. The moral I have learned is, in case of failure of supply from no visible cause look for leaks. Also look for the inventive chap with a club.

Drilling a Tank

In W. H. Wakeman's article on page 1085, Volume 29, he describes how he drilled the tank for his oil gage, using a board cut out as at *A*, Fig. 1.

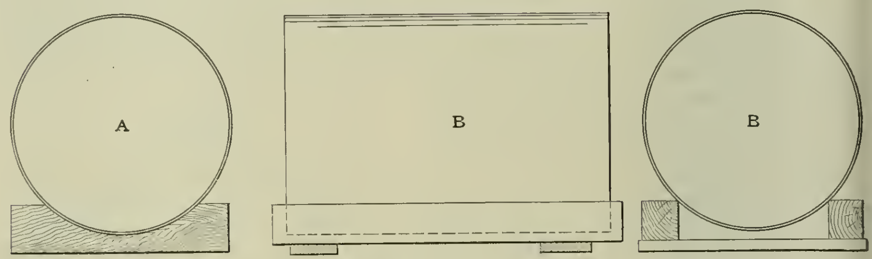

FIG. 1

This method is all right, but it is usually easier to take two pieces of 2x4 or 4x4 stock and fasten them together by nailing two strips or boards across the bottoms, as at *B*. In this way any size of cylinder can be fitted in a minute, and a bandsaw is not always available to circle out with.

If the cylinder or pipe has flanges on each end, the side pieces should be cut so as to go between them. Sometimes where the cylinder is long and the drill-press platen small, it is better to nail several pieces on the bottom.

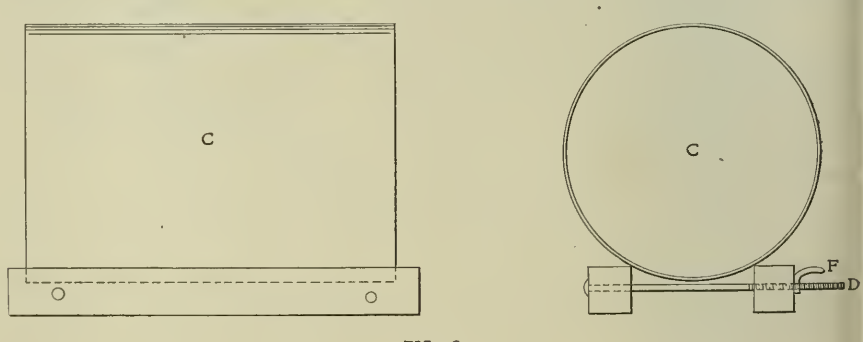

FIG. 2

An adjustable rig used in the repair department of a railroad shop is shown at *C*, Fig. 2. The 4x4-inch side pieces are conected by long bolts *D*, which have a rather loose-fitting "crank nut" *F*. These adjustable supports are not only handy for holding various sizes, but anything placed on them can be quickly leveled by working only one of the "crank nuts."

Edwin Reynolds Dies After a Long Illness

Contemporary of Corliss and Superintendent of the Corliss and Allis-Chalmers Shops Passes Away at Milwaukee; Sketch of His Career

Edwin Reynolds died at his home in Milwaukee on Friday, February 19, after a three-years' illness.

Edwin Reynolds was born March 23, 1831, at Mansfield, a little town in northeastern Connecticut. He was descended from William Reynolds, who had come from England about 200 years before and settled at Providence, R. I. His father's name was Christopher Reynolds and his mother's maiden name had been Clarissa Huntington. There was a large family, six boys and six girls, and Edwin was next to the youngest. His father, though then a farmer, had been a cloth dresser and had on his place a fulling mill run by water power, but this had not been in operation within the boy's recollection. Edwin worked on the farm and went to the district school, his last schooling being in his sixteenth year, and then a change came in his life. He had up to this time little or no knowledge of the machine shops and nothing had turned his thoughts or inclinations in that direction. At the age of 16, Mr. Reynolds started out as a farm hand, engaging first with a neighbor for six months at $13 per month. He had worked only about a month when one day, as he was busy in the middle of a field, a man climbed over the fence and came to him. The man asked first if he was one of the Reynolds boys, and then whether he would like to learn the machinist trade. It was a new idea to him, and he had to think over it for a little while before he said that he would, but he immediately added that it would not be possible to begin just then, as he was engaged to this farmer for six months. The farmer was a reasonable man. On being consulted he said:

"Would you like to learn the trade, Ed?"

"I think I would," said Mr. Reynolds.

"Well, a trade is a mighty good thing to fall back on. I'll tell you what I'll do. You come and help me for a month in July and I'll let you off now."

THE LATE EDWIN REYNOLDS

So a three years' apprenticeship was begun with Anson P. Kinney, or Kenney, who had a general machine shop, with a specialty of sewing-silk machinery; several cards, or carding machines, also being built during Mr. Reynolds' apprenticeship. A country shop in 1847, we can well understand, was a crude affair. There was in the first place no foundry. The tools of the shop comprised one 20-inch engine lathe, one bench lathe, or, as we might now call it, a patternmaker's lathe, one vise and a circular saw. Some creditable machines were, however, turned out, and Mr. Reynolds' apprenticeship consisted largely in learning, not the trade as we understand it, but "how to do things without any appliances wherewith to do them." A memorable event of Mr. Reynolds' apprenticeship was the addition of a 16-inch lathe to the plant. Mr. Reynolds lived with his employer and their relations were more like father and son. His wages were [illegible] the first year, [illegible] and his board, the next year $45 and for the last year $60.

On the completion of his apprenticeship Mr. Reynolds worked as a journeyman for a year with Smith, Winchester & Co., of South Windham, Conn., who built paper machinery, and then he went as a journeyman to the Woodruff & Beach Iron Works, at Hartford, one of the large companies of that time, which built slide-valve steam engines and general machinery. While Mr. Reynolds was working there, Mr. Wright became engineer of the works, and they began the building of the Wright engine. No concern in those days, however, built engines exclusively, and the Woodruff & Beach works, among other things, turned out a lot of wire-drawing machinery, in the building of which Mr. Reynolds soon became a gang boss, eventually taking charge of all that line of work in the shop and in the erection of the machines after they were sent out. This connection continued for six or seven years, or until about 1857, when Mr. Stedman, of Stedman & Co., Aurora, Ind., who had been a classmate of Woodruff, came East looking for a superintendent, and Mr. Woodruff — as some other employers have nobly done, but as some would not have done—recommended his subordinate as precisely the man for the position, and so Mr. Reynolds went to Aurora as general superintendent. The silent partner of Stedman & Co. was a resident of Aurora—J. W. Gaff, a wealthy distiller and steamboat owner—and, with Grey and Gordon, the owner also of the Niles Tool Works. Stedman & Co. had a general machine-shop business, building also plain slide-valve engines, sawmills, farm machinery and pumps for Southern plantations. The designing of large pumps for drainage and irrigation was a promising field which Mr. Reynolds proceeded to develop. Patents of the old Andrews pump and others were offered the firm, but none showed or promised satisfactory efficiency, so Mr. Reynolds decided to design a pump, and in connection with this scheme he made some crude experiments, the results of which have been of value to him in connection with his largest and most daring work of later years.

The breaking out of the war between the States interfered so seriously with the business at Aurora that Mr. Reynolds found himself out of employment and came East, making Boston, New York and other places his quarters for the next few years. These were no more years of idleness than the others had been. He took charge of a shop in Boston for George T. McLaughlin, and besides that he was interested in the development of a number of special machines, either as designer or consulting engineer.

In 1867, Mr. Reynolds, who had become known as a manager combining technical knowledge with executive ability — then, as now, a rarity—was offered a commercial and engineering position with the Corliss Steam Engine Company, whose shops at Providence, R. I., were the largest and most important in the country, if not in the world, for the manufacture of steam engines. The Corliss plan of operations had from the first and always called for salesmen who distinctly were competent engineers. After four and a half years in this position, Mr. Reynolds was made general superintendent of the works, which position he held until 1877. He had not held the position so long without suggestions and invitations to change. His old friend, Mr. Gaff, and also Mr. Gordon, of the Niles Tool Works, tried hard to get him to take hold of that institution, offering an interest in the works on terms exceedingly favorable. Having declined this offer, the acceptance of a connection with the Reliance Works of E. P. Allis & Co., Milwaukee, Wis., may have a rather unaccountable aspect. The position held by Mr. Reynolds at Providence was then perhaps the highest in the engineering business in the United States. He went to the remotest corner of the manufacturing field, and connected himself with a firm practically unknown and in embarrassed circumstances. The firm had failed the year before; they had a ramshackle shop; the foundry, which had been fitted up for pipework, was of a piece with the rest; and, all told, only about 150 men were employed. It is scarcely probable that Mr. Reynolds foresaw what the business would so soon grow to, but he must have seen in it more or less clearly the opportunity of his life. Mr. Corliss had grown rich and dictatorial, seemed to believe that his word was law in steam engineering, and took the position, more or less pronounced, that any man who wanted the best engine must buy it of Corliss and must pay the Corliss price for it without question. In the meantime, Mr. Reynolds, as events would seem to indicate, had ideas of his own about Corliss engines and other things. He evidently believed that the original Corliss engines could be greatly simplified and improved, that he knew the way, and that the improvements, combined with correct business methods, must result in the building up of a great business. There may have been more than a little of sympathetic benevolence in it, also. Here was a concern in a bad way. Neither Mr. Allis nor his sons had engineering knowledge or ability. He could help them, assume an independent position for himself and find full employment for his teeming engineering ideas, and so he became the engineering brains of the Allis works.

It has been erroneously stated, on many occasions, that the attention of Mr. Allis was particularly attracted to Edwin Reynolds by the "Reynolds-Corliss compound engine" exhibited at the Centennial in 1876. As a matter of fact, however, this unit consisted of two simple Corliss engines compounded, and they were of the regular type built at the Providence shops. Further than for his being general superintendent of the works at the time, there is no reason particularly to identify Mr. Reynolds' name with that of the Centennial engine.

After entering upon his duties for Mr. Allis, the first and most essential thing was to place the business on a paying basis. This was done almost at once through the development of the "Reynolds-Corliss" engine, which has become a synonym for simplicity, economy and reliability, collectively expressed. The first engine was a 14x36-inch girder-frame Corliss stationary engine. It was sketched on the back of an envelop during a ride from Milwaukee to Chicago, after his first visit to the scene of what were to be his life's greatest successes. This design was not his best on general principles, but the best to build with the shop equipment at the time. This, it will be understood, was not only miserable, but there were no means at hand for the purchase of better. The first tool put into the shop after Mr. Reynolds took charge was an 8-foot boring mill, furnished by Mr. Reynolds' old friend, Mr. Gaff of the Niles Tool Works. Mr. Reynolds had to and did design the thing which it was possible to build in the shops as they stood, without spending a cent at first for equipment. It was necessary to compromise, not only with the machine shop, but more especially with the foundry, which was worse, and even the facilities, worst of all, for transporting the castings from the foundry to the machine shop had to be yielded to. The frame, then, was made in two parts, so it could be handled, so either right or left could be made from the same pattern, and so, in deference to the lack of skill in the foundry, the core work was reduced to a single simple core in the jaw. At a later time, when the demands of the business were growing faster than the facilities, the wrought-iron-frame engine was designed as a means of relief. The Reynolds engine of 1890 may probably be said to be the first design in which serious concessions have not been made to the facilities of construction or other imperative conditions. Mr. Reynolds' method of work has seemed to be first to make a careful study of all the conditions of the individual case, and first of all with reference to the underlying engineering principles. On these for a foundation he would work out the simplest machine possible, remembering always the possibilities of the shop as well as the idealities of the drafting room. This has usually practically ended the matter. Once the design has been decided upon, he has been prepared to fight for it, and usually successfully, and a very large part of the Allis business has been obtained, not so much by underbidding in price as by embodying the best engineering features.

It would be difficult to overstate the character and importance of the work that Mr. Reynolds accomplished during his unostentatious life. In brief, he was the foremost practical man, the responsible technical manager, in an engine-building establishment which, under his guidance, grew to occupy a position in the very front rank of reputation, and in point of magnitude to surpass all others in the United States. The machinery built by it has been of varied nature; it has included many large Corliss-engine units for pumping service, mining, air compressing, furnace blast, street-railway work and other purposes. In the name of the "Reynolds-Corliss" type of engine, this engineer received one of the deserved marks of recognition which raised him out of anonymity in his business relations with the public.

To him especially is attributed the use of compound and triple expansion engines in manufacturing plants, one of the first large ones employed for that purpose being installed by him in the Eagle Mills, at Milwaukee, in 1878. He was the first to build the low-speed direct-connected type of engine for driving a generator.

Among achievements of his life, long before the close, was the construction, in 1888, of the first triple-expansion pumping engine built for waterworks service, which he installed at Milwaukee, to run under a pressure limited to 80 pounds. The steam consumption proved as low as 13.84 pounds per indicated horsepower per hour. Some time later, two engines installed in the West Harrison street station, Chicago, showed a steam consumption of 12.67 pounds, which was believed to break the existing economy record. An engine built for Omaha, with 40-, 70- and 104-inch diameter steam cylinders had a capacity of 18,000,000 gallons in 24 hours, raised 310 feet. A 30,000,000-gallon triple-expansion pumping engine was built for the Boston waterworks, its installation being completed in December, 1898. It made the world's record for efficiency and economy of operation, its average consumption of dry steam per indicated horsepower per hour being 11.335 pounds, and its duty per 1000 pounds of dry steam, 178,497,000 foot-pounds. A 15,000,000-gallon triple-expansion pumping engine for the St. Louis works, also built by the Allis company, proved a close second, showing an average dry-steam consumption of 10.676 pounds and duty of 179,454,255 foot-pounds.

When constructing an engine for flushing the Milwaukee river with Lake Michigan water, Mr. Reynolds designed a propeller type pump, which was built against strong opposition, but the performance of which amply vindicated his judgment. The efficiency of the wheel was 86.75 per cent. The large centrifugal units for sewage plants, each driven by vertical shaft from a horizontal triple-expansion engine, with piston rods 120 degrees apart, originated in his fertile brain. The centrifugals were originally designed to handle Boston sewage.

Another product of his skill is the Reynolds ore stamp, in which he substituted a solid cast-iron foundation for the wooden spring bottom that formerly had been deemed necessary. The result was nearly 50 per cent. increase of output. This invention added much to the value of the great copper properties.

When he built his blowing engine for the steel works at Joliet, Ill., he stirred up the experts. Although his design marked a radical departure from previous types, its valuable features were recognized at once and received the contract. Andrew Carnegie ordered one like it before it had been running a month, this being the beginning of work for the same company that [illegible] years ago had amounted to $1,000,000.

Among other works of Mr. Reynolds was the combined horizontal and vertical reversing engine built for the American Steel and Wire Company, at Worcester. The cylinders of this engine were both high-pressure, 44x60 inches, the construction leaving one end of the shaft free for direct connection to the rolls and doing away with the gears, which have always been an objectionable feature.

An instance of the marvelously quick inventive genius of Mr. Reynolds was afforded when he designed the engines for the Manhattan elevated railroad, of New York. A staggering problem of getting a maximum of 12,000 horsepower in limited space and without undue weight on the bearings seems to have been very simply solved, and the weight of the flywheel was reduced one-half. This engine may be taken as illustrative of the building up of the Allis business by Mr. Reynolds. The contract was secured because as an engineering proposition the design submitted was so superior to others offered in competition that the price was a secondary consideration. As a sample of the confidence in Mr. Reynolds' judgment and skill, $3,000,000 worth of this type of engine were ordered in a lump before one of them had been built and erected. Regarding the circumstances attending the design of the Manhattan engines, the following anecdote is related.

The Allis-Chalmers Company, having built eleven 4500-kilowatt standard cross-compound, vertical, direct-connected engines for the Metropolitan Railway Company, was called upon for advice as to the type of engines to be used in the immense new power house then being planned by the Manhattan Railway Company in New York City. It was the intention of their engineers to install units of 8000 kilowatts capacity. The first type of engine considered was the cross-compound, vertical machine, similar to those furnished for the Metropolitan Railway Company, and some correspondence passed between Mr. Reynolds and the engineers of the Manhattan Railway Company on the subject, so that finally Mr. Reynolds was invited to visit New York and discuss the matter in detail. Mr. Reynolds left Milwaukee with the question of the type of engine still unsettled, but with the understanding that the straight cross-compound, vertical unit would be used if it were found practicable. Mr. Reynolds was traveling from Albany to New York when the question demanded his attention, and he was informed by telegram that a committee representing the owners of the elevated road would meet him at the Grand Central station. During the ride down along the Hudson he thought the matter over; then, as the train reached the Harlem, he hastily sketched on the back of a letter the substance of the plan ultimately adopted, including the practically unique design of the horizontal-vertical, four-cylinder compound engine, with cylinder sizes and approximate dimensions of all other principal parts, such as crank pins, crosshead pins and main journals. When the work came to be laid out on the board, there was very little variation from his original figures. At this time, Mr. Reynolds, in common with the engineering world at large, was [illegible] to see similar engines installed in all important urban stations where [illegible] were an important consideration; but the steam turbine was then beginning to demonstrate something of its possibilities, and many large projects were held back until the merits of that type of prime mover could be more definitely determined, with the result now universally known.

Mr. Reynolds' ability was not evidenced by his engineering successes exclusively. He was also the man of business. It was by the combination of engineer and business man and all-round manager that the enterprise with which he was connected has so marvelously grown. He was held in the highest esteem by Mr. Allis. In the will of the latter, who died about the beginning of the nineties, he was named as one of the trustees of the Allis estate. Upon the reorganization of the business, which followed, he was elected director and second vice-president of the E. P. Allis Company.

In 1901 the Allis-Chalmers Company, with $50,000,000 capitalization [illegible], was formed to consolidate the E. P. Allis Company, Fraser & Chalmers, Gates Iron Works and Dickson Manufacturing Company. In the organization Mr. Reynolds played a prominent part, being a director and the chief engineer of the new corporation. This gave him the opportunity of laying out at West Allis, a suburb of Milwaukee, the great engineering and machinery building works which constitute one of his greatest monuments. It is so constructed that it never can be what was Mr. Reynolds' personal aversion, an "accretion"—the adding on of one building or bench after another without proper sequence. Instead, it is built throughout on the unit system, the extension of general works being capable of indefinite extension toward the "rear" with [illegible] for the corresponding machine shops to be at right angles between them.

In the fall of 1905 Mr. Reynolds retired from active service, with the title of consulting engineer, and, although in failing health, he maintained a hospitable [illegible] in his beautiful residence on the bluffs overlooking Lake Michigan, loved and honored by all his associates.

Mr. Reynolds was interested in various business undertakings outside of the Allis company, being president of the [illegible] Mills, Milwaukee Boiler Company, [illegible] Mining Company.

The University of Wisconsin conferred upon him the degree of LL.D., and later placed his name upon the frieze of the new engineering building. He has received honors from institutions of learning throughout the civilized world. His election to the presidency of the American Society of Mechanical Engineers for 1901-1902 was a recognition of his eminence in the profession, which the society honored itself by conferring. He was received into active or honorary membership of the leading engineering societies at home and abroad, and he became the first president of the National Metal Trades Association.

The influence of Edwin Reynolds remains expressed not only in mechanical types, but in human personalities. To be a brilliant designing engineer, particularly in the field of power generation and application, is a matter of self-gratulation to anyone so gifted, and is a benefit to many affected by his work; but to lead the way so plainly that others may follow with no uncertain step, to train a large number of young assistants so that they become efficient, original co-workers and themselves the chief officers of engineering works, and to found, develop and leave in sound condition a great manufacturing establishment—such is the province of a master mind, one of the few which a century produces.

A good paint for boiler fronts can be made from asphaltum let down with turpentine or coal tar mixed with graphite and thinned with turpentine.

That Harwood Boiler

In our issue of December 15, under the title "The Lap Seam Boiler Again," we described the finding of a cracked sheet in a boiler belonging to the Charles E. Harwood Counter Company, of Lynn, Mass. The engineer noticed steam coming through the brickwork, put the boiler out of commission, and inspection showed that the middle sheet had cracked. Our original article said: "Removal of the brickwork over the leak revealed a crack 18 inches long in the outer sheet along the row of rivets," and the article assumed that it was one of the hidden cracks the recurrence of which has caused so many failures of lap-seam horizontal tubular boilers.

SHOWING CRACK IN SHEET OF THE HARWOOD BOILER

In our issue of December 22, Arthur M. Clawson presented a more detailed account of the accident in which he said: "The crack was not located under the lap as has generally been found to be the case, but ran parallel to the edge of the overlapping plate."

We have recently had the opportunity to inspect the plate in question, which is in the office of the chief boiler inspector at the State House in Boston, and have obtained the photograph reproduced herewith. The crack is shown in the upper left-hand portion of the sheet just under the lower row of rivets and is very plainly one of the hidden internal cracks occurring, as is usually the case, just under the edge of the rivet heads and so hidden by the inside sheet as to be impossible of detection by any inspection short of unmaking the joint.

Saving Life and Property

The American Anti-Accident Association held open meetings Thursday afternoon and evening, February 11, in the Y. M. C. A. hall, 215 West Twenty-third street, New York City, for the purpose of presenting and receiving ideas as to the true underlying causes of accidents, the best way to prevent them, and incidentally to augment the number of its members.

It is the intention of the organization to establish boards in our towns and cities that would be under the control of the State, with a national head, and similar in a great many ways to our present boards of health. Its purpose is the education of carefulness in homes, schools and vocations, to develop a greater realization of the suffering and afflictions caused by accidents, and to create a public sentiment which in time will cause anything pertaining to the prevention of accidents to command the highest humanitarian consideration. Thomas D. West, president, discussed the fundamental features involving work for the association, and other speakers, such as Edward Bunnell Phelps, editor of *The American Underwriter*; W. H. Tolman, director of the American Museum of Safety, and L. P. Alford, of the *American Machinist*, took up the subject of accidents and their prevention in its different phases.

Some Useful Lessons of Limewater

Interesting Experiments in Softening Temporary- and Permanent-Hardness Waters; the Importance of Chemistry; Its Chief Elements

BY CHARLES S. PALMER

There is one suggestion that may well be made at this point; that is, that you will save time and effort in getting things cleared up and in remembering things if you just *talk* these lessons over with some friend who is interested with you. The reason for the gain is that you will talk your notions out, and you will hear the notions of your friend; you will find your eye, ear and hand working together to help your mind in grasping the facts, in remembering them and, most important of all, in using them. But to get back to the hard water.

FIG. 1

Softening Hard Water

Get two large bottles of clear glass. Common quart bottles will do, but if they are large enough to hold several quarts, so much the better. Pour into one of these, until three-quarters full, a solution of temporary-hardness or carbonate-hardness water, throwing in with it two slips of litmus paper, one red and one blue. Pour into the other bottle, until three-quarters full, a solution of permanent-hardness or sulphate-hardness water, also putting in two similar slips of litmus paper. You may not get many surprising results from the litmus paper, but you will have the satisfaction of knowing that you have kept your eyes open in that direction, and litmus paper will always tell you something. If the solution of carbonate-hardness water is strong with carbonic acid, you may almost get the litmus paper red, but you should remember that litmus paper turned red by carbonic acid will turn blue of itself usually, if taken out of the solution, as it dries in the air; because carbonic acid is volatile and is driven off by the [illegible] acid in the litmus itself. We will return to this subject of litmus paper a little later, for it teaches one much about the acid and the base parts of "salts."

Now throw into the bottle of temporary-hardness water or carbonate-hardness water about a teaspoonful of milk of lime, shaking the bottle well, and letting it stand. You want to learn how to add just enough of the milk of lime to soften the water by Clark's process, and there are different ways by which you can tell this. One way is to let the water settle clear, pour out a few drops and add some filtered limewater; if there is still any carbonate or bicarbonate of calcium in solution, there will be a slight milkiness; and you keep on adding the milk of lime until there is no more milkiness on adding filtered limewater to the clear hard water. Another way to tell whether you have added enough milk of lime to the temporary-hardness water is to watch the litmus paper; as soon as you have added just a bit too much of the milk of lime, the water will change the litmus to blue, because the milk of lime is itself a turbid solution of limewater. To the bottle of permanent-hardness or sulphate-hardness water you will add a solution of soda ash (or sodium carbonate or washing soda; they are all essentially the same thing). You will also know in this case, as in the other, when you have added enough soda ash. Let the water settle clear, and then test a few teaspoonfuls, poured out into a tumbler, with some of the soda solution to see whether there is more precipitation. Keep this up until you get no further precipitate; also watch the litmus paper, it may tell you something.

Now let both bottles of hard water settle, noting the time required to get clear solutions. It may take some hours, sometimes nearly a day or even longer. All this will start you to do some thinking. It will suggest that large settling tanks may be necessary. It may suggest that it will pay you to look up some of the newer ways of clearing hard water. There are some patented methods, with some merits and in some localities, to give really good results; but all this will help the selling agent give you a scientific explanation for what he tries to do, and which he may really be able to do. You will note that the chemistry of softeners is one thing that you have begun to study. You also note the time taken for the water to settle, but it will be well for you to try the settling, sizes and tanks; these things sometimes make all the difference in the world.

But there is another thing that you need to notice; that is the way to mix the softener with the hard water. It is one thing for you to add a teaspoonful to a bottle which you can shake up with your hands; but it is quite another matter to mix a pailful of the softener with a [illegible]-gallon tank of water. It is worth while for you to study how this mixing is to be done. Will you feed the softener [illegible], the water supply to a constant [illegible] stream? Or will you throw in a bucket or barrel of it at a time? The special form of apparatus must attend to all these matters and must do it right.

Then there are some of the other things which get into "hard" water; for, as we have noted already, it is not alone lime and its compounds that make water hard, but often the compounds of magnesium, and perhaps one or two other metals. Also, while much temporary-hardness water has to do with carbonates and much permanent-hardness water has to do with sulphates, yet there are some other complications, such as the *chlorides* of magnesium, which are not only difficult to throw out of the water but which also corrode the boiler iron. As you examine the samples of scale which you will collect you will find some iron in all of them, and this iron stain is or may be partly from the water, and partly from the iron tubes or plates themselves; so you see that all scale is not only in the way, but it is also a corrosive, eating thing. All this suggests that there is much to be learned about the scale-forming substances, and this means that we must use this study of lime as a broad basis for getting hold of enough chemistry to understand the action of both scale formation and burning. And, in the study of burning or combustion, or "oxidation" in its broadest way, we shall have to dip into *wet* chemistry, and *dry* chemistry, for there is a dry combustion and there is a wet or moist combustion. All of this, or some of it, will come along in due time.

But just now turn your eye to the experiment shown in Fig. 1 and note the amount of sediment which has formed or gathered in each bottle. You will see that in both bottles there is the *same* insoluble sediment, plain carbonate; and you must stop and think how it is that you get the lime-like part of the hardness thrown out of solution from either temporary- or permanent-hardness water, as this same old plain carbonate. You will remember that this plain carbonate of lime came from the extra carbonate, by heating or by addition of limewater or milk of lime; and you will see that you get this same plain carbonate from sulphate water and soda ash. But in the case of the temporary-hardness water you left the water nearly pure, while in the case of the permanent-hardness water you had to leave the water as a dilute solution of sodium sulphate.

Testing the Sedimentation

It will be a good thing if you collect the sediments from both the bottles shown in Fig. 1 and test them. First, just note the relative quantity. You will usually find that there is more sediment from sulphate-hardness water than from temporary-hardness water, although both are the same chemical compound, plain lime or calcium carbonate. Again, you will want to test both of the sediments with hydrochloric and nitric acids, when they will entirely dissolve with effervescence; that is, bubbling of some gas which you will rightly guess is carbonic-acid gas. Now if you test the clear solution left in the bottle that had the temporary-hardness water you will find that it is nearly pure water, with a little lime from the slight excess of milk of lime; but when you test the bottle of purified permanent-hardness water you will find that it has considerable sulphate of soda (Glauber's salt) in it. The sulphuric part you can test for by the same way used in the test given near the last part of the third lesson in the February 16 number.

You pour a few teaspoonfuls of the water left in the permanent-hardness water of Fig. 1 into a tumbler or test tube, and then add a few drops of your solution of barium nitrate. Down comes a quick cloudiness, which soon settles as a heavy sediment. Now try this with either hydrochloric or nitric acid, or both; its persistent insolubility shows that it is barium sulphate, the common test for sulphuric acid or the sulphates. But there is still the sodium part of the

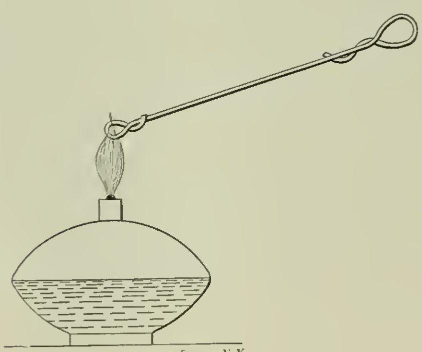

FIG. 2

Glauber's salt, left from the softening of the permanent-hardness water, to test for. It is not easy to throw the sodium out of solution; but if you take a clean bit of iron wire and moisten it with some of the solution of sodium sulphate left from the bottle of permanent-hardness water and then hold it in the flame of an alcohol lamp (Fig. 2), or of a common gasolene or gas stove, you cannot help noticing the strong *yellow* flame produced, and that is due to the sodium. You can always get this yellow flame from any of the sodium compounds, but you cannot easily throw sodium down from solution. Indeed, it is one strange peculiarity of sodium that of all of its hundreds of salts about all of them are soluble in water, and you will find when you get on farther into analyzing things that there is no good, easy way of throwing sodium completely out of solution in the insoluble form, as you can easily do with lime in a score of ways.

Chemical "Elements"

You will have a good deal to do with analysis as you go on with these lessons, and with other studies in chemistry later; for live as long as you will you will never get beyond the study of chemistry, which is the separating of things into their ingredients, putting back those ingredients so that you can get the original substance, the letting of this substance act on that and the reaction of that on this. From the air and water to the earth everything is made up of chemicals, and the curious ways in which things act on each other make up the study of chemistry. As you begin to separate things into their ingredients you get simpler things, and these can be separated into still simpler things, and so on. But before long, you come to a set of things that can't be separated into anything simpler, and those things are called "elements."

There are between seventy-five and a hundred of these elements, but only about twenty or twenty-five are of common importance; and you will have to do with only about a dozen at the start. You have had something to do with the element carbon, which makes up the bulk of coal, and which also is in carbonic-acid gas. You know sulphur, or brimstone, which is the thing at the bottom of sulphuric acid or oil of vitriol—sulphur is another element. The air is mostly made up of two gaseous elements: Nitrogen, which for the most part in the air is only a "filler," as far as burning goes, and oxygen, the element that helps burning. The common metals, iron, lead, zinc, copper and tin, the less common mercury, silver and gold, the new metal, aluminum, these are all elements; they cannot be separated into anything but themselves; at least, not up to date, for in these piping times of new and strange discovery it is not well to say that anything is impossible to the thousands of chemists who are hard at work after the secrets of nature. But if the elements are made up of anything simpler they have forgot to say anything about it, except possibly in the curious cases of uranium and radium; all of which has apparently little to do directly with hard water, but a great deal indirectly, because you want to learn analysis, so you can find out for yourself what are the ingredients, and what are their relative quantities, in the substances you handle every day.

You perhaps have never seen or handled the metal sodium, also an element; but you may like to be reminded that it is probably the stuff which the street fakir on the corner uses to light his pipe when he seems to light it with a bit of ice. He packs his pipe with common dry tobacco and tucks down on top of this a piece of the metal sodium (or perhaps of potassium, which is much like sodium, only stronger); then he touches the "quick" metal with ice, which is only so much solid water, and the heat resulting easily makes fire enough to light the tobacco. Theory says that when metals like sodium and calcium unite with oxygen they should first form the oxides, and calcium does form its oxide, CaO, quicklime, but sodium's oxide is so thirsty for water that it does not stop at the oxide, as calcium does, but at once goes right on to the water compound, NaOH, sodium hydroxide or hydrate, or caustic soda. That the lime metal, calcium, does form both the plain oxide (quicklime, CaO) and the slacked lime, $Ca(OH)_2$, is interesting (as shown in the February 23 number). It is also interesting to know that there is a flame test for this lime metal, calcium, just as there is a flame test for the salt metal, sodium. Take a little of the milk of lime and add just enough hydrochloric acid to it to dissolve it all and leave it barely acid, or nearly neutral. Of course, you now have a solution of calcium chloride. Now make a loop of clean iron wire, as shown in Fig. 2, dip it in the lime solution, and hold it in any colorless flame, as the flame of an alcohol lamp (you can make an alcohol lamp out of an ink bottle), or of a gas stove, and note the bright orange-red flame. That is the calcium flame. There is a special and a beautiful scheme of studying flames (with an instrument called a spectroscope), the science is called spectrum analysis; but these tests of sodium and of calcium are two of the fundamental tests. You can carry this testing of metals on quite a way by yourself, if you file any metal, iron, copper, zinc, lead, tin or silver. Gathering a pinch or two of the metal dust on a sheet of paper, sprinkle them, one at a time, in any hot and fairly colorless flame. You will be surprised to see what elegant and beautiful "parlor fireworks" one can get by simply burning the filings of any common metal in a hot flame; the dust will burn like powder and with a different colored light in each case.

This all goes to show how great is the subject of chemistry; but it will help us if we stop and ask ourselves: What are the really great and important subjects in chemistry? We will not let ourselves get confused by any absurdly complicated answers, but we will stick to a few fundamentals. The great subjects in chemistry are: First, *fire* and *water*; second, *acids* and *alkalies*; and of the acids, sulphuric acid is easily king, as the soda compounds make the queen set of alkalies. But in much of all of this you will find our good friend lime plays an important part. The story of lime has only been begun.

On page 64 of the January 5 number, in John B. Sperry's letter on "Pump Suction Limit," the second half of formula

A_s = *Total suction limit* =

$$H = \frac{v^2}{2g} + F_s$$

is erroneous. It should have been

$$H + \frac{v^2}{2g} + F_s$$

Central Station versus Isolated Plant

As bearing upon the vexed question of the extinction of the isolated plant by the central station, we reproduce the following open letter addressed to the Public Service Commission of the State of New York by Percival E. Moses:

Gentlemen: The question of rate discrimination as between the large and small consumer is presented for your consideration. So far the result of your rulings and investigations on this subject has been twofold:

1. To make the methods of discrimination matters of public record.
2. To make the discrimination practised between various classes of consumers equal as between classes.

"Do you mean to stop here and leave the main question unsettled?

"On behalf of the great majority of users of electricity, and of all whose interests are connected with isolated plants this plea for a 'square deal' is presented. Let the selling price of electricity be based upon the cost of manufacture and distribution plus even a liberal profit and let the present system be stopped of charging on the basis of 'all the traffic will bear.'

"Under present methods the user of a small quantity of electricity is charged three or even four times the rate charged the user of a large quantity, because the small user has no competition to offer, while the large user has, in the shape of the isolated plant.

"Occupants of lofts in large buildings where isolated plants are a possibility, by combining with the owners pay from 5 cents down per kilowatt-hour, while occupants of lofts in small buildings where isolated plants are not economically possible have to pay 10 cents per kilowatt for light and from 10 cents to 6 cents for power. Owners of small stores are charged 10 cents per kilowatt-hour, while owners of large stores pay as low as 5 cents. Apartment-house residents pay 10 cents if the building does not use 150,000 kilowatts per year, but if it does use this quantity the electricity they use is paid for at 5 cents per kilowatt-hour. In all the foregoing instances the cost of manufacturing and supplying electricity to the small users is substantially the same as the cost of manufacturing and supplying electricity to the large user. Where, then, is the justification for a variation in the charges?

"A certain difference in rates between current used during a short period and current used for a long period per day is justifiable because of greater fixed charges per kilowatt-hour supplied, but there can be no justification for any discrimination based on the total quantity of electricity used.

"The Edison and the other companies operate under a monopoly granted by the whole body of citizens, and it is easily understood that all citizens shall be treated equally. Where is, then, the justification for the unequal rates to small and large consumers?

"Mr. *Jones*, occupying a store room, with 20 lights costs the company, let us say, 10 cents—not 10 per cent.—to supply per kilowatt of use than Mr. Smith with 2000 lights. Yet Mr. Jones will pay 10 cents and Mr. Smith less than 5 cents per kilowatt-hour. When Mr. Jones goes home to his small apartment he will again pay 10 cents per kilowatt-hour, but Mr. Smith, if he lives in a big enough building, will pay, or his landlord will pay, only 5 cents per kilowatt-hour. The cost to the Edison company is exactly equal in each case. Is this condition to be continued? If so, why?

"If the Edison company can manufacture and sell current for lighting to the large users, apartment houses, or hotel or other building for from 4½ to 5 cents per kilowatt-hour, the rates to small consumers are far too high and they should be reduced to the rates charged the large consumers for the same kind of service irrespective of the total amount of their use."

Burning Ash

The statement that coal should be burned as completely as possible when it is first on the grates, and that the practice of refiring ash as it is often done is seldom of greater loss than it is of economy, is well borne out by the following results of recent tests conducted in the Arthur D. Little laboratory at Boston.

Just previous to these tests some of the grate bars had burned out very rapidly and allowed a considerable amount of coke and siftings of coal to be taken out of the ash conveyor.

The better part of the ash pile was returned to the coal conveyor and delivered to the bunkers, where it was mixed with the coal and was being returned at the time. At first thought it was considered as the proper thing to do, but a sample of the coal and ashes being sent to the boiler indicated that there was a considerable increase in the percentage of ash in the coal being fed and that the loss due to unburned coke invariably increased with this, so that instead of sending to the stokers New River coal which contained about 6 per cent ash the mixture contained 11.79 per cent ash.

The ashes and refuse being taken from the ash conveyor contain 20 per cent. of combustible, corresponding to a loss of 8.5 per cent.

From these analyses and the analysis of ashes being put into the coal bunkers, the chemist suggested discontinue the practice of ashes being added to the coal, as was done in the past.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for February, 1909, *was (weekly and monthly)* 151,000.

March 2............... 42,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Edwin Reynolds

The death of Edwin Reynolds, announced in another column, has not come unexpectedly. For several years after he had passed the allotted span he continued in active charge of the great Milwaukee works in the creation of which he was so large a factor. But, three or four years ago he began to fail, and his friends have long known that the end was imminent.

The story of his life, as told elsewhere in this paper, is that of another rugged genius who, without exceptional advantages of birth or education, threw himself into his work as he found it, did it not merely for so much per hour but because his interest was there—because he loved to do a good job and to see it *go*—and he naturally became a power in a field where there was a great development and developed with it. It was largely he who molded the slower-speed and larger-sized engine into the forms demanded of it through the successive changes of the development of large central-station work, and who stood ready to adapt the materials of nature to the varying demands of man. The great works which he planned for this purpose, as well as the many notable products of this and other works with which he has been connected, will be living monuments to his genius and industry.

Foundation Vibration

Vibration from generating units causes more or less annoyance in office buildings, and is due to the condition of the soil upon which the foundation is built, the unbalanced condition of the engine and, possibly, unequal distribution of load in the cylinder.

Many unique methods of preventing vibration transmission have been devised with more or less success. In one instance the ingenious engineer carried out the scheme of building a scow upon which were placed a small engine and generator that had given trouble from vibration. The scow was placed in a tank of water, and although the idea cost money it prevented all vibration from being transmitted to the building.

In another instance the engine was to be placed in the basement of a building built on a ledge. In order to overcome the transmission of vibration from the engine a portion of the ledge where the engine was to be set was cut away and a layer of asbestos felt placed under and around the engine foundation, which was then built in the usual manner.

These methods of preventing transmission of vibration have been confined to reciprocating engines, but from recent advices it seems that it has been deemed advisable to take precaution against this trouble in steam-turbine operation. At St. Pancras, England, the borough council has recently put in operation a 2000-kilowatt steam turbine mounted on a special rubber foundation as a precaution against vibration, such as has given trouble from reciprocating engines.

An ordinary concrete foundation has been built, upon which rests the turbine with its rubber foundation. The turbine is bolted to a slab of concrete about two feet thick, which is reinforced by steel bars, and between this concrete slab and the foundation proper are placed a number of 4x3-inch circular rubber pieces. No part of the turbine or concrete slab above the rubber pieces is allowed to come in contact with the floor, thus preventing any possibility of vibration being transmitted to the building.

From what is known of steam-turbine operation this precaution would seem unnecessary if the machine is in proper balance, and there is no reason why it should be put into operation until it is. In justice to the contractors of this installation it can be said that they were willing to guarantee that the turbine would run without vibration.

Cultivate the Habit of Observation

To see without noticing is one of the commonest habits of mankind, and this fact has been taken advantage of by a class of men who call themselves "Business Doctors." They have cultivated and improved the faculty of noticing what they see. They go into business houses and industrial establishments and, without previous experience in any particular line, except that of observation, put their fingers on sources of loss. Under their direction, methods of business are reorganized and industrial establishments are remodeled. Wastes are stopped, losses reduced and production increased. Members of this same class of men have turned their attention toward the power house, and lubricating engineers, combustion engineers, supervising engineers and what not are looking for revenue from the mistakes of carelessness and ignorance on the part of the operating engineer.

Claiming to have saved in some instances as much as ten per cent. of the total fuel used in large industries, by intelligent use of the right kind of lubricating and cylinder oils, the lubricating engineer is able to interest the man who pays the coal bills and he often makes good, because the engineer has not noted the things which he has seen while attending to matters of lubrication. Altogether too often with the engineer oil is oil, and as long as bearings do not unduly heat one oil is just like any other oil. Observation is the long suit of the lubrication expert and he notices every spot where oil is used and how it is applied, and he gets from an apparently simple glance at things in general an amount of information that the engineer would not acquire in a lifetime, because he naturally notices only that which is out of the ordinary, while the habit of observation cultivated by the expert teaches him to see all that is not ordinary in ordinary things.

Sometimes the engineer uses new oil on a part of his plant and filtered oil on the rest of it. Sometimes all of the new oil used in a plant is added to the oil already in the filter as makeup oil and only oil from the filter is used for lubrication. But how often does the engineer know or even think whether the machinery under his care runs with less friction in one case than in the other? In an installation of five hundred or more horsepower, a saving in the amount of friction of even one per cent. is an item which is well worth looking after, and the ignorance of the man who directs the oiling of this plant is the opportunity of the lubricating engineer.

In the boiler room it is the same. Improper and unintelligent methods of firing may obtain, cold air may seep through the known or unknown cracks and openings in the boiler setting, lowering the furnace temperature and the temperature of the products of combustion before they reach the heating surfaces of the boiler, reducing the efficiency of the plant.

Through various channels, the outsider is invading the field that belongs especially to the engineer and with more or less success as the engineer is alert or inert. Obviously, the moral pointed to is that the man who is in the power plant and responsible for its operation should know more about every detail of its operation than any outsider, however well trained he may be. Special knowledge comes only as the result of special application and the engineer has better facilities for special study of his own plant than any other man in the world and should take advantage of them.

State Supervision of Boilers

Even those who most loudly decry paternalism on the part of the State, and governmental interference with the prerogatives of the individual, will not deny the right of the State to insist that steam boilers shall be used under such conditions as not to menace the public safety.

The Massachusetts law contains a provision for a Board of Boiler Rules consisting of the chief of the boiler inspection department, one representative each of the boiler-using, boiler manufacturing and boiler insurance interests and an operating engineer. This board is directed "to formulate rules for the construction, installation and inspection of steam boilers, and for ascertaining the safe working pressures to be carried on said boilers; to prescribe tests, if they deem it necessary, to ascertain the qualities of materials used in the construction of boilers; to formulate rules regulating the construction and sizes of safety valves for boilers of different sizes and pressures; the construction, use and location of fusible safety plugs, appliances for indicating the pressure of steam and the level of water in the boiler, and such other appliances as the board may deem necessary to safety in operating steam boilers."

These rules, when approved by the governor, have the force of law and several sets have been promulgated and reproduced in part in our columns.

It is now contended by some of the boiler manufacturers that certain of these rules transcend the authority of the board in that they are not essential to safety, and efforts are being made to have them repealed. Those to which objection is specially urged are:

Rule 11, sections 2 and 3, specifying that fusible plugs shall be placed in a tube not less than one-third the length of the tube above the lower sheet.

Section 4: "This board does not recommend the use of externally fired boilers over eighty-four inches in diameter."

The specifying of standard sizes of manhole and handhole and prescribing their location.

The requiring of horizontal return-tubular boilers over seventy-eight inches in diameter to be supported from steel lugs by the outside-suspended type of setting.

The requiring of the feed pipe between the check valve and boiler to be of brass.

Another proposed amendment is for the purpose of exempting the boilers of steam fire engines from inspection, and another the exemption of attendants upon boilers and engines used for horticultural purposes from examination and license.

The board requires builders of boilers built in or coming into the State to fill out a report giving sizes and full particulars, including destination, to the end that the department may have a record of every boiler from its setting up to its [illegible]. Another proposed amendment is to the effect that the data so required shall be simple in form, including only information necessary to be known for public safety, and that the manufacturer or person making such report shall not be required to furnish the name of the purchaser or the location of such boiler.

Another proposed amendment provides that the governor shall give notice and hearings before approving rules, and that anybody making or using boilers who shall feel aggrieved or injured by any of the rules may petition the superior court for the annulment of the rule.

Still another amendment to the bill, [illegible] decrees that the board shall make such rules only as are necessary for public safety and revokes all rules heretofore issued not so necessary, without saying who shall decide.

We have had a recent opportunity of examining the system of standardization, inspection and record inaugurated by the Massachusetts department. It is possible that in some respects it does transcend the bounds prescribed by a simple provision for the public safety. A boiler may be perfectly safe with a manhole varying in size from that which the board has adopted as standard and the use of which is prescribed by the rules, and if the case were taken to court it might be found that even the legislature cannot compel a man to use an 11x15 or 12x16 manhole if he wants to use some other size. At the same time a wide variation from these sizes is not practicable in one direction, on account of inadequacy for a man of ordinary size, and in the other for safe and practicable reinforcement of an abnormally large opening in the shell. The rules allow a variation of half an inch in the foregoing dimensions giving a range of from 10½x14½ to 12½x16½, which ought to cover any exigencies of practice, and the advantages of standard sizes does not have to be explained to those who have had to hunt the town for a gasket or to replace a broken plate.

Much is being made of the regulation that brass feed pipe shall be used between the boiler and the check valve, but in view of the proneness of iron pipe to corrosion and scaling up, and of the possible serious consequences of a breaking out or obstruction of this pipe inside of any valve or possible means of shutting off, is not brass pipe better and safer? It requires only a nipple between the check valve and the boiler to comply with the rule, and the tendency which would be induced to put the check valve nearer the boiler is also in the direction of safety.

The right of the board to require information of new installations is indisputable, and if they are reported the department learns in that way of the destination and location of all new boilers whether made in Massachusetts or imported. Why, then, should the manufacturer object to reporting the destination or purchaser of a boiler as well as its dimensions and proportions?

It would be well enough to provide for hearings by the governor before he approves rules, but protests should be first made to the board, and if the protestants were not able to convince the board of the injustice and inadvisability of a rule it is unlikely that they could convince the governor to withhold his approval. [illegible] necessary [illegible] and manufacturers of the country [illegible] necessary in the [illegible] tion."

International Harvester Gas Engine

The engravings presented herewith illustrate the details of the latest two-cylinder vertical gas engine manufactured by the International Harvester Company of America, Chicago. As apparent from Fig. 1, the design conforms in many respects to standard construction for vertical single-acting four-stroke-cycle engines, having an inclosed crank case and splash lubrication, valves in the cylinder heads operated by push rods and rockers, and a flyball governor controlling the admission of mixture to the intake manifold. In working out the details, however, absolute interchangeability of parts has been the guiding principle, and there are no "rights and lefts" in its construction. Any piece used for any given purpose on one cylinder may be used equally well on the other, and the positions of the cylinders themselves may be transposed at will.

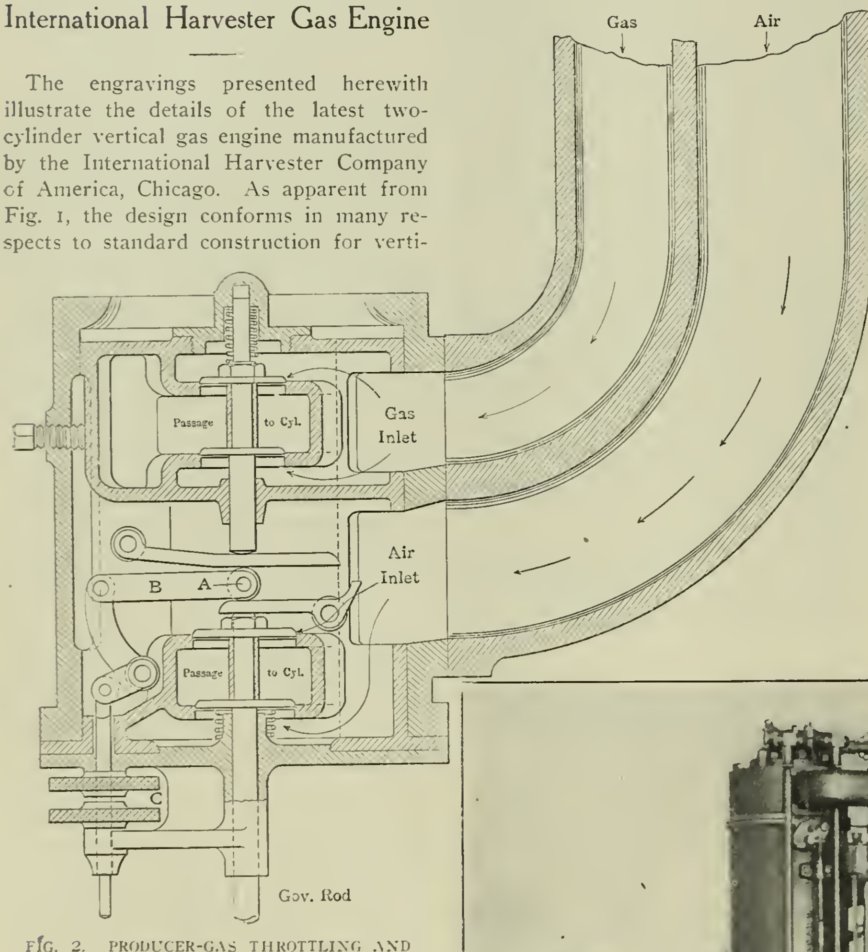

FIG. 2. PRODUCER-GAS THROTTLING AND VALVE MIXER

As shown in Fig. 5, both the inlet and the exhaust valves are in the cylinder heads, and both are mechanically operated from a half-time cam shaft located in the crank case. One size of valve cage is used for both inlet and exhaust valves, and the cages are held in place by two large studs instead of several small ones. To reduce the velocity of the entering and outgoing gases in the valve ports, the valves are made as large in diameter as consistent with the size of the cylinder. The inlet valves are integral with their stems, but the exhaust-valve heads are screwed on their stems to permit renewal of a disk alone if it should become necessary.

Regulation is effected by throttling the mixture of gas and air according to the load requirements. The governor is gear-driven from the cam shaft and is equipped with a spring mechanism designed to take up the shock and jar caused by the cam action. The vertical governor spindle, which extends up through the crank case, as shown in Fig. 5, carries three lugs, which correspond to three similar ones on the governor yoke. Between these two sets of lugs are interposed coil springs, so that the governor-valve stem is not affected by momentary changes of speed due to shock or jar, backlash of the gears, or other similar causes.

Fig. 2 shows in section the combined

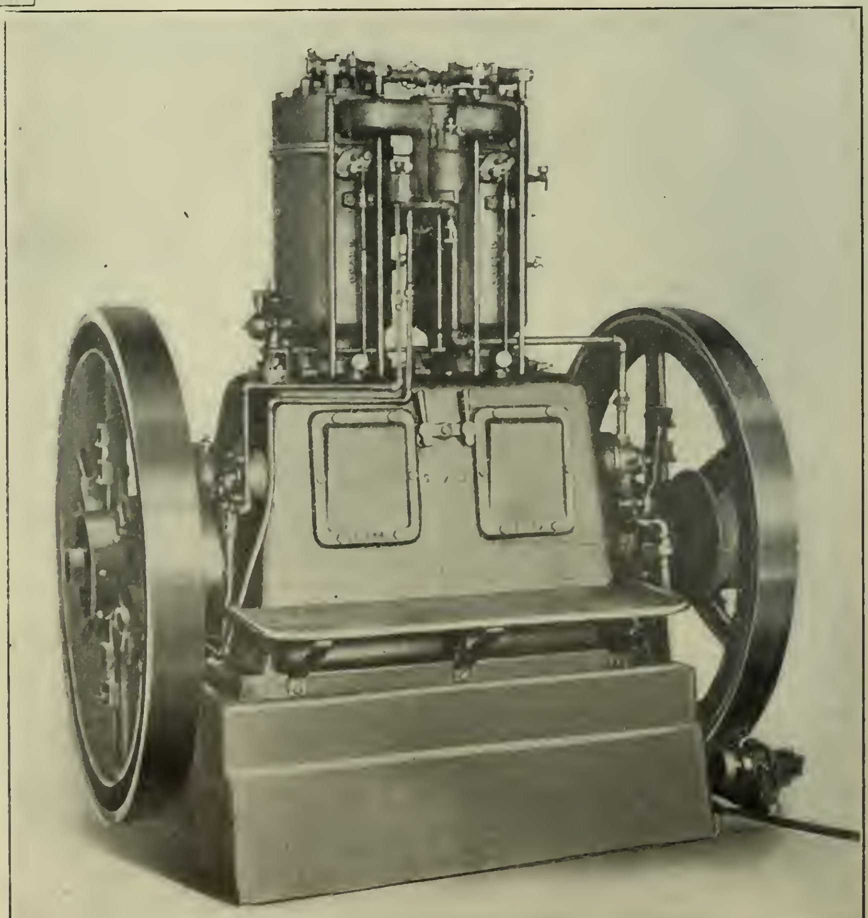

FIG. 1. INTERNATIONAL HARVESTER COMPANY'S GAS ENGINE

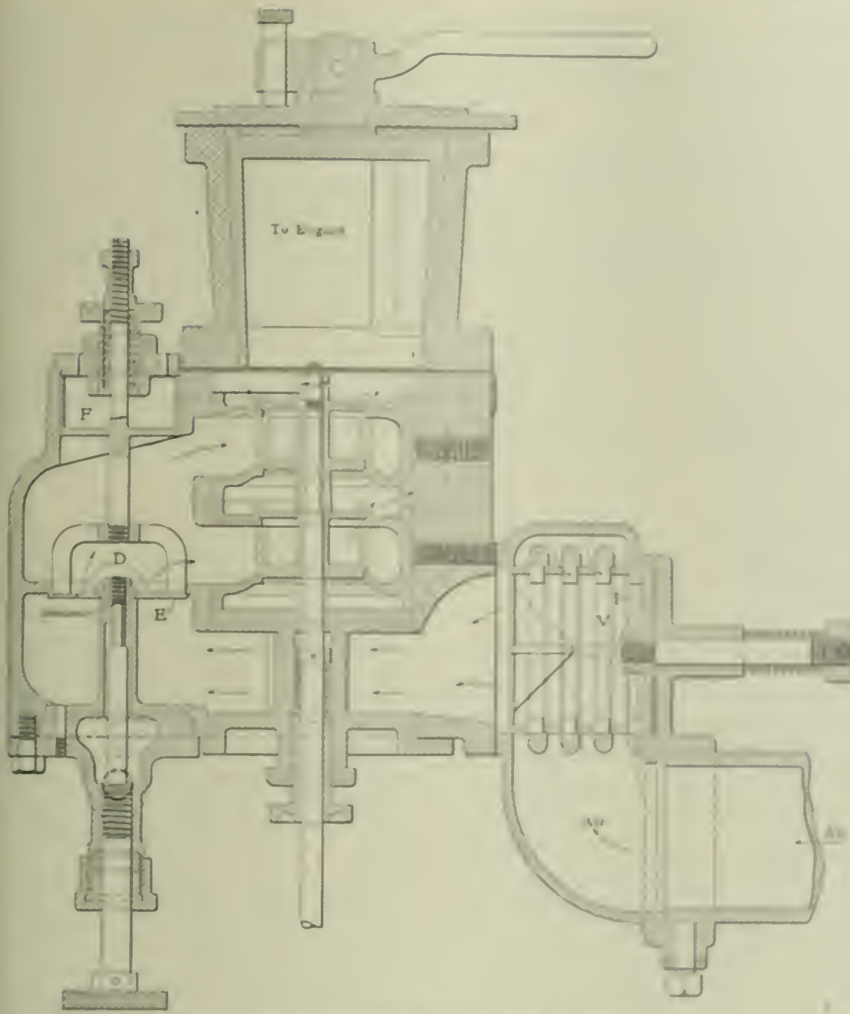

FIG. 3. GASOLENE VALVE AND MIXER

throttling and mixing valve for the producer-gas engine. Both the air and the gas valves are of the balanced poppet type and are raised or lowered by the governor reach rod. It will be noticed that between the gas and air valves is interposed a roller A, mounted on the end of an arm B, the position of which is adjustable horizontally through a set of links by the adjusting nuts C. When the roller is in the position shown both valves will have equal lift, but when it is shifted over to the right the lift of the gas valve is less than that of the air valve, and vice versa. By means of this mechanism any desired quality of mixture may be obtained within reasonable limits.

The engine is also built to run on gasolene, in which case shorter pistons are provided and lower compression is used. The gasolene-mixing attachment is shown in Fig. 3. The liquid fuel is introduced into the mixing chamber through a cone-shaped nozzle which reduces it to a fine spray. Air is admitted in direct proportion to the opening of the balanced throttle valve V, the movement of which is due to the air piston P responding to the engine suction. The spring on the horizontal stem pulls the valve back to the closed position after each suction stroke. At light loads, and on starting, all the air passes through the opening D, in an auxiliary air valve E, the stem of which is attached to the diaphragm F. All the air then comes in contact with the gasolene vapor and produces a rich mixture, insuring regular explosions. On heavier loads, however, the increased suction pulls down the diaphragm F, and opens up an annular passage around the outer edge of the auxiliary air valve, allowing additional air to pass through as indicated by the dotted arrows. This arrangement is provided so that with the increased amount of gasolene required at heavy loads, the mixture will not become [illegible].

Like the valve cages, the igniter plugs are held in place with yokes and large studs, which, making them easy to remove. Make-and-break ignition is used and the movable electrode is provided with an outside bearing to support the end of the spindle and reduce the liability to leakage. Near the top of the crank case, in Fig. 1, will be seen attached to the igniter rods two notched cams. By turning these, late ignition for starting may be obtained, and when the engine is up to speed they are turned back for early ignition. Further adjustment of the ignition timing is made by means of right- and left-hand threads on the igniter trip rods.

Starting is accomplished with compressed air by throwing out the valve gear on one cylinder in the usual manner and turning on compressed air for a few revolutions. The feature of the starting mechanism is the air valve through which the air is admitted and exhausted from the cylinder. This, as shown in Fig. 4, consists essentially of a tapered rotary valve or plug cock W, which is fixed on the end of the cam shaft J and rotates with it. The rotating part of the valve is movable endwise on the shaft and, when the engine is in operation, it is held away from its seat by the [illegible] K and a small helical spring, so that no wear takes place. When it is desired to use the

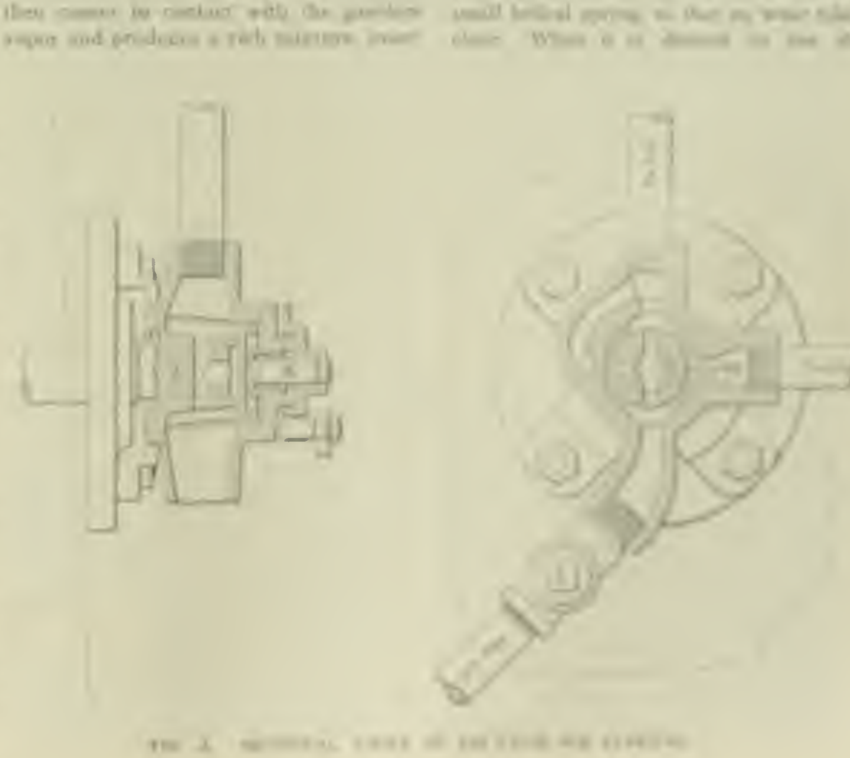

FIG. 4. SECTIONAL VIEW OF AIR VALVE FOR STARTING

valve, the air is turned on by means of an ordinary plug cock L in the supply pipe, the lever of which is connected by an arm with a collar on a beveled seat connecting with the pin K. The action of turning on the air withdraws the pin K, allowing the air pressure to seat the valve tightly, and it then operates as an admission and exhaust valve until the air supply is shut off, which allows the pin to force the valve from its seat again.

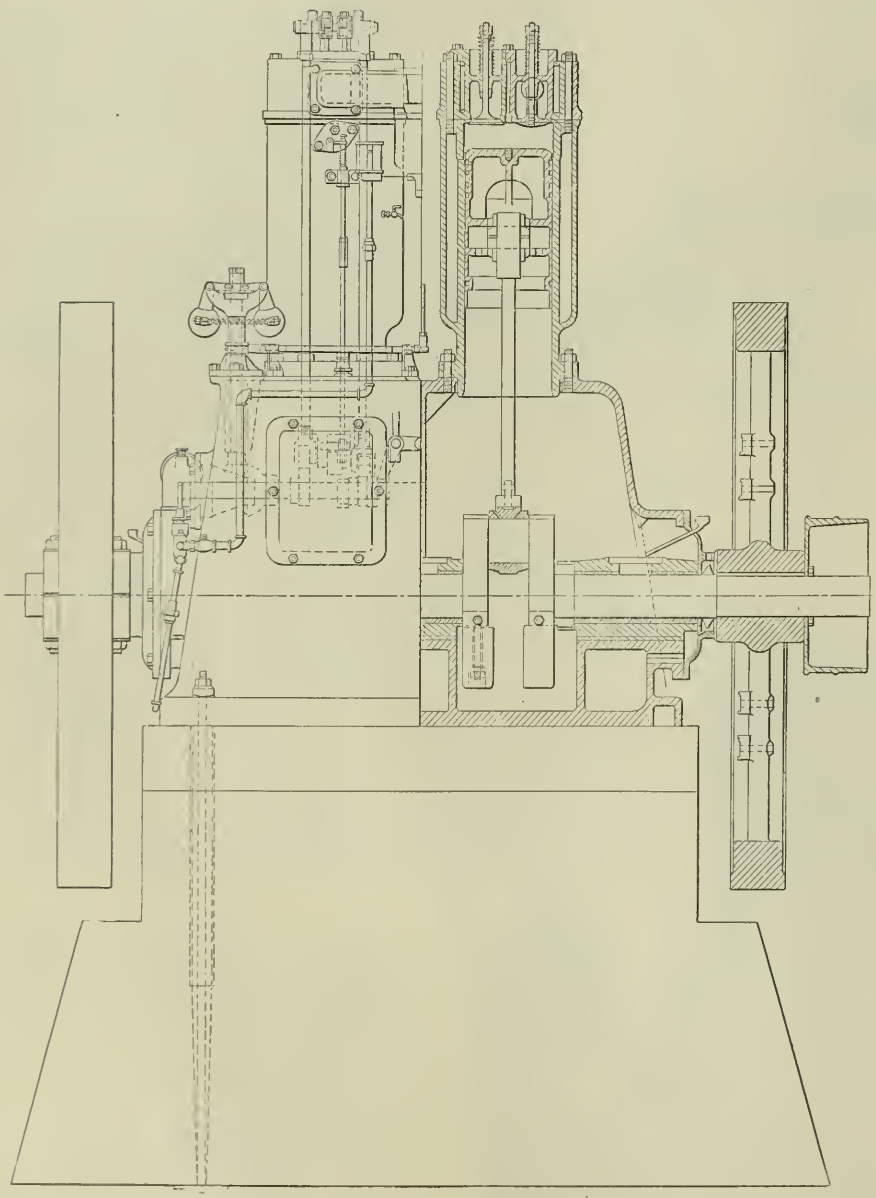

FIG. 5. SECTIONAL VIEW OF INTERNATIONAL HARVESTER COMPANY'S GAS ENGINE

The shaft runs in three babbitted bearings set into the base and resting on flat surfaces, so that they can be easily shimmed up when necessary. Ribbed projections are cast in the crank case so that the dripping oil from the top will run into the main bearings and insure ample lubrication. The upper or wristpin box of the connecting rod is slotted out of the solid forging and has brasses with wedge adjustment. The top of the rod carries an oil pan, draining to the pin, and the lower end of the rod contains oil pockets on each side which collect the oil and carry it to the crank pin.

"Eureka" Belting

The Eureka Fire Hose Manufacturing Company, 13 Barclay street, New York City, has been at work for a number of years perfecting its "Eureka" solid-woven cotton belting, which was recently placed on the market. This belting is intended for both transmission and conveying. It is manufactured on special machinery, owned by the company, the invention of the president, B. L. Stowe.

"Eureka" belting is woven under an immense tension in one solid body and, therefore, has no plies to separate. A natural tendency of the belt in work is to form itself into a coil, adhere to the pulley and make a powerful drive. The texture of the belt allows of the escape of air between the pulley and the belt. It is made treated and untreated. Treated belt will stand moisture and climatic changes, and both styles are so solidly put together that what stretch is necessarily left in the belting is minimized, avoiding the necessity of tighteners and annoying delays in taking up.

Removal of Oil and Grease from Boiler Feed Water

By Arthur E. Krause

Among the many problems with which steam users, managers of power plants, ice manufacturers and others have to contend, and have always been attempting to solve, that of completely removing the oil or grease from condensation water has probably been the most baffling and difficult, particularly that portion of it which is in the finely emulsified state indicated by the cloudy or milky appearance of the water.

This emulsion is caused by the churning of the mixture of condensed steam and lubricating oil in the steam-engine or steam-pump cylinder. It passes out with the exhaust and is found in the hotwell water resulting from the condensation of the steam. Attempts to remove the oil sufficiently to make a safe boiler water by means of separators in the exhaust line have been successful only at so much expense, uncertainty and vigilance that many stations reject the water from surface condensers and purchase city water at enormous costs.

Coarser particles or drops of oil which have not been emulsified or gone into the milky condition can be readily removed by either skimming tanks or coarse filtration through hay, excelsior, turkish toweling, terry cloth, etc. It will be found, however, that no matter how fine the filtering material has been, the milky appearance of the water caused by the oil has not appreciably changed, showing that considerable quantities of oil are still retained and leaving it unfit for ice making, boiler feeding or other purposes where a clear and pure water is the most important consideration. As long as this cloudy appearance remains, the water will be unsafe for boiler feed and will sooner or later be sure to result in serious trouble.

It may also be mentioned that by the use of coagulants and chemicals involving reactions of various kinds, the oil and milky appearance of such water may be removed, but any chemical treatment which necessarily leaves in solution many substances deleterious for ice manufacturing or boiler purposes cannot be recommended nor trusted by careful engineers, owing chiefly to the well known harmful effects of chemicals upon the valves, boiler plates and brass fittings.

In consequence of this, oily condensation water in large quantities in power plants, ice plants and other industrial establishments is now run to waste, which, if the oil were completely removed, would be ideal water for boiler feeding, ice making and many other purposes, and which, if saved, would result in considerable economy, particularly in cities where water rates are high, and on shipboard, where special evaporators must be used to obtain pure water.

In seeking some suitable substance that would clear this condensation water completely, and without chemical treatment with its attendant evils, the writer has discovered among the magnesian products of serpentine quarries a peculiar fibrous sand which is practically insoluble and, by reason of its extraordinary physical property of attracting and retaining the oily matter in condensation water, is eminently fitted and suited to remove the last traces of oil from the latter. Its strong physical property of attracting greasy matter may be judged by the fact that the material will retain or absorb from 50 to 100 per cent. of its own weight of emulsified oil from the water after the coarser oil particles have been removed.

That this method of purifying or freeing water from oil or grease is a purely physical and not a chemical one is shown by the fact that by suitable solvents the oil can be readily removed from the spent fibrous magnesian filtering material, and the oil so obtained may be used over again for lubricating, etc.

The process, which is patented, and which is now being introduced, requires no more care than an ordinary sand filter, needs no expert attendance and is continuous in operation, the only special requirements being a pressure pump of the requisite capacity.

An additional advantage of this process is that by passing through the serpentine fiber or material the effects of the free sulphuric and other acids found in certain streams and brooks throughout the coal regions become neutralized and the water rendered entirely safe and serviceable for boiler use.

I have also discovered that this serpentine waste or fibrous serpentine sand has the property of removing the coloring matter and peaty substances contained in many well and other waters when these are filtered through or otherwise brought in contact with the before-mentioned material.

The apparatus for this process is manufactured by Alexander Miller & Brother, Jersey City, N. J.

A New Pipe Joint Cement

The H. W. Johns-Manville Company, of New York, recently placed on the market what is known as "H.O." pipe joint cement. This cement is put up in powder form and can be kept in stock indefinitely, as it does not dry out or deteriorate, it is claimed. To use the cement it may be mixed with water or linseed oil.

The chemical properties of "H.O." cement are said to be such that it expands after the joint is made up, thereby making a perfectly tight joint. It does not harden and the joint made with it can be easily broken at any time without danger of breaking the fittings. It is not poisonous.

Water Power in Tasmania

Consul Henry D. Baker, of Hobart, Australia, reports that there is considerable agitation at present in Tasmania for governmental aid for the development of the large water power resources of that island. The premier of Tasmania said that the difficulty is to induce capitalists and companies to utilize the power if it were developed. The cost of such works would be hundreds of thousands of pounds (£1 = $4.86). The government only required some guarantee that the power would be utilized if made available, and it would be willing to go ahead in the matter.

At present the only water-power development in Tasmania is at the city of Launceston, where for thirteen years a portion of the water power available in the South Esk river has been used by the municipality for the electric lighting of the city. The power station is about two miles from the city and the machinery comprises four three-phase generators and turbines of 450 horsepower each. In the city there are over thirty miles of streets lighted by electric lamps, and business places and private houses use the electric light largely. Electricity is also used for motors and heating appliances. The municipal council of Launceston has so far spent over [illegible] in construction work.

No state in Australia has such abundant water power as Tasmania, but so far, however, there has been no systematic investigation, either by the government or by private persons, as to the cost of developing most of this power, or as to whether or not the power could be produced in sufficient amount at all seasons of the year and cheaply enough, so that it would pay manufacturers to carry on industries of considerable importance in Tasmania in competition with those of the mainland of Australia.

The centre of Tasmania is mainly 2500 to 3000 feet above sea level. The tributary lakes, though from the northwest discharge most of their contents on the first highlands they meet. In the northwestern part of this plateau there are a number of large lakes, the four principal ones being St. Clair, Echo, Great lake and Lake Sorell. In the northwestern part of this lake country the rainfall is said to average 80 inches, but at the southeastern end only about 35 inches. Any successful power plant, therefore, would probably necessarily be located in the northwestern part of the lake region. It has been roughly estimated that from Lake St. Clair could be produced a minimum of 48,000 horsepower, from Lake Echo 9000 horsepower, and from Great lake 27,000 horsepower, a total of 84,000 actual horsepower. These three lakes are from 2000 to over 3000 feet above sea level, and natural reservoirs.

As it is probable that the power could not be profitably utilized at the different power stations which might be constructed in the lake region, the power would have to be transferred to places where it is required.

In case it should be possible to make Hobart the manufacturing centre of Australia, among other reasons, on account of her facilities in producing inexpensive and reliable power, the 84,000 horsepower at the different power stations in the lake region would be reduced by about 40 per cent. (namely, by converting the mechanical energy into electric force, by friction and loss on line from power stations to Hobart, and by reconverting the electric current into mechanical energy), and the power which could be distributed at Hobart would be, say, 50,000 actual horsepower.

At present but 1000 horsepower is consumed in Hobart for tram service and for lighting, but if it be a true maxim that "supply creates demand," and if inexpensive and plentiful supply of electric force were offered here, the demand would increase; perhaps, under such conditions, Hobart itself might absorb from 5000 to 7000 horsepower, and 40,000 horsepower would be available for large manufacturing industries.—Consular and Trade Reports.

Enlarging a Central Station

The Union central power station, Pittsburg, Penn., is being entirely rebuilt and greatly enlarged to handle the increased load. William Boyle, who has had charge since the plant was first installed, retired February 1, going into business for himself as consulting heating and ventilating engineer, [illegible]

Some Useful Homemade Apparatus

By R. O. Richards

A few months ago I received a letter from the manager of a small plant, under whom I once was employed, requesting me to devote my spare time to aiding his engineer to remodel the steam plant. Besides installing some fuel-saving auxiliaries and simplifyng the piping system, which was in such an intricate state that it could be likened only to a lot of snarled fishing lines, we introduced some novel apparatus and methods of our own.

To distinguish the different steam pipes and valves we had several pipe-covering bands painted various bright colors (a suggestion obtained from Power), and these were secured to the pipes at every turn, in each side of such walls as the pipes penetrated and on each side of every valve. We found, however, that these were distinguishable only in the daytime, the night watchman discovering that all colors looked alike to him. To overcome this obstacle, each valve was given a number, which was painted on a glass tag framed with tin. A card was hung in the engine room, showing the location, color and number of each valve.

A card system for keeping track of all work done was also introduced (another suggestion from Power). Thus, one card would tell how often the pump valves were renewed, another would show how long the rod packing lasted, etc. Then, when the drummer came around, the engineer would show him a record of his wares, and if a disgruntled salesman went to the office and hinted that the engineer must be accepting graft from a competitor, the "old man" knew better, for the records were always accessible.

This plant is situated near the retail section of the town, and we were up against the smoke question. Provided the fireman stoked according to instructions, we feared no smoke inspector, but —well, I guess we have all been up against these conditions. Moreover, we were troubled with lack of draft. A request for stokers was turned down at the office, on the ground that if we could sometimes fire for a whole day without producing smoke, the management failed to see why we could not always fire that way (there is a moral here for firemen). They were, however, willing to have a fan installed, and this gave me a chance to try a certain form of furnace that I often thought would at least be handy, if not economical.

A New Type of Furnace

After seven months' constant use, I am beginning to feel proud of it, and as I have not seen anything similar to it, a short description follows. The reader will bear in mind that this is a small plant consisting of one 72-inch and one 60-inch return-tubular boilers. The plan was to use forced and natural draft at one and the same time. Fig. 1 gives a good idea of it. It will be noticed that two one-brick-width walls divide the ashpit into three parts. The jog in the sidewalls of the furnace is such as to admit of one extra grate bar on each side. The letters *F D* stand for "forced draft" and *N D* for "natural draft."

Green coal is thrown on the grate subject to the forced draft. After coking, it is spread over the natural-draft grate. Barring and spreading is done through the small door *A*. The opening is just large enough to admit the free handling of the bars, and is so constructed as to form a hump to act as fulcrum, thus greatly facilitating the throwing over of the caked coal. Sections through one of the castings forming the bar doors are shown in Fig. 2. With the improved draft and the greater grate surface, the engineer is able to dispense with one boiler and not have to force the one in use unduly. The fireman, believing that the method of stoking produced this result, religiously adhered to instructions. Indeed, he has to, for I have never yet seen a furnace that will stand less monkeying with.

The forced draft is at no time objectionable, having but a slight tendency outward when the furnace doors are opened—just sufficient to prevent the inrush of cold air while coaling. Control of the forced draft is obtained by connecting the balanced throttle valve of the fore engine to the cord of the regulator, the fore engine being made, however, to close ahead of the damper. There are also the usual hand dampers in the ashpit. Fig. 2 shows the manner of clearing the forced-draft grate The bars are raised and lowered by the chains shown and manipulated by a handwheel at the side of the boiler. The necessary extras were made and attached to a common "hoo-hoo" grate by ourselves. The chains are used only while the boiler is being fired, the regular cleaning being done through the large doors in the usual manner.

A phenomenon of this furnace is that when the forced-draft grate is properly coaled, the natural draft exerts itself sufficiently to keep steam up; but when the green coal is caked the forced draft seems to kill the natural draft. This works advantageously, as the fireman is compelled to fire just so, for, unless the

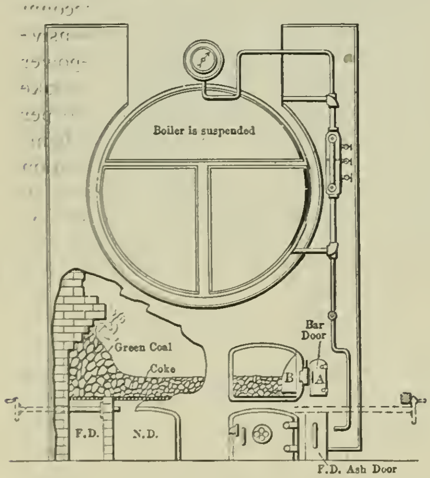

FIG. 1. SPECIAL TYPE OF FURNACE

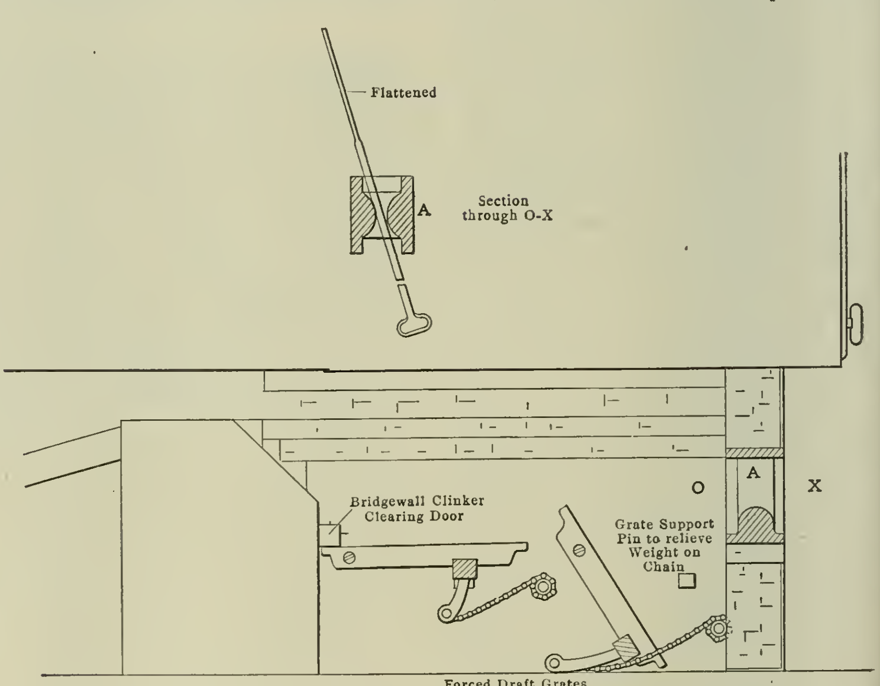

FIG. 2. SHOWING SECTIONS THROUGH CASTING FORMING THE BAR DOOR, ETC.

natural-draft grate is covered with good live smoke-consuming coke, the steam pressure will drop and any attempt to put on green coal (which would produce smoke) is paralyzed by the extra work required to keep the steam up. If, however, the firing is done according to instructions, no difficulty is experienced.

Two tons of coal is burned per ten hours. The evaporation per pound of coal is 8.39 pounds, as against 8.11 pounds previously. The design of the furnace could easily have been improved, but we had to bear in mind that should it not be a success we would have to restore it in a very short time to prevent a shutdown. All that is necessary is to break down the dividing walls in the ash-pit and either natural or forced draft may be used under the whole furnace.

Hydraulic Damper Regulator

The writer believes that the only place left to practice economy is in the boiler room. A great variety of expensive devices are in use to save 2 or 3 per cent., while the fireman has a free hand to waste 10, 15 or even 20 per cent. of the coal pile. Therefore, an engineer is justified in installing anything that will *compel* his fireman to do his duty with due regard to economy. Such devices may be an insult to a good man, but good firemen are rare articles—somehow they quickly climb up to the engine room.

There is provided a cast-iron pit-round plate which makes it necessary to keep the dead plate clear. Fig. 3 shows an hydraulic damper regulator to which is attached the cup *A*. When the piston of the upright hydraulic cylinder rises, water enters the small pipe *B* and flows into the cup, from which it trickles through the pipe *C*. When the damper is wide open and water is automatically shut off from entering the cup, the regulating cock *D* is so set that it takes a certain definite time to empty the cup.

We all know that with the fires in good condition, with no air holes in them, the damper will be continually playing from open to shut, unless the boiler is unduly forced. When, however, they need attention, the damper will remain open and a fireman onto his job will get busy. The careless man will wait until the steam drops 5 or 10 pounds, so that he can put in a greater amount of coal when he does get up. The purpose of the cup and the float is now apparent. If the damper remains open beyond a definite, certain and reasonable time, the cup becomes empty and the nut *E*, pressing on the terminal contacts of the wires shown, causes the ringing of a bell, which will or should bring the wise engineer to the boiler room.

Discretion must be exercised, of course, and every ringing of the bell should not merit a call down; but when it begins to work overtime, don't expect to reach that best evaporation record. Maybe the device has something to do with the success of the furnace described; for the fireman seems very anxious not to have that bell ringing. One thing is certain, it has certainly made a good man of him.

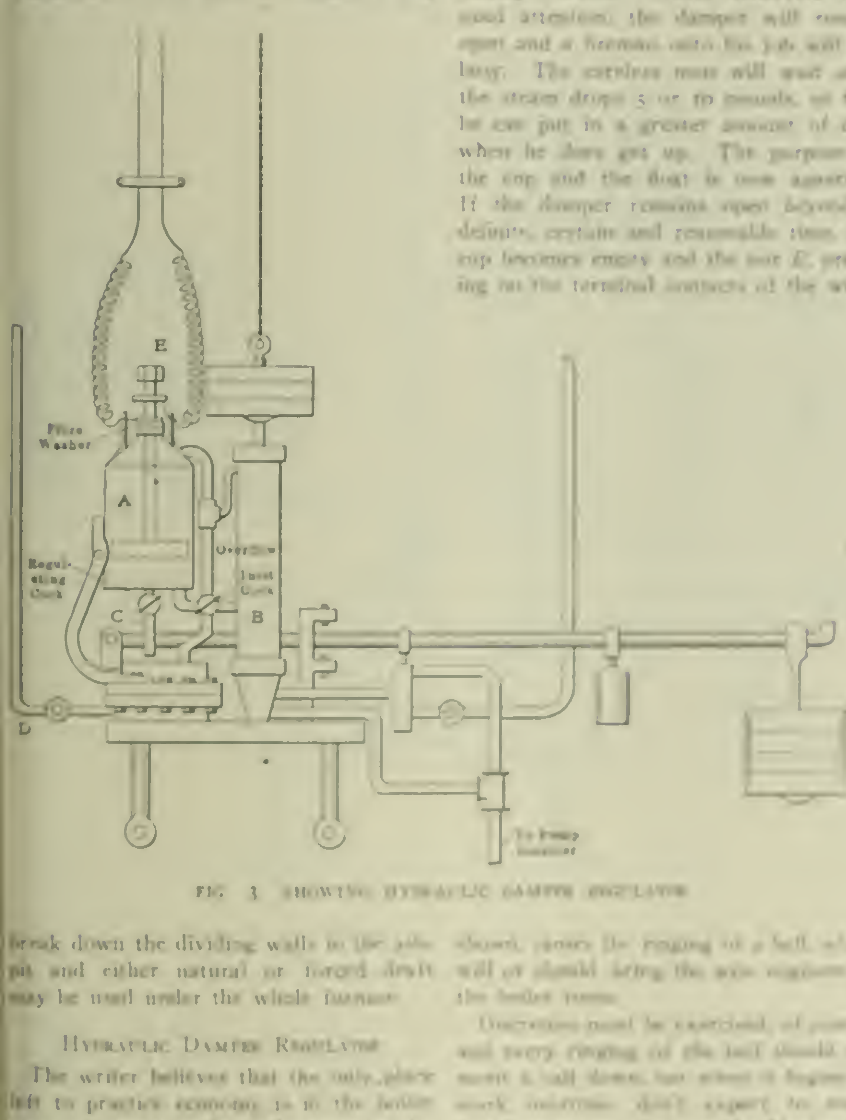

FIG. 3. SHOWING HYDRAULIC DAMPER REGULATOR

A Bypass Telltale

Another telltale as shown of fig. 4 [illegible] for a careless fireman in a small plant is by letting the water in the boiler get too high, necessitating a hasty, often clandestine, jerk on the bypass valve.

From a record kept by the engineer, after we had installed the device shown in Fig. 4, it was found that the bypass valve had been opened four times in twenty-four hours, and at no time had it been opened wide. How much good boiling water went out that way, and how much dirt, there was back of the valve, that could not pass through the limited opening but was gradually working its way under the valve seat, would be difficult to estimate. This device shown (Fig. 4) would tell us (1) how often the bypass valve was opened, (2) if it was opened wide, (3) the time it was opened, (4) if opened with the engineer's permission or without the [illegible] at the time.

The device is extremely simple and can be made. Referring to the sketch, it will be seen that [illegible] the bypass valve [illegible]. This [illegible] the [illegible] of which has been removed. A piece of [illegible] is attached to *F* and to *E*.

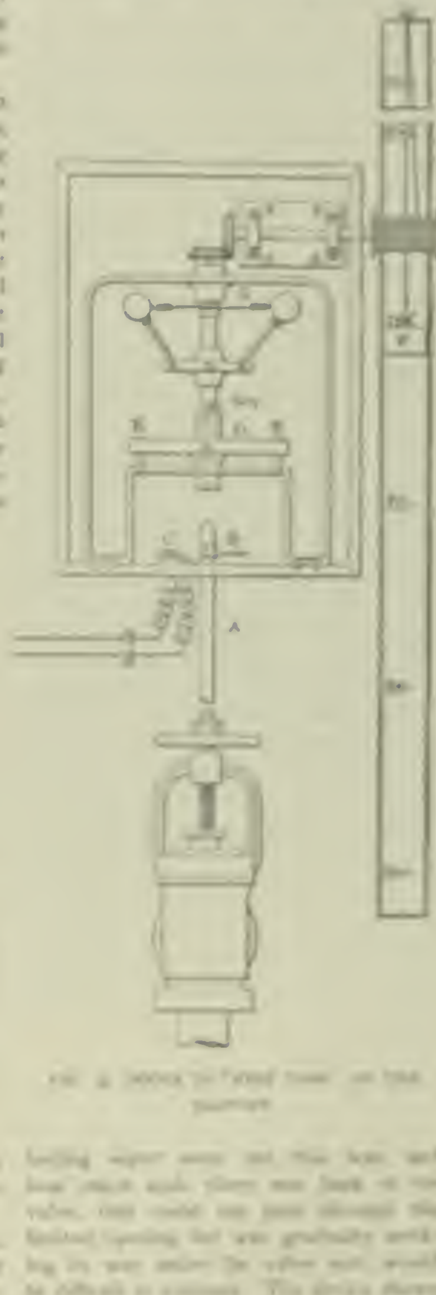

FIG. 4. DEVICE ATTACHED TO [illegible] ON THE BYPASS

is a watchman's pushbutton, which connects with a needle in the magneto clock. It is evident that the blowoff valve cannot be opened even halfway without pushing the button, thus the time the boiler is blown down is read from the paper dial, and the pressure at that particular time is obtained from the recording steam-pressure gage.

Those not possessing a pressure-recording gage may easily fix a needle point to the finger of a small gage in such manner that the projection *B* will cause the needle to punch a strip of paper placed under it. The position of the punch mark will show the pressure at the time the blowoff valve was opened. When the blowoff valve is wide open the extension rod *A* will come in contact with and raise a small casting *D* which is free to slide along the spindle of the governor shown. This will release the stop pins *E* and the weight *F* connected to the governor by the cord-and-miter gears shown and start it revolving.

It is evident that without something to retard the downward moton of the weight *F* the mechanism would have to be wound up daily. So, connecting the governor balls and supporting them, with one turn around the stationary guide, is the stout cord *G*. It was found to work better by putting a light spring on each side in series with the cord. A small tube is provided in the cover of the box to carry a drop of oil once in awhile to this cord. By marking on the long board to the right distances equal to the daily travel of the weight *F*, when, say, a gage of water is blown out, we would very nearly determine the actual quantity of water that left the boiler via the blowoff valve. The weight *F* should be boxed in and the cover locked, for if open the operator is liable to watch the descent of the weight, instead of watching the water in the gage column. These automatic affairs are liable to get out of order.

Apparatus to Control the Power Pump

For boiler feeding we had a duplex steam pump and a belt-driven power pump of the crank and crosshead type. Of these the power pump was preferred, and to control it was built the apparatus shown in Fig. 5, which was installed in a conspicuous but out of the way corner in the boiler room. On the flanges of the base elbows shown are the diaphragms *A*. Resting on the right-hand one on a suitable lever are the weights *B*; on the other rests the stem of the 2½-inch valve *C* on the suction line of the pump. The thread by which this valve is ordinarily operated is removed and the stem neatly bushed, so that it opens and shuts with a sliding motion.

Between the two diaphragms is a solid body of water, so that any movement of one diaphragm causes a corresponding movement in the other. The weights *B* balance a certain hight of water in the apparatus, as shown by the gage glass. When this hight is exceeded, the valve diaphragm *A* is depressed and valve *C* will consequently open. It was found, however, that this was not quite sensitive enough, so the float shown in the cut (and taken from an old steam trap) was added to balance the weight of the valve stem and disk. On top of the receiver will be seen in section a small cylinder, the pistons *D* of which connect by the levers shown to the diaphragm weight lever *B*, so that any fluctuations in the hight (weight) of the water in the receiver will cause a reciprocating movement of the pistons *D*. Between the two pistons a certain water pressure is maintained by the small pipe shown, which connects with a common float tank stationed near the roof. In the position shown this pressure is also maintained in the pipe *E* which, as clearly shown in small sketch, leads into another small cylinder *F*, causing the piston contained therein to shift the belt onto the loose pulley.

In the same manner, when the pistons *D* move upward, the pipe *G* will then be under pressure, and as it connects with the cylinder *G* the belt is shifted to the tight pulley, while the water in cylinder *F* is now free to empty into the receiver. The quantity of feed water is, as in all other pump receivers, governed by the cold-water valve *L*.

Pump controlling, however, is only one of the many uses of this apparatus. For instance, it would immediately tell when one of the steam traps leaked, for then no water would show in the glass, and the weight lever *B* would be up against the stop *H*. Thus it becomes an excellent means of "keeping tabs" on the steam traps. When a trap leaked, the vent was opened, until that trap could be bypassed and fixed. Again, we could tell exactly how much steam any live-steam apparatus in the plant was consuming by weighing the water of condensation as drawn out through the valve *K*; we could get a fair idea of the efficiency of our pipe covering, and the highest water level that could be carried in the boilers and still furnish dry steam. We even have disconnected it and used it to condense the exhaust from the fan engine, air pump and tank pump to find the actual amount of steam consumed by these appurtenances. For this purpose is the spray plate shown. Any back pressure could be maintained in the receiver by shifting the weights *B*, piping a gage at *M* and careful manipulation of the cold-water valve.

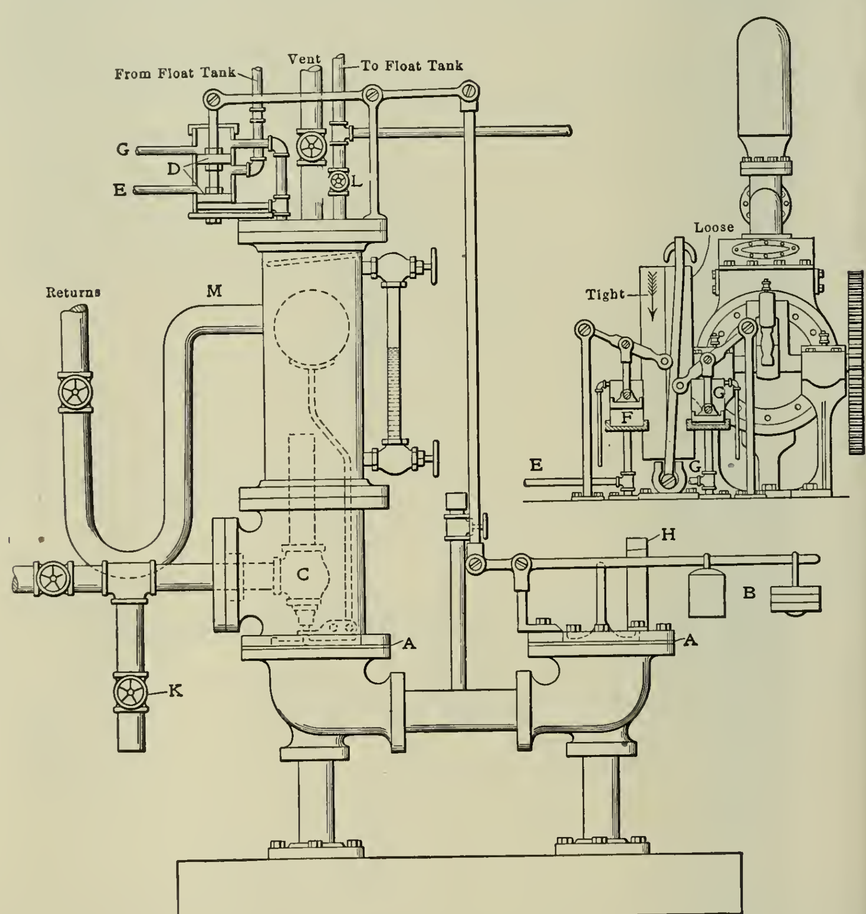

FIG. 5. APPARATUS FOR CONTROL OF THE POWER PUMP

Potblyn, P. D.

By John Watson

"Say! I believe she put him up to it, don't you?" I had been so deep in a series of calculations that I had not heard my office door open, and the above query was the first intimation that I had of the "Doc's" presence. I swung around in my chair, put down my slide rule and pushed back my papers, as an indication that I was a willing listener.

The "Doc" had just returned from a trip South and I was anxious to hear about the results of his surgery. I knew that he had performed a successful operation, for the smile on his face was that kind of a smile. He had three kinds of smile and I had learned to recognize them. When he was contented with himself, the world in general and yesterday's baseball scores, he wore one kind of a smile and was a very agreeable sort of a chap. If things were going sort of crosswise, he grumbled and swore a lot in a half good-natured sort of way. If he thought that a man had not used him right, and he was "mad" clear through, he also smiled, but it was a still different sort of smile, and at such times it was well to let him alone. The gage indicated fair weather this time, so I settled back in my chair to listen to his tale. Of course it was some time before we reached the point, for the "Doc" had first to discuss the news of the day and a prizefight or a murder case was even more interesting to him than the baseball scores. The recent murder in New York, where a girl was held as accomplice of the man on trial, held the floor until we had clearly proved her to be guilty and then we could take up the pump problem.

"Well, 'Doc,' what was the matter with it anyway? Was it the suction pipe this time?"

"Doc" grinned at the reference to his hobby, for it was well known that just as some M.D.'s always diagnose any kind of a stomachache as appendicitis, especially if the patient has money, so Potblyn, P.D., usually started out on a case with the firm conviction that the suction pipe leaked. It was astonishing the number of cases that he had operated on for leaky suction pipe and effected permanent cures.

"Naw! It wasn't the suction pipe this time, but the darned thing leaked, though, and needed fixing just the same."

Having got a fair start the "Doc" proceeded to tell his story about as follows:

"Say! Of all the complications of diseases you ever heard of, this pump had 'em all a-goin', and had me a-goin' for a while, too. You remember the trouble, don't you? Old 'Whiskers' wrote you all about it. Say! You don't know old 'Whiskers' do you, except by his letters? You ought to see him—made of odds and ends and got the 'Yaller Kid' and 'Happy Hooligan' beat for first money. Gee! but I had to laugh when I saw him. Didn't look as if he knew enough to pound sand into a rat hole. Well he took me out back into the woods where the pumps are located. There's got two little compound duplex direct-actin' pumps, just alike. One ran slick as grease; you couldn't ask for anything better. The other feller, right side of it and just like it, was knocking to beat the New York Sun.

"Opportunity knocks but once, but this darn thing had opportunity left at the post, for it was knockin' seventy-five to eighty times a minute right along. Old 'Whiskers' was discouraged and felt like doing a little knockin' on his own hook. First look out the corner of my eye, I seen they had separate suction pipes—and I put on my 'Gosh! this is easy' kind of a smile; but, say that wouldn't do for 'Quaker Oats,' for it came off—way off—before I got the blamed thing fixed.

"I let 'er run awhile and I loafed around the engine and boiler room rubber-neckin' the place and lookin' wise. I finally saw the old goat was gettin' nervous because I didn't do something, so I got into my warpaint and started to imitate a man getting busy. I shut her down and looked over the water end. The valves were in pretty good shape; I guess you wrote him to make sure that they were all right. Then I traced out the suction pipe; lucky there wasn't as much of it buried as there was on that job up in Massachusetts. I found several leaks but they were small ones and didn't amount to much.

"Next, I tried the air chamber and found it solid full of water. No wonder she pounded. I put on an air-chargin' rig and a glass gage and thought that I had things all fixed and my job done. We started up again and got the air chamber full of air, and about then your uncle began to get interested in the game, but while the heavy pound had disappeared there was still a decidedly hard knock that seemed to be in the steam end.

"I knew that the water end was all right, so I shut 'er down and as soon as she had cooled off a bit I opened up the steam end. It seemed to be the left-hand side that was 'bumpin'' so I opened up the right-hand side first, just to be sure not to miss anything, as I wanted to make a complete job of it this time. I looked over both the high- and low-pressure pistons and found them all right. Then I opened up the left-hand side and found the low-pressure piston loose on the rod. 'Eureka!' says I, and I called 'Whiskers' over to show him where the trouble was. He was so pleased to have found the trouble that he gave me a treat. 'Say! I was as badly fooled on that cigar as I was on the pump. He handed it out to me with the regulation two-for-a-quarter wave, instead of shovin' it at me like a three-for-five.

"I fixed the piston, closed the cylinder and told the engineer to start up. I was through. I lit my cigar and started to get my overalls off. Bill! an uppercut right in the jaw. I felt as if I had got one when that pump started out just the same as ever—bang, bang, every stroke; gosh, it was enough to make a perfect little saint swear. Two operations and no cure. 'Whiskers' probably wished he had kept his cigar; so did I, for by this time I was looking for a chance to lose it.

"It was getting late, so we concluded to wait until mornin' before investigating further. Let me tell you the time was when I would have lost sleep a long time worrying over a job like that, but I'm too old for that now and besides, I had a card or two up my sleeve to play in the mornin' when the game opened. I can't say much for the hotel in that measly town. The soap in my room wasn't worth luggin' away. The darnedest lot of loafers around there; they think 'Fire' is all [illegible] and hasn't got any light left to lose. What's the use of talkin' to fellers like that?' I couldn't convince them of nothin'.

"Old 'Whiskers' was on deck bright and early in the mornin'—darn these country hotels anyway—and we went back on the job. I had concluded that there was too much power somewhere that made her hit the heads and first off I had a look for the old enemy, cross-talkin'. 'Nothin' doin'.' Then I opened up the steam chests and had a look. Once more I smiled but this time I kept quiet; I didn't want any more cigars. Say! I wish I'd brought you one of those just for luck.

"Well, there was the left-hand high-pressure valve cocked up well over one side [illegible] on the guide so that that side was three-eighths to one-half an inch off the face and the steam had a chance to blow right through into the low-pressure chest. That side was takin' high pressure while the other side was running compound. No wonder the piston did get loose [illegible] the rolling [illegible].

"I slipped the valve back into place, closed her up again and started off once more. By [illegible] if she didn't still knock [illegible] as ever [illegible] the knock was still there, [illegible]. Up to this time I had been sort of [illegible] lookin' for the usual things in the usual places and applyin' the usual remedies. Things were beginnin' to look suspicious and I didn't just know what to look for next.

"I opened up the whole steam end and looked it over carefully. Then I had the engineer run the pump while the heads and covers were off and I watched the pistons and valves, one at a time, to see that they were all right and fitted throughout the full stroke. In this way I discovered that the same old high-pressure valve cocked up on one end and allowed steam to blow through. Looking for the cause I found that the valve rod was bent between the high- and low-pressure chests. Evidently somebody had dropped a carload of freight on to it but, of course, they wouldn't investigate to see if a little thing like that had damaged the pump in any way.

"Well, I took out the valve rod, straightened it, made sure that the valve seated properly and then closed her up and started again. Knocked out in the fourth round—I had got her fixed for keeps this time and she ran as smooth and slick as could be. I tell you I felt somewhat relieved, for, after the way things had been goin' I didn't know what might show up next.

"Pumps are as bad as kids. When they get cantankerous it is safe to expect most anything and some pumps, like some kids, seem to ketch everything there is goin', and no reason for it, either. Old 'Whiskers' was pretty well pleased and thought I was quite a fellar. I guess he will get along all right, now, without any more trouble, but say, you fellars ought to put gage glasses on all of your air chambers.

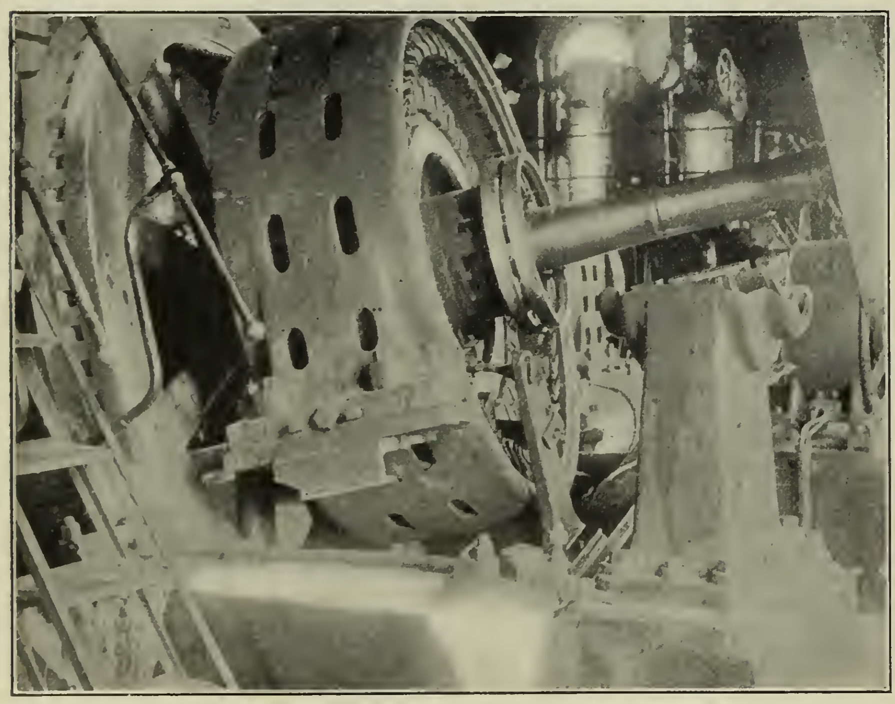
"What good is an air chamber full of water? They'll fill up sure as preachin' and how is a man goin' to know how they stand unless you put a gage on? What's the use of being a tightwad? Loosen up a little, give a fellar something for his money and when you send out an air chamber send a gage glass with it."

With this parting advice the "Doc" departed for the shop. I had hardly turned to my work again when he opened the door, just enough to stick his head through, and remarked.

"Say! I wish you could see 'Whiskers,' he's a peach."

Broken Shaft Wrecked Engine and Generator

The accompanying illustration depicts the wreck due to the breaking of the main shaft of a 440-ampere generator at its center bearing. It will be seen that the frame supporting the generator field is broken, also that the top of the outer pillar block was wrenched in pieces. The real cause of the accident is not known, but it is supposed to have been due to a flaw in the shaft. No one was hurt, but the engine was entirely wrecked and almost a total loss.



WRECK DUE TO BREAKING OF SHAFT

Boiler Specifications

We design a large number of horizontal tubular boilers for our assured and patrons, giving them the benefit of the wide experience of our steam-engineering experts. These specifications are, of course, unprejudiced, and the boilers designed by us can be readily built by any modern shop. We have not, for several years, designed a boiler using a lap-joint, double-riveted, horizontal seam. We have been fully aware of its inherent weakness. We have had no difficulty whatever in convincing our patrons of the superiority of the butt joint as against the lap joint. Some recent disastrous explosions due to the lap-joint type of boiler indicate that our view is sound.

In the standard butt joint, the net section of the plate between the rivet holes is the weakest part, although this runs theoretically from 84 to 94 per cent. of the solid plate. In practice, however, with ordinary punched rivet holes, due allowance should be made for the injurious effect of the punch on the plate, and this is an unknown quantity. All authorities agree that the metal is injured, but differ as to the extent. Various experiments show, however, that the injury increases with the thickness of the metal.

If the rivet holes be drilled full size in flat plate, we would have the usual bend strain between the rivet holes when the plate was being rolled up. On the other hand, if the rivet holes in plates ½ inch and under are punched ¼ inch below size, we have more metal to resist the bend when rolling. Bearing this in mind, together with the injury done by punching, we have adopted the rule of calling for all rivet holes to be punched ¼ inch below size, then the plate to be rolled up, assembled and the holes reamed out to full size, thus removing the evil effects of the punching and having the rivet holes in perfect alinement. The reaming of the holes is today done with pneumatic tools, and is a simple, cheap and rapid operation. This change has received the approval of several authorities and commends itself to every thoughtful engineer as far better than the common practice of reaming the hole 1/16 or ⅛ inch.

In this connection it is well to note the increase in sizes of horizontal tubular boilers. A few years ago a 60-inch shell was called a large boiler, while today the larger per cent. of the boilers being installed are 72 inches by 16 to 18 feet in length, practically doubling in capacity the 60-inch size. It is also true that the evaporation per square foot of heating surface has been increased, when soft coal is used, by artificial drafts, mechanical stokers, etc. With the heavier plate used in the large sizes of shells, greater care must be observed in keeping the boiler free from scale, grease and deposits of sediment, and all appliances must be in the best of order.—Fidelity and Casualty Company's *Bulletin.*

Personal

Harry J. Marks, formerly mechanical engineer of the Empire State Engineering Company, has become associated with Edward P. Hampson, 170 Broadway, New York City, in a general engineering business, including the handling of a line of engines and boilers and making a specialty of the American Ball angle-compounds.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer.

Safe Speed for Cast-iron Flywheels

I have an engine running at 250 revolutions per minute and I should like to know if it is safe to increase the speed to 300 revolutions, the flywheel being 78 inches in diameter?

W. A. L.

With cast-iron flywheels a rim speed of 90 feet per second should not be exceeded. At 300 revolutions per minute the rim speed of a 78-inch wheel would be more than 102 feet per second and manifestly unsafe. A cast-iron wheel running at 300 revolutions per minute should not be more than 66 inches in diameter.

Windings for Choke Coils

Is there a simple rule for determining the winding for a "choke" or reactance coil?

A. P. K.

Two rules are necessary, one for the size of wire and the other for the number of turns in the coil. To ascertain the size of wire, multiply the current to be carried by 1500; the result will be the cross-section of the wire in circular mils. To ascertain the number of turns required, multiply the desired counterelectromotive force by 13, for 60-cycle current, or by 9 for 125-cycle current, and divide the result by the cross-sectional area of the core measured in square inches.

EXAMPLE: A core having 1 square inch cross-sectional area is to be wound for a counterelectromotive force of 40 volts, at 60 cycles frequency, and the wire must be large enough to carry 10 amperes without overheating.

To carry 10 amperes, the cross-section of the wire must be not less than

$$10 \times 1500 = 15,000$$

circular mils. No. 8 is the nearest commercial size, its cross-section being 16,510 circular mils. To give an electromotive force of 40 volts, at 60 cycles, the number of turns must be not less than

$$\frac{13 \times 40}{1} = 520.$$

The disposition of these 520 turns will depend on the length of the available coil space along the core; the coil should occupy the full length of the space, leaving its thickness to come as it may.

Large Engines, Steam and Gas

Please tell me the rated horsepower and dimensions of the George H. Corliss engine used by the Pullman Car Company, Pullman, Ill. Also, what is the largest single unit in the world, steam or gas, used for the generation of power?

F. J. E.

The horsepower of the Corliss engine at the Pullman works is [illegible]; the steam pressure 30 pounds and the revolutions per minute, 36. The dimensions are: Cylinder diameter, 40 feet; stroke, 10 feet; piston rod, 6¼ inches in diameter; connecting rod, 25 feet long; bearings, [illegible] inches; walking beam (cast), 25 feet long; flywheel, 56 tons, 29.7 feet in diameter, 24-inch face, 216 teeth with 5¼-inch pitch. The largest stationary steam engine or power generator is the Manhattan engine. The largest steam turbines are those in the Commonwealth Edison Company's station in Chicago. They are rated at 14,000 kilowatts maximum continuous load. The largest gas engines for power purposes are the engines built by the Snow Steam Pump Company for the California Gas and Power Company. The cylinders are 42x60 and the engine runs at 88 revolutions per minute. A larger cylinder is 44x54 inches, but it does not deliver as much power as the Snow engine, as the revolutions per minute are 83⅓ and the gas used is of much lower heat value.

It is understood that there is a gas cylinder 52x55, single-acting, developing 700 brake horsepower at 90 revolutions per minute with furnace gas, but this unit is in Germany. The largest engine known in this country is a 25,000-horsepower rolling-mill engine at South Sharon, Penn., at the Carnegie Steel Company's plant. The frames and slides are cast in one piece and weigh 118 tons. The total engine weighs 330 tons. This is a horizontal twin tandem rolling-mill engine, with cylinders 42 and 70 by 54, to operate with 175 pounds of steam, condensing, at from 150 to 200 revolutions per minute, developing its maximum power at the highest number of revolutions.

Book Reviews

MECHANICAL WORLD ELECTRICAL POCKET BOOK. Published by Emmott & Co., Ltd., Manchester, Eng. Cloth, 278 pages, 4x6 inches; illustrated; many tables. Price, 8 pence, postpaid.

The 1909 edition is considerably more comprehensive than the previous one. The topical scope now includes [illegible], rotary converters, motor generators, [illegible], balancers, boosters and electric [illegible]. The discussions, however, are brief [illegible] the verge of perfunctory [illegible].

MECHANICAL WORLD POCKET DIARY AND YEAR BOOK. Published by Emmott & Co., Ltd., Manchester, Eng. Cloth, 350 pages, 4x6 inches; 61 illustrations; many tables. Price, 8 pence, postpaid.

This is the twenty-second annual edition of this useful little manual, and it shows the effects of revision notwithstanding its long life. The discussion of friction clutches has been made more comprehensive; the steam-turbine section has been extended to keep abreast of recent developments, and a section devoted to [illegible] drive has been added. The section devoted to gas power remains inadequate, as before.

THE TEMPERATURE-ENTROPY DIAGRAM. By Charles W. Berry. Published by John Wiley & Sons, New York, 1908. Cloth; 393 pages, 5x7½ inches; 109 illustrations. Price, $2.

This is the second edition of Professor Berry's excellent work, and a mere comparison of bulk would suffice to indicate extensive revision, as the present edition [illegible] more than twice the number of pages in the first edition. The chapter on the flow of fluids has been thoroughly revised; a graphical method of passing from the pressure-volume plane to the temperature-entropy plane for perfect gases has been worked out and its application illustrated in two chapters on hot-air and gas engines; a chapter on the thermodynamics of gas and vapor mixtures has been added, and the various factors affecting the efficiency of actual gas-engine and steam-engine cylinders are discussed. For the information of those unfamiliar with the first edition it may be stated that the work is mainly mathematical in character; the discussions are, however, correspondingly accurate and complete.

NOTES ON MECHANICAL DRAWING. Victor T. Wilson and Charles L. McMaster. Second edition. Published by Wilson & McMaster, Lansing, Mich. Cloth, 190 pages, 8x6 inches; illustrated.

Students of engineering, whether at school or engaged in home study, will find in this book nearly if not all the instructions needed by one who desires clear, intelligent and concise instructions in the elements of mechanical drawing. Exercises as such for the purpose of training the hand and eye in the use of drawing instruments have been reduced to the smallest possible number, and practical problems substituted. Minute directions for every operation in the process of mechanical drawing are given in the belief that these, if followed by the student, will give a ready grasp of the subject. Differing from the ordinary methods of textbooks on this subject, lettering is made the subject of the first chapter, which is followed by chapters on projection, straight-line drawing, curves, sections, geometrical drawing, working drawings, [illegible] sketching and miscellaneous instructions. The [illegible] being [illegible] the work is [illegible].

Books Received

"[illegible] Tables." By [illegible]. [illegible]. Cloth; [illegible] pages, [illegible] inches.

"[illegible] Lectures on Electrical Engineering." By [illegible]. [illegible] & [illegible]. Cloth; [illegible] pages, [illegible] inches; illustrated; indexed. Price, $2.

Silk City Council Entertains

Silk City Council No. 18, Universal Craftsmen, Council of Engineers, of Paterson, N. J., held its first annual entertainment and reception at Turn hall, Paterson, on Friday evening, February 12. The engineering craft was largely represented, as well as the various Masonic lodges, there being many visitors from nearby cities. The first part of the evening was devoted to the rendition of an enjoyable entertainment, following which Past Worthy Chiefs William Brameld, F. W. Johnson and Edward Livingstone were presented handsome jewels. The grand march then took place, and dancing was enjoyed until the early morning.

The committee in charge of the arrangements comprised Edmund Whittaker, R. Templeton, E. B. Lupton, F. W. Johnson, Edward Livingstone, George Robinson, B. Chandler, C. Van Gieson, D. McHenry, R. McCullough, C. McLean, W. McDonald, J. McCullough, A. Thomas, F. W. Johnson, William Patrick, Andrew Young, M. Zocklein and Alexander Young. Robert J. Hanna was stage director. It was an especially enjoyable occasion.

Stevens Institute Alumni Dinner

The alumni of the Stevens Institute of Technology had their annual dinner on Friday, February 19, at the Hotel Astor, Broadway and Forty-fourth street, New York. There was an attendance of about 350, and great enthusiasm prevailed. The toastmaster was Henry Torrance, Jr., of the class of '90, and the speakers were President Alexander C. Humphreys, of Stevens Institute, who spoke about the institute; Alfred Noble, past-president of the American Society of Civil Engineers, and a former member of the Panama canal commission, who advocated the lock system for that great enterprise and gave an authoritative review of the whole project; Col. H. G. Prout, vice-president of the Union Switch and Signal Company, who spoke of the ethical and ideal aspects of engineering; John A. Bensel, commissioner of the Board of Water Supply of New York City, whose subject was New York's water supply; and Col. George Harvey, who wittily commented on the remarks of the preceding speakers, and in more serious vein referred to the engineering features of the Panama canal.

Business Items

The Boston branch of Charles A. Schieren Company is now located at 641 and 643 Atlantic avenue, opposite the South station. There they have a floor space of about 5500 square feet with one of the best-appointed leather stores and belting shops in Boston.

George W. Hoffman, Indianapolis, Ind., manufacturer of the United States metal polish, reports a rapidly increasing business since the first of the year. This polish has been improved and Mr. Hoffman aims to keep it the best on the market for all classes of bright work around a power plant. A free sample will be galdly sent to any engineer upon application.

A directory of engineers and power plants of Greater New York for 1908 and 1909 has just been issued by the Engineering Directory Company, 100 Nassau street, New York City. An alphabetical list of plants is given, together with their capacity and names of engineers-in-charge; also, an alphabetical list of licensed engineers in Greater New York. The price of this directory is $10.

A new style of hot-blast heater coil, distinguished by a positive flow of steam, water of condensation and air in the natural direction due to gravity, and suitable for use with live and exhaust steam and also with water for heating or cooling purposes, was recently placed on the market by the Green Fuel Economizer Company, of Matteawan, N. Y. They advise us that they have made recent sales of this apparatus to 25 well-known concerns.

The Wm. B. Scaife & Sons Company, of Pittsburg, Penn., manufacturer of the "We-Fu-Go" and Scaife water-softening, purifying and filtering systems, has found it necessary to build an addition to the present plant at Oakmont, Penn., to accommodate the increased business in the building of systems for the purification of water for steam boilers, industrial and domestic uses, and is about to begin the erection of a shop 40 feet wide by 200 feet long, equipped with the latest improved machinery, which will be used in addition to the present shops for manufacturing the "We-Fu-Go" and Scaife systems. They have under construction at the present time for steam-boiler plants systems aggregating 95,000-horsepower, in addition to plants for softening and clarifying water to be used in manufacturing processes, such as dyeing and bleaching in woolen and cotton mills, and for washing in laundries; also a number of mechanical gravity filter systems for manufacturing and domestic use.

A shipment of unusual note was recently made to the Isthmian Canal Commission. Colon, Isthmus of Panama, consisting of seven 2½ kilowatt generator sets, built to meet the requirements of the I. C. C. Circular No. 472, Class 3, which called for them to be "built for high speed, self-oiling and automatically governed, and to be able to control, and also strong enough to withstand a change from no load to full load, to be of sufficient capacity to drive the 2½-kilowatt dynamo at the proper speed when under full load and with initial pressure of 60 pounds per square inch," etc. The Fort Wayne Electric Works, of Fort Wayne, Ind., which was awarded the contract furnished and shipped to the American Blower Company's Detroit plant, seven Type M. L. Frame D, 110-volt generators for mounting upon the extended subbases of seven 3¼x3 ABC vertical inclosed self-oiling Type A engines. The combined sets were tested and inspected by a Government inspector and readily approved.

New Equipment

City of Newton, Ala., voted to issue $8000 bonds for water works.

T. H. Marsden, Brady, Tex., will establish an ice plant and cotton gin.

The Torrington (Conn.) Electric Light Company will enlarge its power house.

The Board of Trade, Spencer, N. C., is considering erection of electric-light and power plant.

The Union (Ia.) Electric Light Company contemplates the construction of an electric plant.

Plans have been completed for the construction of the municipal electric-light plant at Bergen, N. J.

W. A. Potter, Mizpah, Minn., has been granted franchise to construct and operate an electric-light plant.

The Bluestone Traction Company, Bluefield, W. Va., will install additional equipment in power plant.

The city of Brewton, Ala., contemplates the installation of engine and dynamo in the light and water plant.

The city of Franklin, N. C., will vote on issuance of $30,000 bonds for water works and other improvements.

The output of the municipal electric-light plant at Anderson, Ind., is to be increased. About $20,000 will be expended.

The Tryon (N. C.) Hosiery Company contemplates enlarging mill and will need new equipment, including boilers, engines, etc.

The Rockford (Tenn.) Cotton Mills, whose electric plant was recently destroyed by fire, is making arrangements to rebuild same,

The Hobart (Okla.) Water Power Company recently incorporated, is said to be planning to construct a hydroelectric plant. C. T. Blake is president.

Plans for installing a motor for pumping water in the municipal electric-light and water plant at Rockport, Mo., are under consideration. W. E. German is manager.

Plans are being prepared for a new factory for L. Adler Bros. Company, Rochester, N. Y. Equipment of plant will include four boilers, automatic engines, generators, motors, blowers, etc.

The Alabama Railway and Power Company is planning to start work on the proposed electric railway between Birmingham and Chattanooga. J. H. Hill, Fort Payne, Ala., is vice-president.

It is reported that the New York Edison Company will soon commence the construction of a central power station in the upper part of the city. Plant will have an output of about 20,000 horsepower.

Bids will be received until March 1 for the construction of a municipal electric-power plant in Lethridge, Alb., Can. George W. Robinson is secretary and treasurer. Smith, Kerry & Chace, Toronto, consulting engineers.

The Williamson Cold Storage Company, Williamson, N. Y., has been incorporated with $75,000 capital to conduct a cold storage, refrigeration and ice-making business. Incorporators, W. B. Freer, W. P. Rogers, K. M. Davies.

Plant in Public Service Building, Milwaukee

A Large Noncondensing Turbine Plant Operating against 22 Pounds Absolute Back Pressure to Furnish Exhaust Steam for District Heating

BY OSBORN MONNETT

It is not often that a noncondensing turbo-generator plant of 4500 kilowatts capacity is designed to operate against a back pressure of seven pounds gage, or 22 pounds absolute. There is such a plant in operation in Milwaukee, and aside from the unusual fact that it is a simple noncondensing plant, there are operating features and conditions under which it was installed which make it of more than ordinary interest. Whenever possible, it is customary to locate a plant where the operating conditions will be most favorable; nevertheless, the engineer must, when necessity arises, be ready to design an installation and operate it when conditions are just the reverse. In the plant under consideration it would hardly have been possible to impose a more formidable array of adverse conditions, and the solution of the various problems are especially interesting from an engineering standpoint.

The plant was installed by the Milwaukee Electric Railway and Light Company and occupies the basement of the Public Service building in the heart of the business district of the city. This building is used as a terminal and waiting room for the various interurban street railway systems and for the general offices of the company. After the building was nearly completed the company undertook a contract to furnish exhaust steam to

FIG. 1. THE TURBINE ROOM, MILWAUKEE PUBLIC SERVICE BUILDING

the Milwaukee Central Heating Company for its American district steam-heating system, and it became necessary to arrange for a plentiful supply of exhaust steam. It was not desired to rely entirely upon either the Oneida or Commerce street stations to supply the [illegible] and in any case it would have been necessary to install additional noncondensing equipment in these stations or to limit the capacity [illegible] of the [illegible] stations [illegible] ing. So the extra generating capacity, instead of being divided up between the existing stations, was concentrated in an independent plant, the peak electrical load of which would come on simultaneously with the peak heating load.

Ordinarily it would not appear advisable to tie up such a heavy investment in noncondensing machinery, which would of necessity be idle for several months in the year, and which could be relied on in emergency during this idle period only at a great sacrifice of economy. However, in every lighting system there is a considerable part of the generating capacity which [illegible] but which is necessary to meet the peak load of short duration in the winter. The [illegible] of peak load generating capacity for the [illegible] lighting system [illegible] mind it can be seen that the existence of the plant is justified.

As the building was about completed before commencing to install any of the equipment, the machinery had to be lowered into the basement at the rear, literally through "a hole in the sidewalk," conveyed a distance of some 200 feet and erected under limited head room without cranes or other conveniences. The installation is a simple, noncondensing steam plant consisting of boilers, heaters,

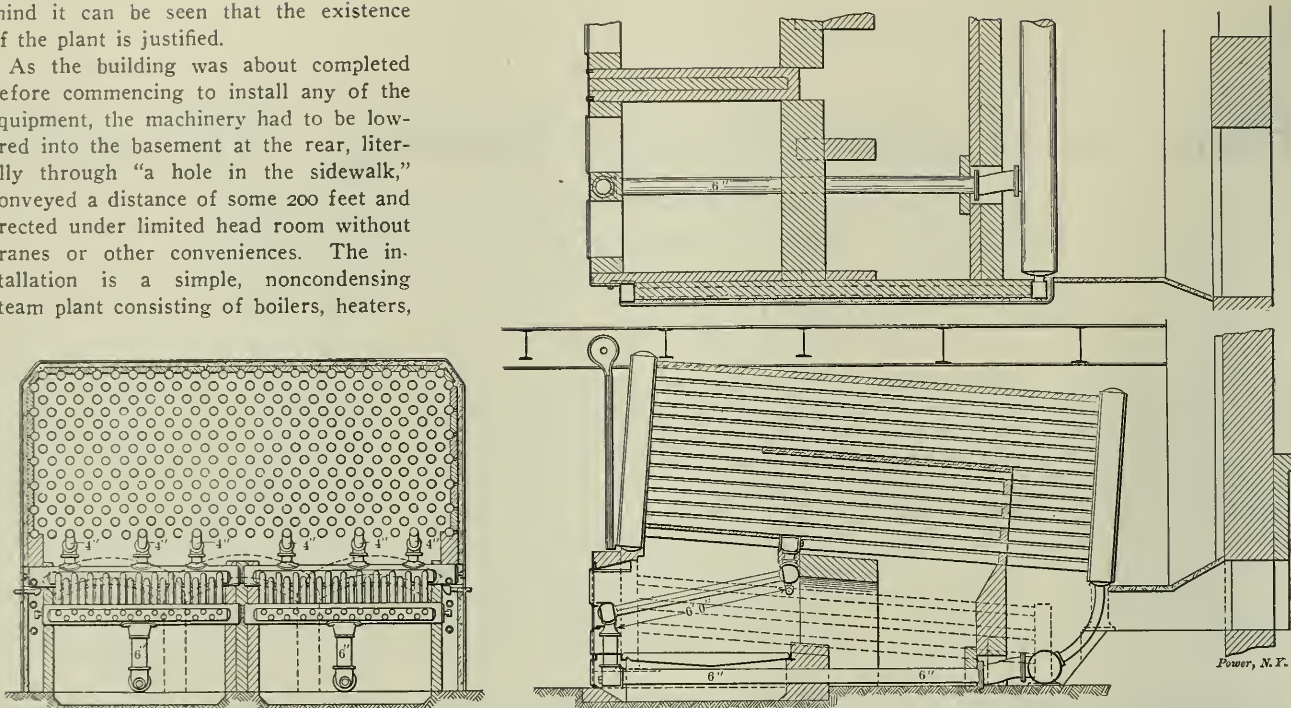


FIG. 2. ARRANGEMENT OF BOILER SETTING

feed pumps, generating units and the switchboard. Absence of the usual amount of auxiliary machinery in a plant of this size is marked, what there is of this pertaining more to the building as an office building than to the generating plant.

Steam Generating Equipment

For generating steam there are installed ten Edge Moor water-tube boilers of the drumless type, each rated at 400 horsepower on a basis of 10 square feet of heating surface per horsepower when neglecting 1500 square feet of superheating surface in the tubes above the water line. They occupy the southern side of the basement, as shown in Fig. 4, so that the space under the sidewalk becomes convenient for the storage of coal, a capacity of approximately 2000 tons being available. Youghiogheny screenings, which is the fuel used, are brought to the plant by wagons, dumped into the storage bin and fed to the furnaces by hand, and a motor-driven ash hoist elevates the ashes to the street level and loads them into wagons.

The columns of the building are supported on pedestals which spread out over a considerable area below datum and rest on piles, and owing to the slope of the foundations only a limited amount of excavating was permissible, this being done at the expense of the floor space. For this reason a head room of only 11 feet 10 inches could be obtained between the boiler-room floor and the I-beams of the ceiling. By arranging the highest points of the boilers to come between the I-beams, as shown in the elevation, the equipment was installed.

With the exception of having no steam drums, the boilers are of the standard Edge Moor construction. The handhole plates are made up with lead gaskets below the water line and with asbestos gaskets above, as superheat of some 30 to 50 degrees is obtained in the upper tubes. The mud drums slope forward from the rear header to conform with the limited floor space and are fitted on each end with two 2-inch Chapman gate valves in series. Squires feed-water regulators are used, and there is a feed valve on each side of the boiler, the feed entering each end of the mud drum.

One of the features of the boiler setting is an arrangement whereby some of the heat ordinarily radiated from the side walls is saved. This arrangement consists of a water leg, extending downward

FIG. 3. VIEW IN BOILER ROOM

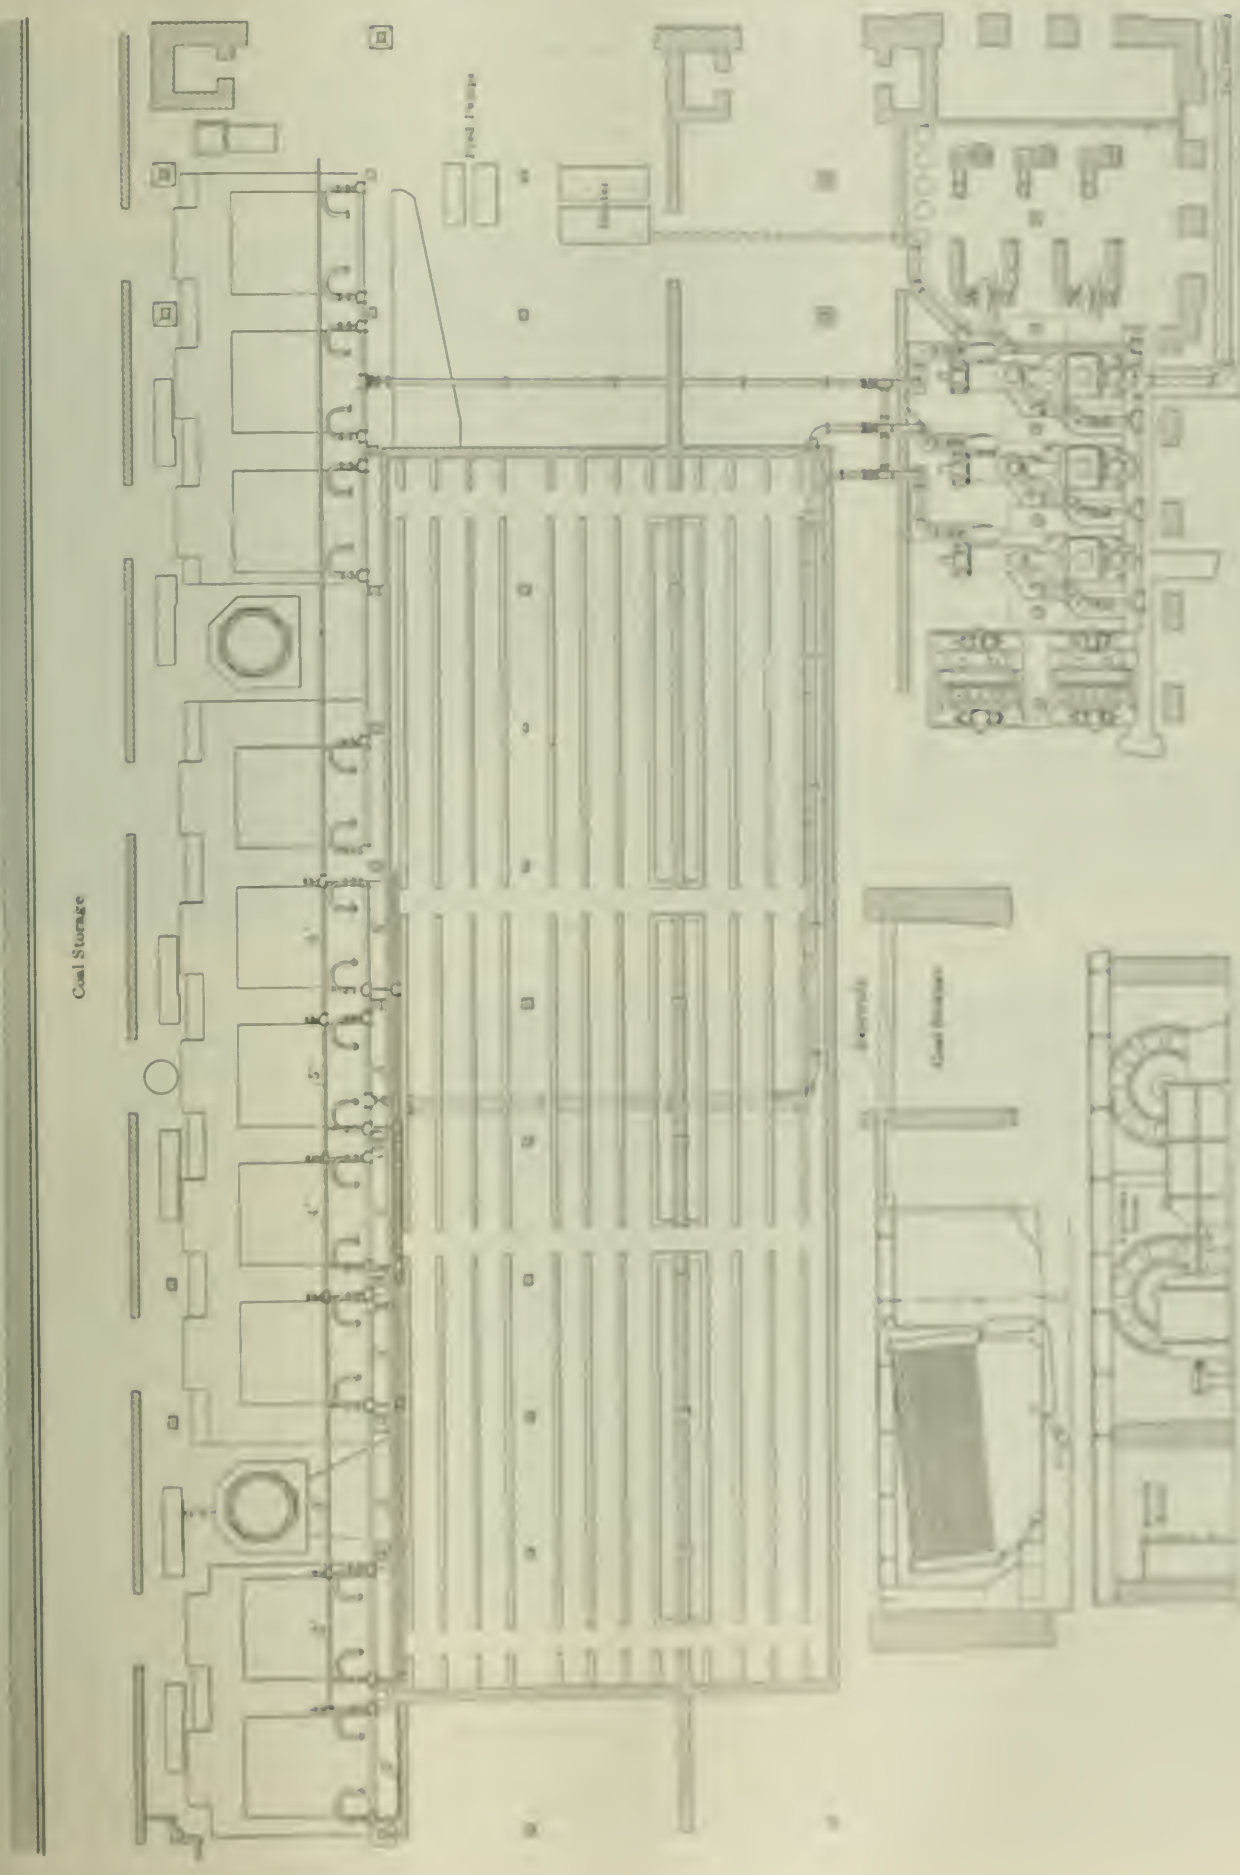

Fig. 4. PLAN OF POWER PLANT AND SECTIONAL ELEVATIONS OF BOILER AND TURBINE ROOMS

on each side of the front header, into which tubes are expanded and terminate in similar legs connected to the mud drum to allow free circulation of the water. The construction is indicated in Fig. 2.

Steam is taken from the top of the rear header on each side and passes to a 10-inch steam main immediately behind the boilers, through two 5-inch short-radius bends and Chapman stop valves. Hollow staybolts are provided in the front header for blowing the tubes. Fig. 3 shows a front view of the boilers. The piping is arranged so that the boilers are divided into three groups, each connected to its independent 10-inch header. These headers have no bypass connection with each other at the boilers, but the feeders to the turbine room are so tied together that any group of boilers may furnish steam for any turbine unit. Four boilers are connected to the first header and three to each of the two remaining headers. From the center of each header there extends a 10-inch line to the outside of down from the rear header to the mud drum, thence through the horizontal central tubes to the lower manifolds at the front and up through the water-tube grates to the front header.

Feed water comes from the city mains to either of two 1500-horsepower Hoppes open feed-water heaters. It is fed to the boilers by two Worthington 14x8¼x15-inch outside center-packed pot-valve pumps which are controlled by Mason regulating valves in conjunction with the feed-water regulating system. It was necessary to excavate to get sufficient head room for the pumps.

Two stacks, each 9 feet in diameter and 150 feet high, serve the boilers, five boilers to each stack, the gases being collected in rectangular flues and uptakes built of blast-furnace-slag cement.

Turbine Room

There are three Allis-Chalmers-Parsons type of noncondensing turbo-generators installed, each of 1500 kilowatts capacity, pump to be used in starting and in emergencies.

The principal point in which the turbines differ from the standard condensing turbine is in length of rotor, a shorter machine being required for noncondensing service. The velocity of the steam is not enough to demand the low-pressure blades, which, if supplied in this case, would have had a velocity greater than could have been utilized by the steam under the excessive back pressure at which it goes to the exhaust. The machines were installed under a guarantee to develop a kilowatt-hour on 44 pounds

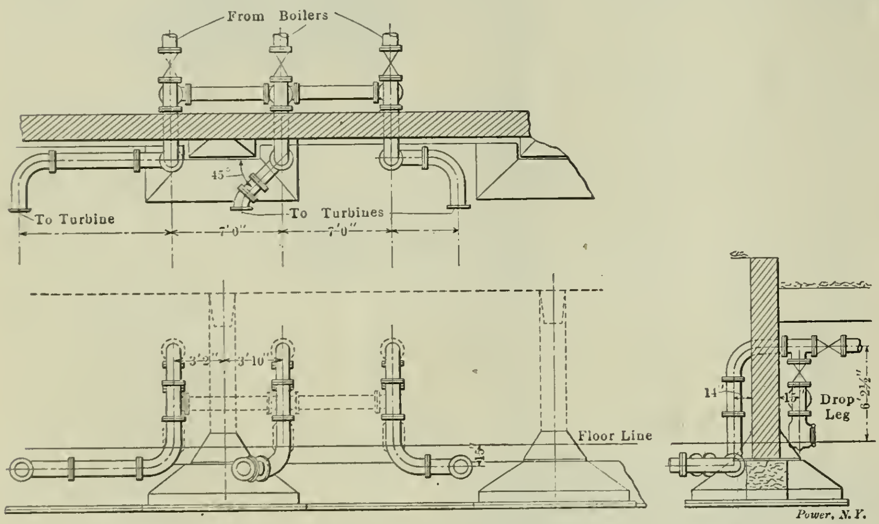

FIG. 5. STEAM HEADER MANIFOLD BETWEEN BOILERS AND TURBINES

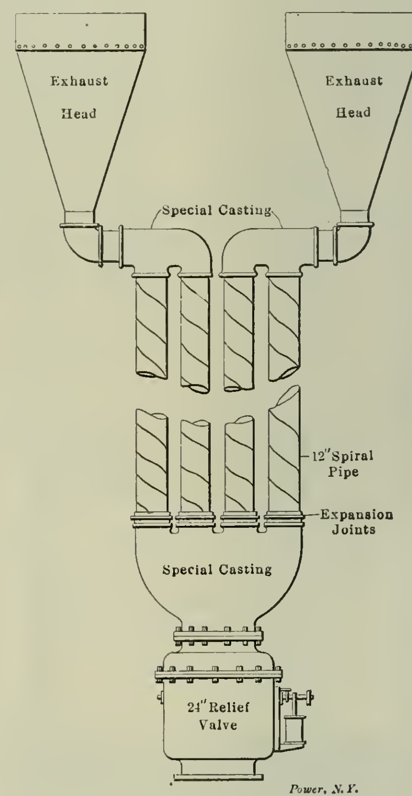

FIG. 6. DETAIL OF EXHAUST RISER

the turbine-room wall, where the three lines are connected to a 10-inch manifold. By this arrangement any one of the steam lines may be cut out and steam supplied by the remaining two. Fig. 5 shows a plan and elevation of this arrangement. It will be seen that there is a drop leg under each steam line to collect condensation, if any should occur, and if desired the manifold may be cut out entirely and each unit be run on steam from its own battery of boilers. On passing through the turbine-room wall, the steam lines drop below the floor and at this level connect to the turbine throttles.

Owing to the restricted head room the boilers were necessarily made wide to get the required heating surface, and this construction permitted the installation of two Hawley down-draft furnaces. The upper manifold of each furnace is connected in three places to the lower tubes of the boiler. Circulation is then running at 1800 revolutions per minute and developing with star-connected generators 60-cycle three-phase current at 2300-4000 volts. To avoid vibration was the primary reason for installing turbines, but aside from that, it is extremely doubtful if the necessary engine capacity could have been put in place under the conditions of head room and floor space available. Even under the circumstances some ingenuity had to be exercised in making the exhaust connections, on account of the extended character of the pillar foundations. These were cut away sufficiently to allow the placing of a special rectangular casting connecting each turbine with the exhaust main.

Each unit has an oil-circulating system driven by worm gearing, by which the bearings are lubricated and which is also used to actuate the throttle valve under control of the governor. There is also installed an independent motor-driven oil of dry steam at half load, 40 pounds at full load and 41 pounds at 25 per cent. overload. It has been the practice to carry just sufficient load on the turbines to furnish the demand for steam on the heating system, and up to the present time there has not been enough demand to carry an economical load for long periods.

The accompanying boiler test, taken under ordinary working conditions, shows that, with an economical load on the turbines, a kilowatt-hour can be delivered at the switchboard for 4.23 pounds of coal, and this figure, it must be remembered, is obtained while operating against 22 pounds absolute back pressure.

The turbines exhaust into a 24-inch main which leads to the tunnel of the Central Heating Company. On this main is a 24-inch Crane relief valve with risers extending to the roof. There was no room which would permit of a 24-inch outlet

TEST OF ONE OF THE EDGE MOOR BOILERS.

Duration of test, hours	9
Heating surface, square feet (including Hawley furnace)	3,930
Superheating surface, square feet	1,504
Grate surface, square feet	2 Hawley furnaces 6'x6'x6" each
Barometric pressure	29 3

being installed, and it was finally found necessary to utilize a narrow space in one of the elevator shafts. As shown in Fig. 6, a special casting was made fitting the relief valve and having four connections. Twelve-inch spiral pipe was run from these connections to the roof and here by the use of more special castings the pipes were run into two 16-inch Cross exhaust heads.

ELECTRICAL INSTALLATION

Practically all of the electrical output of the station is used on lighting service, either as 2300-volt three-phase current or on the Edison three wire 220-volt system. Alternating- and direct-current busbars connect with the other two stations and the plants operate in multiple both on the alternating-current and direct-current sides, using for the latter service two [illegible]-kilowatt Allis-Chalmers motor-generator sets and a storage battery of 320 chloride cells. Each motor-generator set consists of a [illegible] three-phase synchronous motor driving a [illegible]-kilowatt direct-current generator at [illegible] revolutions per minute and delivering current at 220-250 volts. The units are started from the direct-current busbars.

Each set has a generator panel carrying a Westinghouse edgewise ammeter, voltmeter, double-throw main switch, a Thomson recording wattmeter, alternating-current voltmeter, a direct-current field meter and power-factor indicator. There is a booster panel controlling a 150-kilowatt General Electric 1200-ampere booster for charging the storage battery. Two battery panels are provided with edgewise Weston ammeters and cell switch indicators and controlling apparatus. Twenty-four three-wire direct-current feeder panels, Fig. 7, are installed, with edgewise Weston ammeters on each wire of the three-wire system. There are no circuit breakers between the load and the direct-current side of the motor generators, but on the alternating-current side automatic circuit breakers are provided. Six lighting panels with a double set of busbars control the circuits in the building, each circuit having a double-throw switch so that it may be thrown on either the direct- or alternating-current side of the system.

FIG. 7. SWITCHBOARD

The storage battery consists of 320 [illegible] chloride cells of 1500 ampere-hours capacity, divided into two sets having 20 end cells each. It is charged during the day and discharged on the peak load which comes between five and six in the evening.

Although ordinarily furnishing direct current, the motor generators on the alternating-current and direct-current sides [illegible]

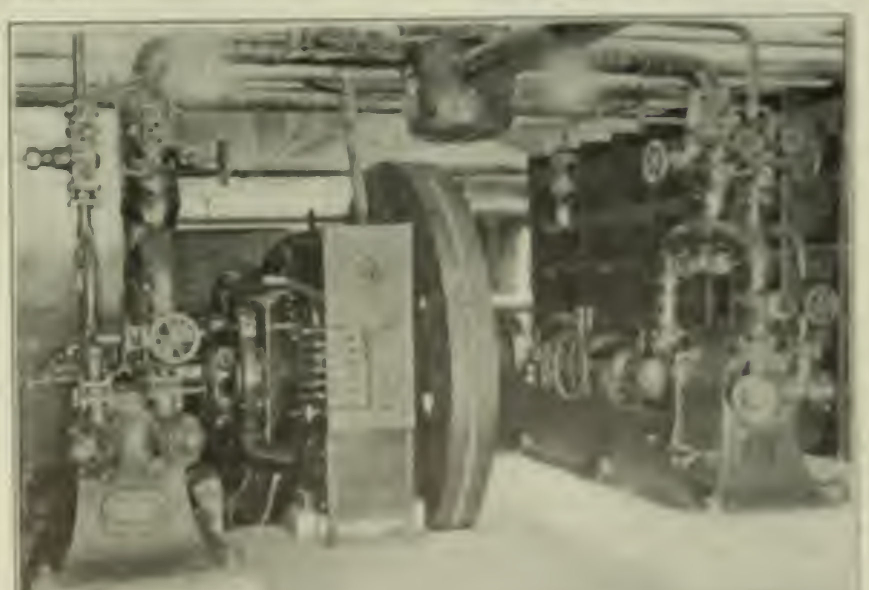

FIG. 8. [illegible] MACHINES

Minor Apparatus

To cool drinking water in the building, a 25-ton Vilter refrigerating machine has been installed and is driven by a variable-speed Crocker-Wheeler motor, direct connected to the shaft. Waukesha water is brought in tank cars to the building and turned into two 10,000-gallon cement tanks in the basement. The expansion coils of the refrigerating machine are located in these tanks, and the exchange of heat is direct, without the intermission of a brine system. Two Yoeman motor-driven centrifugal house pumps circulate the water. The refrigerating equipment, shown in Fig. 8, is much larger than necessary for its present use, but it is the intention in the future to supply refrigeration to outside parties. Foundations are installed for a similar unit of the same size.

Other modern devices characteristic of a first-class office building are a vacuum cleaning system, the vacuum of which is obtained by a steam aspirator; and a Lamson pneumatic tube system for the transfer of papers, etc., from one department to another, this service being maintained with two 150-cubic foot Christensen motor-driven air compressors. A Stromberg auto-telephone system combined with the Bell system is installed for intercommunication and for outside calls. The building is heated with the Paul system of vacuum return, and for fire service there is provided a 6-inch single-stage Lawrence centrifugal pump driven by a General Electric 85-horsepower motor running at 750 revolutions per minute.

The plant as a whole is satisfactorily fulfilling the special purpose for which it was intended. It was designed and installed under the direction of C. J. Davidson, chief engineer of power plants.

The Use of Wooden Rings in Water Mains

By William Kavanagh

In laying large pipe intended for conveying water the employment of wooden rings, shaped to suit varying angles and inequalities between elbows, tees, etc., and also to act as lengthening pieces between fittings and flanges, will be found to be very important. In general, large pipe cannot be handled with the same facility as small pipe, it being practically impossible to force heavy pipe into line should fittings be tapped angularly or out of true, and in some cases the nipples or lengths of pipe will screw up farther into the fittings than anticipated, shortening the pipe. Sometimes lengths of pipe or nipples will be found bent, either through handling or because of some defect of construction, and when large pipe is to be connected and erected at a place remote from a shop having tools large enough to cut and thread it, the ingenuity of the pipefitter is taxed to remedy such troubles.

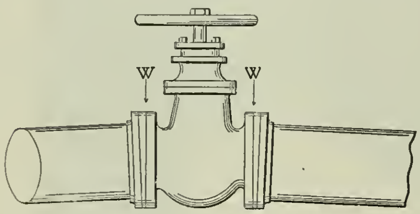

FIG. 1

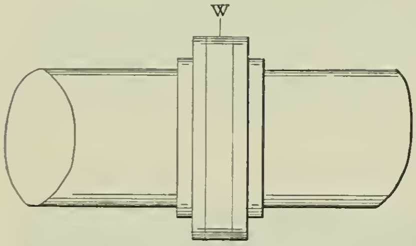

FIG. 2

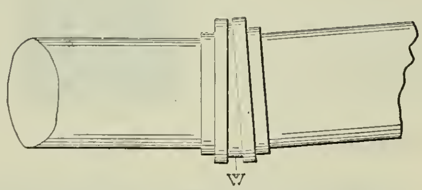

FIG. 3

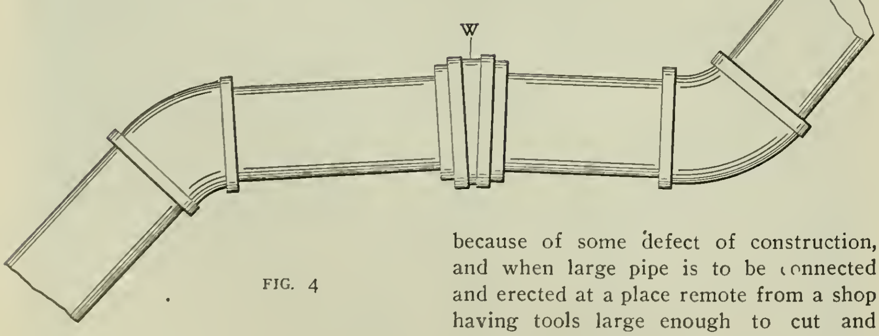

FIG. 4

Not long ago numerous difficulties were overcome, in the erection of a large water main intended for conveying water under a pressure of 150 pounds per square inch, by the employment of wooden rings shaped to suit requirements. The size of the pipe was 14-inch, and its installation through various winding passageways and crooked, narrow places called for the use of numerous short pieces of pipe, together with the usual flange unions, valves, tees and elbows. Whenever it was found expedient, a wooden ring was used. The ring was first shaped, then drilled and fitted to suit the bend or alinement of the fittings. After this, a rubber gasket was fitted to each side of the ring, or wedge, and the whole inserted in the desired position and bolted in place. Whenever the thickness of the wooden ring exceeded a certain amount, the length of the bolts had to be increased, and when the angle of the bend became acute the diameter of the bolts had to be decreased, in order to pass them through the holes.

Fig. 1 shows how the nipples approached the main stop valve and the application of the wedge-shaped wooden rings to fill out deficiency of alinement is shown at *W W*. Fig. 2 shows how a wooden ring *W* was employed to overcome deficiency of length. Here the nipples screwed into the fittings farther than was expected and the distance was made up by increasing the thickness of the ring, which in this case was 2 inches, a rather large amount to stretch a piece of 14-inch pipe. Fig. 3 shows how two nipples approached each other, having a flanged-union connection. It was found impossible to spring the nipples sufficiently to enable the bolting up of the union and at the same time have it face properly. The use of the ring *W* compensated for this deficiency.

Fig. 4 shows how the nipples and flanged union from two 45-degree elbows appeared when connected. The elbows and nipples lay close along a heavy stone floor, making it impossible to manœuver the elbows so as to have the union face properly. A wedged-shaped wooden ring, similar to that in Fig. 3, was employed, and it filled the requirements nicely. Fig. 5 illustrates the use of the wedge-shaped wooden ring between two 90-degree flanged elbows. Here it was found impossible to cant or swing the nipples so as to enable the correct facing of the elbows and permit of bolting them together. The use of the ring *W* was all that could be desired and it facilitated the connection of this part of the line more rapidly than if the heavy stone wall, over which the pipe had to run, were cut away.

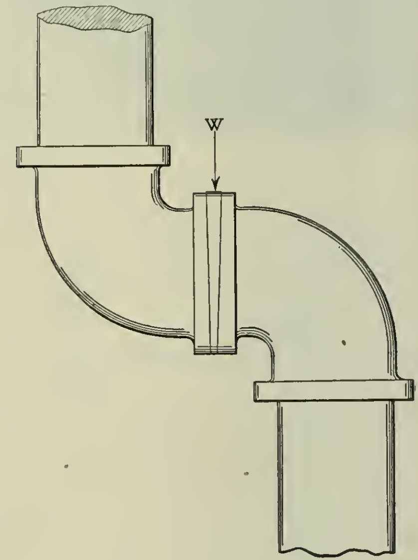

FIG. 5

In all cases the joints in which the wooden rings were used were water tight and satisfactory in every respect.

A New Binding Agent for Coal Briquets

Consul George Eugene Eager, of Barmen, Germany, gives the following details regarding the advantages of briquet making by the use of sulphite pitch (zelpech), with a preliminary statement concerning the making of coal briquets with tar pitch in general:

Only fifty years ago the dust of coal was considered to be entirely useless, but since then a great change has taken place and at present in Rhenish Westphalia the Ruhr coal district alone produces 3,000,000 tons of such briquets each year. The same increase is shown in the other European coal districts, i.e., Silesia, Belgium, England, etc.

Up to the present, coal-tar pitch (so-called brai) has been used for making coal briquets, and its production in the past ten years has increased about 100 per cent. Most of the coal-tar pitch is produced in England and Germany, the latter country only being able to produce for its own consumption, while England supplies the remaining consumers, i.e., America, Russia and Belgium. As stated, the coal-tar pitch production is limited, and consequently in the United States and Russia only comparatively few briquet manufactories are to be found.

The coal-tar pitch is an excellent binding agent for baking and coking coal, especially bituminous; it burns easily and gives the briquets hardness for long-distance transport, but various qualities of good briquet material cannot be bound with it, thus making its common availability impossible. Its numerous disadvantages are as follows: It produces very much smoke and has a very disagreeable odor; it cannot stand high temperature, and becomes soft and difficult of use in hot or extreme weather; the dust and fumes of coal tar, being corrosive, are very injurious to the skin, eyes and lungs of the workmen employed, causing diseases of these organs. The low temperature at which it ignites, although an advantage when used with soft bituminous coal, becomes a great disadvantage when the attempt is made to use materials that burn less easily. The coal tar becomes soft and burns much more rapidly than the coal flowing out of the briquet, leaving the coal to fall to pieces in dust and remaining unconsumed.

NEW MATERIAL FROM WOOD CELLULOSE

For this reason it has been impossible to briquet anthracite, semi-anthracite, or coke gravel with coal tar pitch, it being unable to resist the heat and pressure of the blast furnaces; therefore a binding agent which overcomes all of the difficulties mentioned ought to have the most brilliant prospects for the future.

This long-sought-for binding agent has been found in the "sulphite pitch." The material is obtained in the process of manufacturing sulphite cellulose. The wood is put through a washing process in lye by which the fiber is cleaned of all resinous ingredients, it being pressed out from the wood pulp. Thus far this material has been entirely useless. Through a cooking process it is reduced to a highly glutinous substance called "sulphite pitch."

The sulphite pitch possesses many qualities which show its excellent advantages as a binding agent. It is intensely glutinous and possesses a high binding power. In the ordinary briquet of bituminous coal from 7 to 10 per cent. of coal tar is used to give it the proper hardness, and with the use of sulphite pitch the same results can be obtained by the use of 5 per cent. There are qualities of coal and ore that can easily be made into briquets with from 2 to 3 per cent. of the sulphite pitch.

Sulphite pitch burns without smoke or odor and is an ideal fuel for the household as well as for industrial purposes. In cities where the smoke nuisance has heretofore prevailed the use of briquets made with this sulphite pitch will form a solution of the smoke question. Trials have already been made with coke briquets made with this new process in blast furnaces and on torpedo boats, with the most sanguine results. The former tests not only showed a saving of 20 per cent. coal, but the iron showed almost an entire freedom from sulphur. In its trial on the torpedo boats it not only proved a perfect fuel, but the entire absence of smoke proved its advantage over other fuels in time of war. Ocean liners, warships, railway engines and factories could all use this fuel to advantage and not only economize in the amount of fuel necessary, but would relieve the cities from the smoke nuisance.

AVAILABILITY OF MATERIALS

Sulphite pitch does not soften under heat and burns at a high temperature. It can be ground to any consistency or can be produced directly in any form of powder; it can be had in every country where there are cellulose mills and it is very cheap, while the coal-tar pitch, which is rare and expensive. Many attempts have been made to briquet anthracite, semi-anthracite, coke gravel, or dross, even with a very high per cent. of coal tar, but without success. These disadvantages all disappear with the use of the sulphite pitch. Anthracite briquets for household use (egg form for American stoves) manufactured with sulphite pitch burn smokeless and odorless; therefore, they are not only an excellent substitute for the anthracite coke, but are even superior to them.

Recent trials to briquet coke gravel and dross the remainder of coke (gasworks cinders) with tar pitch have proved failures, but the situation changed immediately as soon as sulphite pitch was used as the binding agent, and the results show a briquet that can be considered a perfect substitute for coke. Practical trials of these briquets in both blast and cupola furnaces have shown that the briquets do not fall to pieces even under the highest temperatures, but keep while gradually shrinking. On account of their consistence they sway deeply into the melting zone of the furnace, thereby positively contributing materially to the melting effect. Fine ore, bog iron ore, brown ore, manganese ore, pyrite, furnace cadmia (flue dust from blast furnaces), and other ores can all be made into briquets by the use of sulphite pitch and successfully melted in the furnace. All trials of these materials with coal-tar pitch have failed, because the binding agent burned away at a lower temperature, leaving the material in dust as before. With sulphite pitch it is possible to briquet furnace cadmia so that it can be melted in a blast furnace. This alone means a great saving to the iron industry.

CONSTITUENT ELEMENTS—PROCESS OF MAKING

In general, sulphite pitch consists of the following substances: Coke, 25 to 35 per cent.; volatile matter, 50 to 60 per cent.; ashes, 8 to 12 per cent.; water, 10 to 15 per cent.

The latest chemical tests have proved that the percentage of ashes can be materially reduced. Through the origin of sulphite pitch its ashes contain sulphur up to 20 per cent., or 2.5 per cent. of the sulphite pitch. The sulphur, however, is tied up to iron and lime, which latter substances are always present in abundance, so that the sulphur remains in the ashes and cannot do any damage. It is true that sulphite pitch can be dissolved in water, and that briquets made from it are not waterproof; but this is of no great importance, as in most cases a waterproof briquet is not needed. The sulphite-pitch briquet is, however, more waterproof than the lignite briquet, the making of which has become a flourishing industry. The sulphite briquet is not hygroscopic and can be made absolutely waterproof, if it is necessary, by a simple special treatment.

It is not supposed that sulphite pitch will in any way interfere with the coal-tar pitch in its use for soft bituminous coals, but the superiority of sulphite as a binding agent for the harder coals and cokes, also iron dust and other ores, opens up a new and very important industry. Already a large coke-briquet factory has been built in Langenberg near Barmen-Elberfeld, and the entire output of the factory was sold out at once. Another large factory is in process of construction in Aix la Chapelle [illegible] and [illegible] Europe.

Guide to Small Station Switchboard Design

General Instructions and Suggestions for Station Managers for Laying Out Switchboards for Small Alternating- and Direct-current Plants

It frequently happens that the switchboard equipment of a small station must be almost if not entirely superseded by a new switchboard in order to meet the requirements of increased load and unexpected changes in the character of the load. In many such cases, the work of laying out the new switchboard devolves upon the operating head of the plant because the owners consider it too small to justify the employment of a consulting engineer. To meet such cases, the General Electric Company has formulated general fundamental instructions and suggestions which will be found most helpful to station managers confronted with the conditions mentioned. Because of the highly useful character of this material we reprint herewith that portion of it which relates to alternating-current stations of 2300 volts and direct-current power plants of 575 and 275 volts.

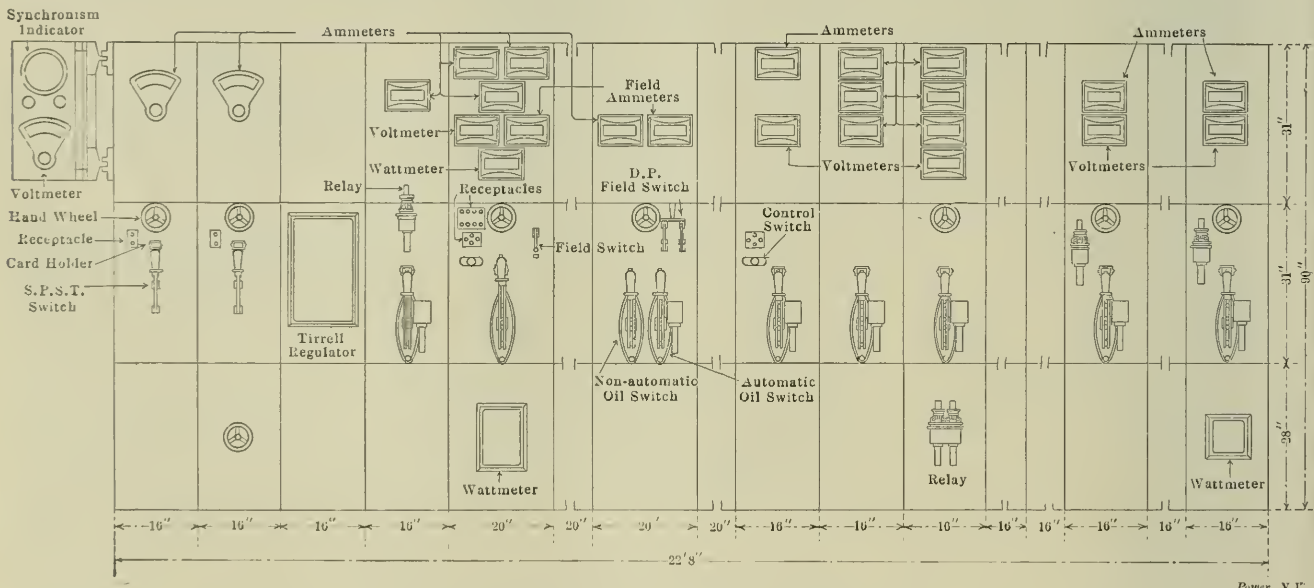

FIG. I. FRONT VIEW OF 2300-VOLT SWITCHBOARD

2300-volt Alternating-current Switchboards

Exciter Panels

The exciter panels should preferably be arranged for the control of only one exciter from each panel for the reasons that the panel and the exciter can be considered as a unit, and can be disposed of together if any change is made in the equipment; a more symmetrical arrangement can be made of the instruments and other devices, and the switchboard can usually be laid out with a fewer number of sizes of panels.

The equipment recommended for exciter panels is as follows: One ammeter, one field rheostat handwheel, one single-pole, single-throw switch and one two-point potential receptacle. Negative and equalizer switches should be mounted on or near the machines. A fuse on a base behind the panel may be added, if desired.

The best plan, as a rule, is to use only one voltmeter for the exciters, and mount this on a bracket at the end of the switchboard. If a voltmeter is used for each exciter, it may be mounted on the corresponding exciter panel; a potential receptacle will then be unnecessary.

Induction-motor Panels

When exciters are driven by induction motors, it is necessary to provide a panel for the control of the motor. The equipment should consist of one ammeter, one triple-pole single-throw automatic oil switch with bell-alarm switch, and one inverse time-limit overload relay. If a Tirrill regulator is installed, there will usually be room for it on this panel.

This arrangement is used also because the induction-motor panel is usually placed between the exciter panels and the generator panels. If for any reason the induction-motor panel is not so placed, it is better to use a separate panel for the regulator.

Generator Panel

The standard equipment of a three-phase generator panel is as follows: Three ammeters, one polyphase-indicating wattmeter, one voltmeter, one field-circuit ammeter, one single-pole single-throw field-circuit switch with discharge clip, one handwheel and chain mechanism for field rheostat, one four-point synchronizing receptacle, one eight-point potential receptacle and four-point plug, one triple-pole single-throw nonautomatic oil switch, two current transformers and two potential transformers.

A synchronism indicator is recommended in all cases. The best place for it is on a swinging bracket at the end of the board.

If the generators are rated in current output, as is customary with some builders, it is advisable to install ammeters on these panels in order that it will be possible to ascertain at any time exactly what current each machine is delivering. All three-phase systems are more or less unbalanced; therefore, in order to obtain correct readings, it is necessary to install an ammeter in each leg of each generator circuit.

Indicating wattmeters are important, as it is not possible to determine by any other means the division of load between two alternating-current generators running in multiple. The ammeters cannot differentiate between the idle component and the work component of the current from a machine, and are therefore of no use in determining the division of load.

Field-circuit ammeters are useful, but not absolutely necessary. They serve as a check on the generator in case of trouble, and are valuable when testing for trouble.

Voltmeters are, of course, used to read the voltage of the machine before it is connected in multiple with any other. They are also used to indicate the potential of the busbars. The eight-point receptacle on the panel is provided to connect the voltmeter to any of the phases.

The field-circuit switch is equipped with a discharge clip, in order that the inductive discharge which occurs when the switch is opened can be dissipated through a resistance without injury to the machine or any of the other apparatus.

The synchronizing plug is used to connect the generator to the synchronizing busbars leading to the synchronism indicator. The General Electric Company has always recommended synchronizing between machines, and for this reason two types of plug are furnished with its switchboard equipment, one marked "Machine running," and the other "Machine starting." If a synchronism indicator is used, the proper connections will be made by means of these plugs, so that the synchronizing indicator will show whether the starting machine is operating too slow or too fast.

Usually the rheostat is too large to mount on the back of the panel. The handwheel can be mounted on the panel and connected to the dial switch on the rheostat by means of a sprocket wheel and chain or bevel gears, etc., or in some cases the dial switch of the rheostat can be placed on the panel and connected to the resistance by leads. The latter arrangement is objectionable on account of the great number of leads and the expense. If rheostats are placed at any considerable distance from the switchboard, it is better to operate them electrically and mount simply the control switch on the panel.

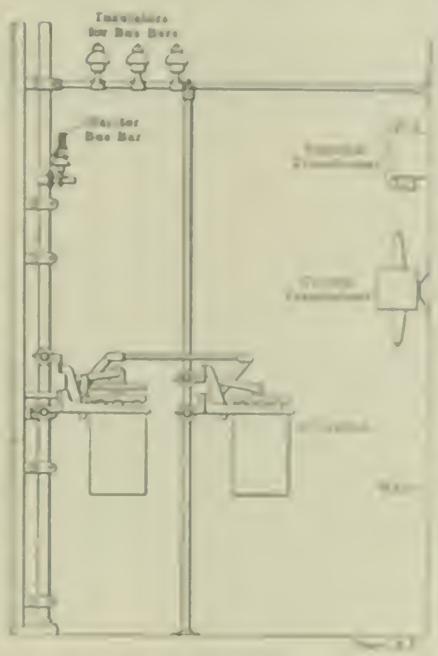

FIG. 2. SECTION THROUGH SYNCHRONOUS-MOTOR PANEL

Many engine builders furnish means to adjust the governors of their engines, and it should be ascertained in each case whether such a device is to be furnished, and the type of motor used, in order that the proper switch can be mounted on the panel.

No automatic protection is recommended for alternating-current generators for several reasons. If automatic switches are used, there is great danger of shutting down the plant at the time of putting machines in parallel if the machines are not exactly in synchronism when they are connected together. If a short-circuit or overload occurs on any feeder, the generator switches are liable to open at the same time as the feeder switches, causing a shutdown. Most alternating-current generators are so designed that they are not injured by momentary short-circuits.

Synchronous-motor Panels

When motor-generator sets are used for furnishing either Edison three-wire direct-current service, or 550-volt railway or power service, the synchronous-motor panels should be equipped with one main ammeter, one field ammeter, one double-pole single-throw field switch with discharge clip, one rheostat handwheel and chain mechanism, one triple-pole double-throw automatic oil switch (automatic on one throw only), with bell-alarm switch, one triple-pole single-throw non-

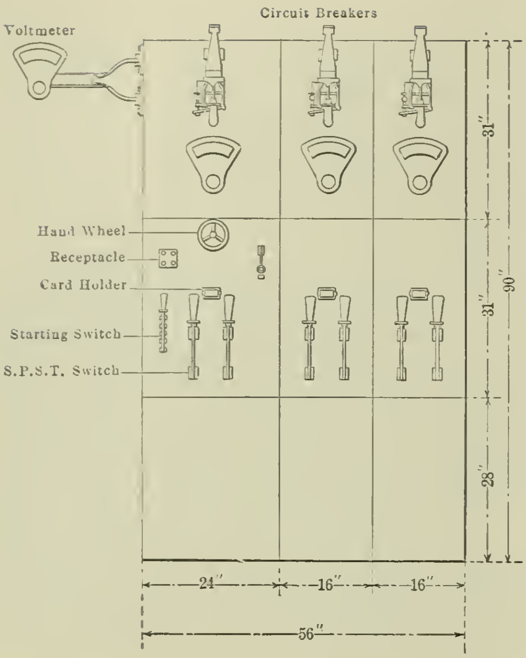

FIG. 4

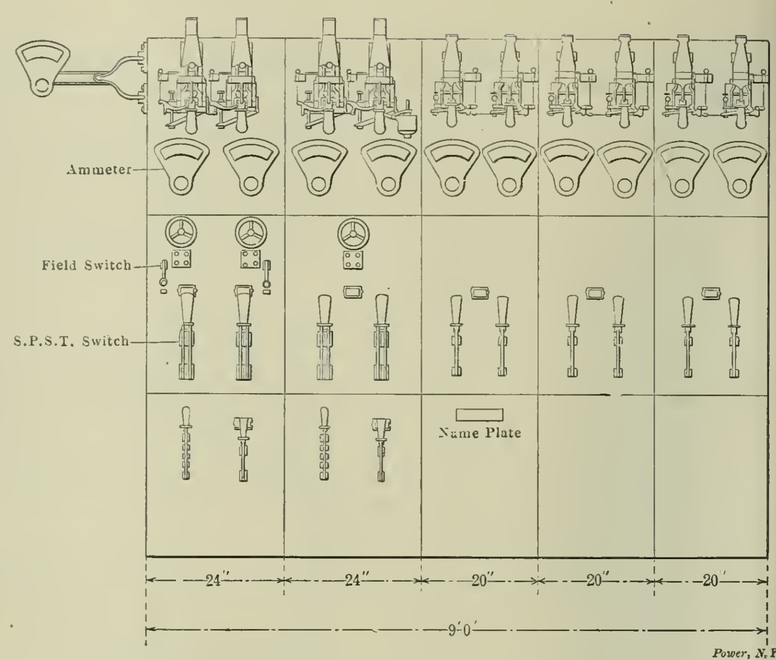

FIG. 5

FRONT VIEW OF DIRECT-CURRENT SWITCHBOARDS

automatic oil switch for compensator, and two current transformers.

If the synchronous motor sets are started only from the direct-current side, the main switch should be single-throw. If, however, they are started from the alternating-current side, the main switch should be made double-throw, in order that the motor can be connected to the starting taps on the compensator and then thrown over to the line by the switchboard operator.

When the sets are started from the direct-current side, it is necessary to synchronize and to add a voltmeter and potential transformer to the panel for reading the potential when synchronizing.

The arrangement of the field rheostats on these panels should be similar to the arrangement of the rheostats on the generator panels.

Rotary Converter Panels

Where rotary converters are used the alternating-current panel for the converter should have the following equipment, assuming direct-current starting: One main ammeter, one voltmeter, one synchronizing receptacle, one triple-pole single-throw automatic oil switch, with bell-alarm switch, two current transformers, and one potential transformer.

When rotary converters are used for furnishing Edison three-wire service, it is customary to install a regulator on the alternating-current side of the rotary, in order to be able to control the potential of the direct-current service. This regulator is usually motor-controlled, and in such cases a double-pole double-throw control switch should be mounted on the panel. The voltmeter is not necessary if no potential regulator is used.

Three-phase Feeder Panels

Three-phase feeders are frequently used for lighting, but are more generally used for power service. The equipment of each three-phase feeder panel should consist of three ammeters, one triple-pole single-throw automatic oil switch with

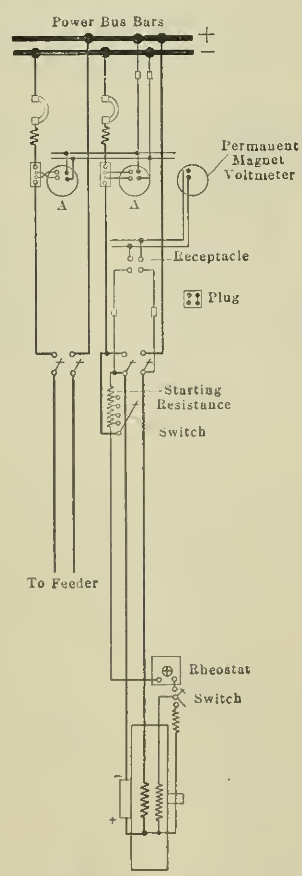

FIG. 6

bell-alarm switch and two current transformers.

If three-phase feeders are used to supply lamps as well as motors, the preferable method for operating the lighting circuits is to connect the lamps to one phase of the three-phase feeder and apply a regulator to this phase; this will afford complete control of the lighting. The usual equipment of a panel for controlling a circuit of this kind is as follows: Three ammeters, one voltmeter, one voltmeter compensator, one handwheel for the control of the regulator, one triple-pole single-throw automatic switch, with bell-alarm switch, four current transformers and one potential transformer.

If the regulator is located at a considerable distance from the switchboard, it is preferable to operate it electrically, and a double-pole double-throw control switch, instead of the handwheel, should be mounted on the panel. If the regulator can be placed close to the panel, however, it can be connected to the handwheel on the panel by means of either a sprocket wheel and chain, or by beveled gears.

Single-phase Feeder Panels

If single-phase feeders are used for lighting, the equipment should comprise one ammeter, one voltmeter of the compensating type, one double-pole single-throw automatic oil switch with bell-alarm switch, one current transformer and one potential transformer.

In case regulators are used, the same arrangement should be made on this panel for the control of them as is outlined for the three-phase panels.

Relays

The General Electric Company has developed what is known as the diaphragm-type relay, which operates on the inverse time element principle; that is, it can be adjusted to operate in a predetermined time with certain currents. If so adjusted, the time of operation is inversely proportional to the amount of current, and approaches an instantaneous value in case of a short-circuit. The use of this relay is recommended on all feeder circuits, alternating current rotary converter panels and synchronous- or induction-

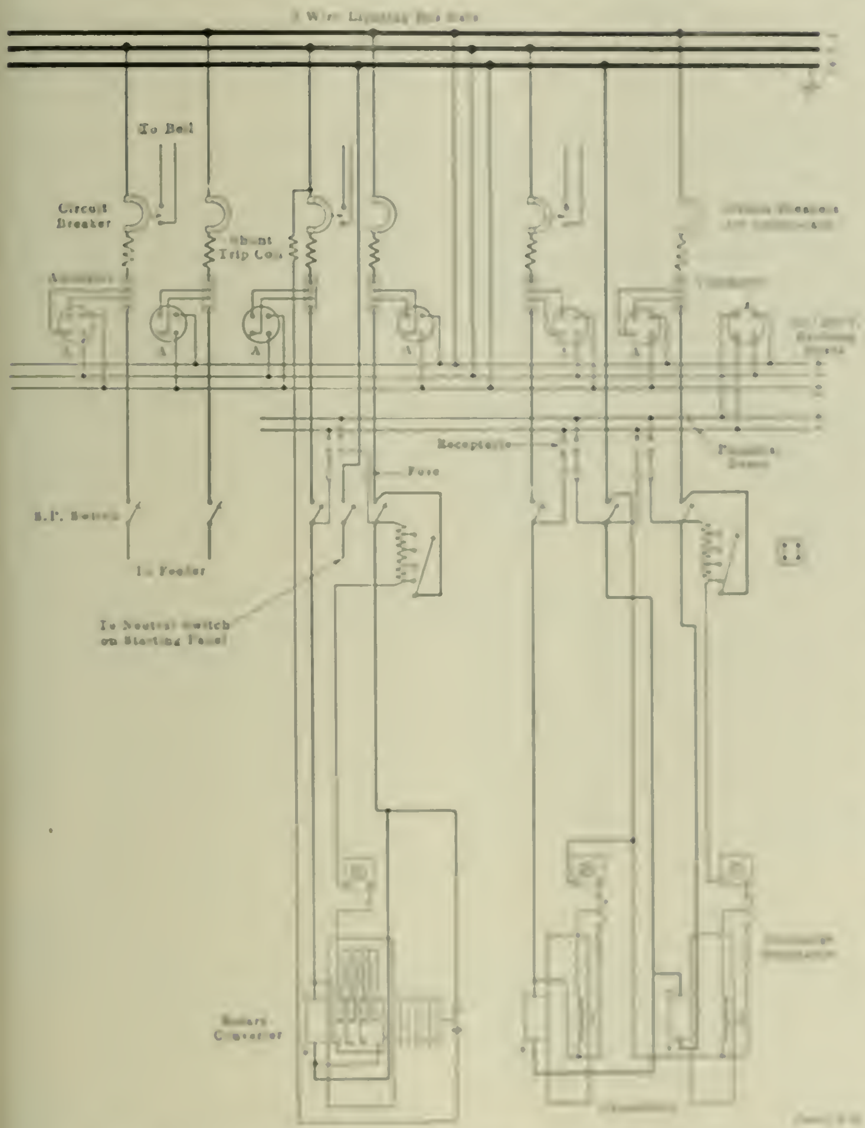

FIG. 7. DIAGRAM OF CONNECTIONS OF ALTERNATING-CURRENT SWITCHBOARDS

motor panels, as it prevents the shutting down of the circuit by a momentary overload, yet will disconnect the circuit practically instantaneously in case of short-circuit or similar trouble.

Ground Detectors

It is desirable to use an electrostatic ground detector connected to the busbars. This can be mounted on a stationary bracket at the top of the switchboard, or on a swinging bracket at the side of the switchboard. The bracket at the top is preferable, as it places the instrument beyond the reach of the station attendant and removes all high-tension apparatus from the switchboard proper.

Arrangement of Apparatus

There are many possible arrangements of the oil switches, current and potential transformers, busbars and connections. The best arrangement to employ depends on the design of the station and the proposed location of the switchboard. With the arrangement shown in Fig. 1 the busbars are mounted on a pipe framework at the top of the panel and the oil switches on the panel-pipe supports. The use of remote control switches makes a preferable arrangement, as the connections can then be made in a position so as to make the backs of the panels more accessible for testing, or for any changes or repairs which are found necessary.

Under no conditions should the current and potential transformers be mounted on the back of the panel, because with such an arrangement the panel would be covered by the connections to and from the transformers, and thereby made inaccessible. In some cases the connections would be so crowded as to make the switchboard unsafe. The preferable location for these transformers is in the leads from the generators beneath the floor, if the leads come in from below, or on the wall in case they come from above. Transformers connected to the feeder circuits should be mounted on the wall if the feeders go out above, or beneath the floor if they go out underground.

Fig. 3 is a rear view of the switchboard in Fig. 1, showing the connections between the various instruments and operating devices.

Direct-current Switchboards

Fig. 4 shows a direct-current switchboard arranged for 575-volt power service. The panel shown at the left of the drawing is exactly the same whether used with a rotary converter or a generator driven by a motor or an engine, excepting that no field switch is needed for converter panels. The equipment of this panel should be one circuit-breaker with bell alarm switch, one ammeter, one handwheel and chain mechanism for the rheostat, one single-pole single-throw field switch with discharge clip, one four-point potential receptacle and two single-pole single-throw lever switches.

One voltmeter should be mounted on a swinging bracket placed in some convenient location.

If machines are equipped with speed-limit devices it is customary to provide low-voltage release or shunt trip coils on the circuit breakers.

If the generator is a part of a motor-generator set and is to be arranged for direct-current starting, a [illegible] starting switch should be mounted on this panel. If the generator is driven by an alternating-current motor, the alternating-current panel already described should be used for the control of the latter.

Feeder Panels

The equipment of the feeder panel should consist of one single-pole circuit-breaker with bell-alarm switch, one ammeter and two single-pole single-throw feeder switches. If desired, one of these switches can be omitted, the remaining switch being connected to one side of the circuit and the circuit-breaker to the other.

250-Volt Three-wire Switchboard

Fig. 5 shows two direct-current generator panels, one is for the control of two low-voltage generators operated on the three-wire system, and the other is the direct-current panel for a rotary converter. The panel for controlling the two direct-current generators would be exactly the same for motor-driven machines and should have the following equipment: Two circuit-breakers with interlock and bell-alarm switch, two ammeters, two handwheels for field rheostats, two single-pole single-throw field switches with discharge clips, two four-point potential receptacles for voltmeter plugs, three single-pole single-throw lever switches and one four-throw starting switch (for motor-driven generators). If the two generators are engine-driven, of course the starting switch can be omitted.

The direct-current rotary converter panel should have the following equipment:

Two circuit-breakers with interlock, shunt trip coil and bell-alarm switch; two ammeters, one handwheel for the field rheostat, one four-point potential receptacle for the voltmeter plug, three single-pole single-throw lever switches and one four-point starting switch.

It is generally preferable to start either a rotary converter or a motor-generator set from the direct-current side, as this causes much less disturbance of the system, which of course is important in lighting work.

The panels described are arranged for shunt-wound generators and converters as these machines are usually employed for lighting. If, however, compound-wound machines are used, equalizer busbars should be placed at a convenient point and the equalizer switches located either on the machines or on pedestals near the machines.

In the case of the two compound-wound machines supplying the three-wire system, it is necessary to have the series-field winding of the machine which operates on the positive side of the system connected in on the positive side of the machine. The machine operating on the negative side of the system should have its series-field winding connected in on the negative side of the machine; the circuit-breakers should be connected in the leads running to the neutral busbar. The reason for this is that the neutral is usually grounded, and as only one circuit-breaker is furnished for each machine, it is advisable to have this connected on the side of the machine which is grounded, in order to properly protect the machine against a ground in the leads from the machine to the switchboard, or on the machine itself.

A voltmeter should be mounted on a swinging bracket, as indicated in Fig. 5.

Feeder Panels

The feeder panels shown in Fig. 5 are each arranged for one three-wire grounded circuit. These panels should be equipped with two circuit-breakers with interlock and bell-alarm switch, two ammeters and two single-pole lever switches. There may be installed on one of these feeder panels a six-point receptacle, in order that the potential can be read between each leg of the system and the neutral when the rotary converter is running alone. There may also be installed a four-point receptacle for reading the potential across the outside of the three-wire service when only the generators are running. Figs. 6 and 7 show the proper connections for Figs. 4 and 5, respectively, as viewed from behind the switchboards.

Bridgewalls in Theory and Practice

By W. H. Wakeman

The chief engineer of a large manufacturing plant believed that the hot gases resulting from the partial combustion of coal could not be thoroughly consumed unless they were caused to pass through a narrow passage on their way to the chimney; therefore, when he installed two new 72-inch boilers he had the bridgewalls built in the form of an inverted arch, corresponding to the form of the shell, and the space between the top of this wall and the boiler shell was 3½ inches. See Fig. 1. Through this space all of the products of combustion passed on their way to the chimney and, according to the idea of this chief engineer, they became thoroughly mixed and burned during the process.

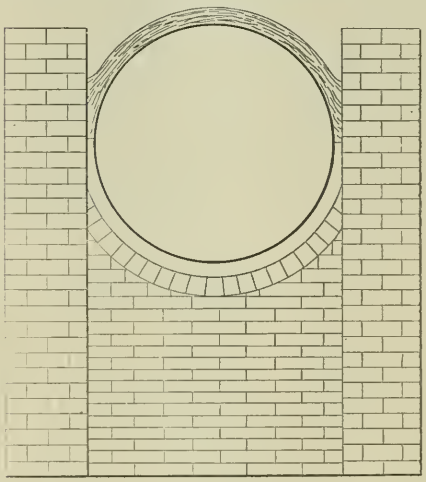

FIG. 1

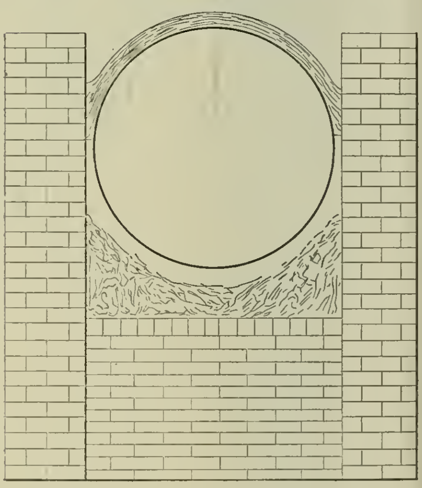

FIG. 2

Fortunately the chimney of this plant created a very strong draft, otherwise the boilers would not have generated steam enough to supply the demand when a full load was on, as the following calculation shows: The internal diameter of a 3-inch tube is practically 2.8 inches, and the area is 6.157 square inches; therefore, the combined area of 120 tubes is 738 square inches, and it is safe to assume that the area of the passage for hot gases should not be less than this at any point between the boiler and the chimney. If the space above the bridgewall extends around one-half of the circumference of the shell, its area is

$$3.5 \times 108 = 378$$

square inches, or almost exactly one-half the area of the tubes; consequently, the draft is less than it would be if this space were twice as large, although the length of this contracted passage is short, which is a point in its favor. The temperature must be very high at this point, but the boilers were not damaged by it as long as they were kept clean.

There were 18 other boilers in this plant supplied with bridgewalls that were straight and level on top, with a space above them about 12 inches high at its lowest point. This chief engineer claimed that when these bridgewalls were clean, thus making the full area of the passage effective, the efficiency of the boilers was reduced, because the hot gases were not completly consumed on their way to the chimney. His remedy for this evil was to allow soot and ashes to collect at this point, as shown in Fig. 2, and he would not allow this to be removed.

The real object in building a bridgewall is to hold the fuel in its proper place; therefore, it should be high enough for this purpose, and anything more is a waste of labor and material.

Bridgewall Too Low

The fronts of a pair of boilers that I had charge of for five years were designed so that the grates were about 20 inches below the shells. As Lehigh nut coal was burned in these furnaces at this time, a bridgewall 12 inches high above the grates was sufficient to hold the coal, even when the fires were banked; but, later, bituminous coal was adopted, and when this was shoved back to the bridgewall and the mass covered with fresh fuel to keep it from making steam during the night, the bridgewall was too low, as it was difficult to keep coal off it. To remedy this difficulty I had it raised 4 inches by setting firebrick on edge, as illustrated in Fig. 3.

This reduced the space from the bridgewall to the shell from 8 to 4 inches, but it did no harm. One of these boilers leaked badly at the girth seam near the bridgewall, and although the seam was chipped and calked several times in a workmanlike manner, it soon leaked again. Thirteen new rivets were put in and headed down while hot, thus causing them to hold more firmly when cold on account of shrinkage of the iron, but the leak was in evidence again within a few days. This would have proved conclusively to some engineers that the con-

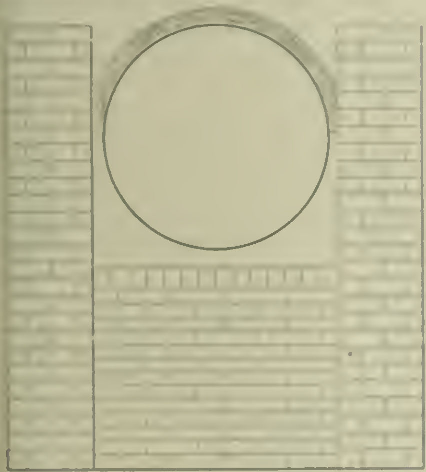

FIG. 3

centration of heat at this point was the cause of trouble; but this did not convince me, because I knew that the internal surface of the shells was practically clean at these points.

These boilers were fed through the blowoff pipe with water that was heated nearly to the boiling point by a good exhaust steam heater, but when this arrangement of piping was discarded and internal feed pipes installed the leaks disappeared and never returned. This experience shows that it is unsafe to decide on the cause of trouble of this kind without thorough investigation.

BRIDGEWALL TOO HIGH?

No objection was made to this high bridgewall by the boiler inspector as long as I remained in charge of the plant, but when visiting the place a few months after taking charge of another plant, I found the bridgewall cut down as illustrated in Fig. 4. It was reported that this was done by order of the boiler inspector, who objected to the high bridgewall because it resulted in the concentration of too much heat at this point.

Since then I have read the opinion of a careful writer on this subject, who points out in an earnest manner what is a fact to him beyond dispute, namely, that a bridgewall should never be cut down in this way, because nearly all of the hot gases will rush for this part of the passage and the result will be a ruined boiler. If either or both of these conclusions were correct, as illustrated in Figs. 3 and 4, it is certain that when a boiler is set as shown in Fig. 1, it would soon be rendered unsafe for use, yet, this is not true in everyday practice; hence my conclusion that a bridgewall is designed to hold the fuel in place and should be strictly so considered. If this part of a boiler shows signs of overheating, it is probably due to other causes.

Fig. 5 shows what was left of a certain bridgewall after wood had been

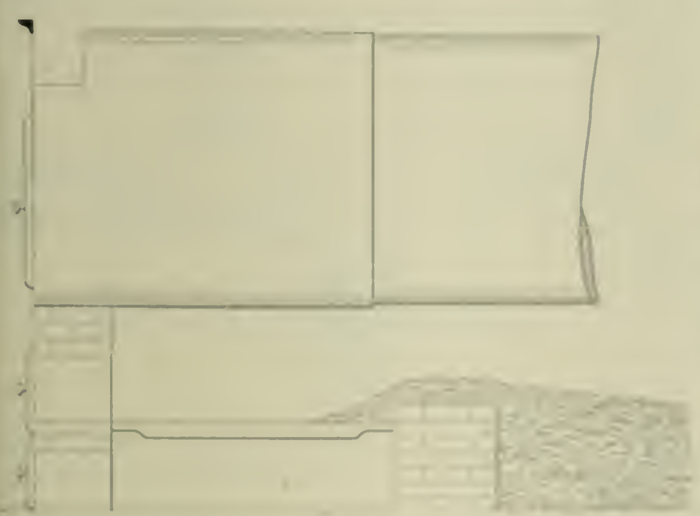

FIG. 5

burned in the furnace for several months. Heat is not concentrated at the point directly above this bridgewall, yet if the internal surface of the plate were covered with cylinder oil it would be overheated and rendered dangerous. The fuel burned in this furnace is not kept in place by the bridgewall for anything short, and while this plan admits of burning long wood and thus saves the labor of cutting it into shorter pieces, there is nothing else to recommend it. On the other hand, when an engineer allows his bridgewall to get into this condition and is satisfied to use it without improvement

he will probably be contented with slipshod conditions elsewhere in the plant, to the detriment of first-class service. If this bridgewall should be properly maintained as shown in Fig. 3 and the wood cut into suitable lengths to enable the fireman to keep the grates evenly covered at all times, it would result in saving much fuel, and be more satisfactory on other accounts.

Fig. 6 illustrates a properly built bridgewall with ample space behind it for combustion to be completed. I know of no

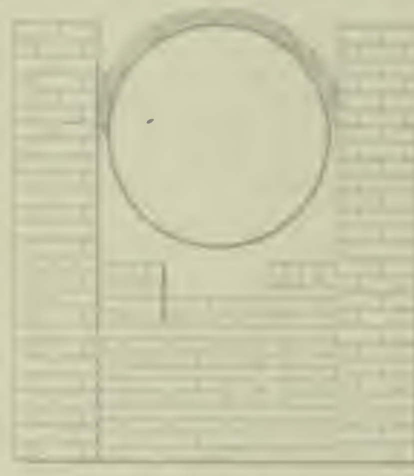

FIG. 4

FIG. 6

better plan, after thirty years' experience along this line, and I therefore consider it as best [illegible]. The heavy dotted line represents the plan outlined by some engineers, as they claim that when the sharp bend comes to be turned, the products of combustion pass over the bridgewall more readily, as the currents of heat; but it is doubtful if this view be correct, because I have never discovered evidence to prove that it is [illegible] the gases to come over [illegible] of a square bridgewall [illegible] what is commonly called a [illegible].

Draining High-Pressure Steam Lines

Why Water Should Collect in the Steam Piping, Its Effect on the System and Methods of Draining it Back to the Boilers or to Atmosphere

BY WILLIAM F. FISCHER

Probably the greatest source of danger to engines of the reciprocating type is the liability of water collecting in the steam-piping system, which unless stopped by a separator eventually finds its way into the engine cylinder in "doses" or "slugs" carried over with the steam flow. This is particularly dangerous in high-speed engines, owing to the small clearance space at each end of the cylinder.

Water Hammer

Pipes are usually proportioned so that the steam travels at the rate of about one mile a minute, or in some cases much faster, hence if a slug of water is picked up by the steam and carried along with it, an accident is apt to occur, either by the rupture of an elbow at a change in the direction of the flow, or by the water entering the engine cylinder. Although in some cases the quantity of water in the steam mains may not be sufficient to cause serious damage, it may, however, cause disagreeable knocking and hammering, which causes vibration, and in time causes the joints to leak. This knocking and hammering, so common in steam-heating plants, is what is known as "water hammer." Professor Thurston has experimentally shown that the pressure produced by water hammer may be as much as ten times, or more, that which the pipe, fittings and valves were originally expected to sustain in their regular work, and this fact is borne out in practice by the number of accidents traced to this cause alone.

Radiation and Pipe Covering

The presence of water in steam mains is due to the condensation of steam in the pipes, and in some cases to priming or foaming of the boilers, where water at times is carried over with the steam in large quantities. Heated surfaces naturally lose heat when brought into contact with a cooler surface or element, thus between two bodies near each other and at different temperatures there exists a tendency toward temperature equalization by radiation, conduction and convexion. A pipe carrying steam at a temperature of from 212 degrees and upward coming in direct contact with the surrounding atmosphere, the temperature of which seldom exceeds 100 degrees, is naturally a cause for rapid radiation of heat from the surface of the pipe to the atmosphere. This rapid radiation of heat causes condensation in the pipes, and is also a direct loss of the heat units derived from the fuel and stored up in the steam, and for this reason should be prevented as far as possible by covering all live-steam lines with a good nonconductive pipe covering.

Condensation and Superheat

Condensation may be divided into two parts: "static" condensation, which occurs when steam fills the pipe, but is not flowing through it, and "dynamic" condensation, which takes place when a valve is opened permitting the steam to flow. It

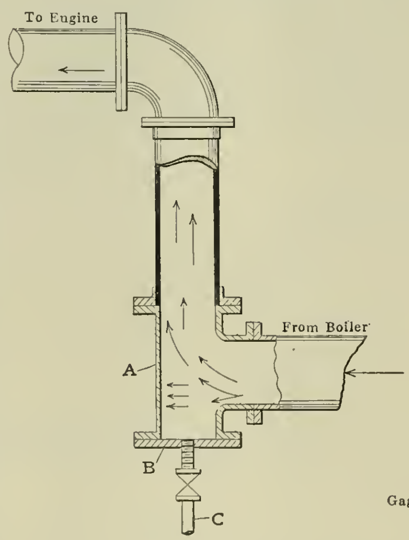

FIG. 1. A CONSTRUCTION OFTEN USED

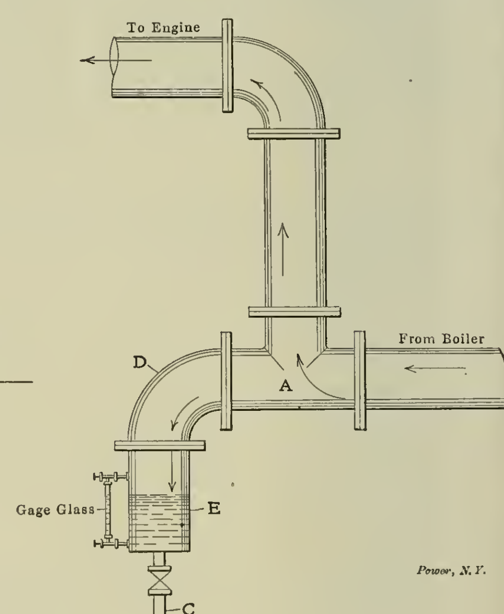

FIG. 2. A BETTER ARRANGEMENT

has been found to all practical purposes that the amounts of condensation are almost equal in both cases.

In modern plants with the use of superheated steam and the proper pipe covering, the condensation losses are reduced to a minimum as long as there is a rapid transference of steam from the boilers to the engines, but there are nearly always certain lengths of idle pipe in the system in which there is no flow; here the steam is bound to condense while the pipes are kept alive, and if they are shut off, there is danger of water forming in them when they are again opened to the steam. Before any water of condensation can form with superheated steam, the surplus heat units or superheat must first be extracted from the steam, or, in other words, the superheated steam must first be reduced to saturated steam at the same pressure, or less, before any condensation occurs.

Initial Condensation

Water has a large capacity for absorbing heat, and when allowed to accumulate in the steam mains has a tendency to condense part of the steam flowing therein. Any steam thus condensed, though perhaps in small amount, must be replaced by the boiler, and the extra steam generated for this purpose alone will amount to considerable money in fuel in a year's time. Initial condensation in an engine cylinder is a good example of this.

Water lying in the cylinder, or swept in by the steam, chills the cylinder walls, which in turn condense part of the steam entering at the next stroke of the piston. Consequently a greater amount of steam must be admitted to the cylinder than would otherwise be required to do the work. This initial condensation causes a corresponding drop in pressure at the engine throttle, and causes pounding and disagreeable knocking in the engine cylinder, as the water is slapped back and forth at each stroke of the piston.

Water in Steam Pipes and Its Effect

The presence of water in the steam mains also causes unequal straining in the piping and at the joints, as it tends to reduce the temperature of the lower side of the pipe as the water is swept along. Some boilers, when heavily fired or forced beyond their rated capacity, especially quick steamers and those having insufficient steam space, have an aggravating habit of throwing over large quantities of water into the steam header. This priming or foaming is also caused by impurities in the feed water, or is sometimes due to the presence of oil in the boilers. Then again, a sudden reduction of pressure in the steam main, such as is likely to occur when an extra engine is quickly cut into service, or to a sudden increase in the load, causes a corresponding reduction of pressure at the boilers, liberating the heat stored in the water. This heat flashes part of the water into steam, and in doing so, causes violent ebullition, and part of the water is entrained and carried over with the rapidly flowing steam to be deposited in the main steam header.

If this water is drained off as fast as it forms, no danger can possibly result from it, but if allowed to accumulate to any extent, the effective pipe area is gradually decreased to such an extent that when a heavy load is thrown on the station the resulting rush of steam toward the engines is bound to set the water in violent motion, projecting it with great force against a fitting or blind flange, and a rupture may result. Pockets or low spots in the piping where water can collect should be avoided, or if impossible to do away with them entirely, they should be dripped to insure keeping them free of water at all times.

Steam connections from the boilers frequently enter the main header at the bottom. This practice should be avoided as it leaves a pocket for the condensation from the header to drain into when either of the boilers is shut down. If it is attempted to run the water of condensation against the steam flow, water hammer is likely to occur, unless the pipe is exceptionally large and the velocity of the steam much below the average, as in heating plants, etc. The steam lines connecting the main steam header with the boilers should enter the header at the top or on the side, and should drain toward the header. All steam lines to the engines should be taken from the top of the header where possible to do so, and should drain toward the engine separator.

Drip Pockets

Tapping a small pipe connection into the bottom of fittings on high-pressure steam mains for drainage purposes is not to be recommended as the steam flowing past a small opening sweeps the water over with it. Drip pockets of large cubical capacity should be used, having an opening or inlet equal in diameter to the steam main to which they are connected, on sizes up to 12 inches inclusive. For pipe above 12 inches in diameter, there is no advantage in increasing the size of the drip pocket, as the capacity of a 12-inch drip pocket is ample to handle all drips from the larger size pipe. These drip pockets provide an opening sufficiently large to catch the water before it is carried past them by the steam, and will also take care of any water carried over with the steam from the boilers should they prime.

All drip pockets should be fitted with gage-glass water gages operated from the floor so the valves can be quickly closed without danger of scalding the operator should the gage glass break. These gages show at a glance the hight of the water in the pocket at all times, also indicating whether the trap or drip return system is operating properly. In all cases it is a good plan to attach a drip pocket at each end of the main steam header, to keep up the circulation and relieve the header of condensation when either of the end boilers is shut down for cleaning or repairs. The greatest flow of steam is necessarily toward the largest outlet in the header, consequently the piping should be dropped through a drip pocket at this point, as water will be swept toward this outlet with the steam flow from each end.

Long lines of piping should be dripped at least every 150 to 200 feet. A tee and 3 or 4 feet of pipe, capped at the end with a blind flange drilled and tapped for a drip connection, is a good substitute for a cast drip pocket, but should be fitted with a gage glass, as mentioned already. Drip lines under different pressures should never be run into one line, but each should be trapped separately.

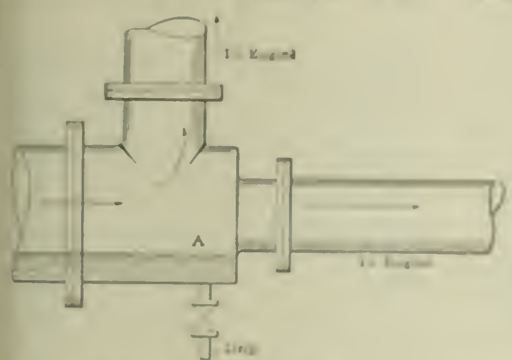

FIG. 3. REDUCING TEE

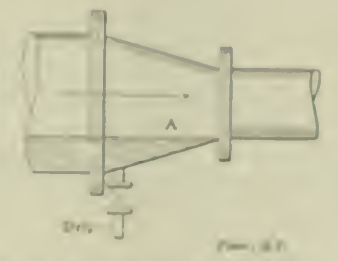

FIG. 4. REGULAR TYPE OF REDUCER

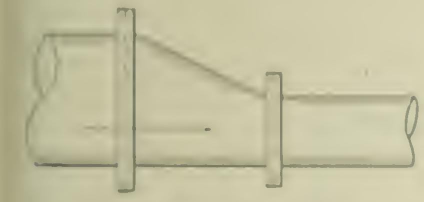

FIG. 5. ECCENTRIC REDUCER

FIG. 6. ECCENTRIC FLANGE

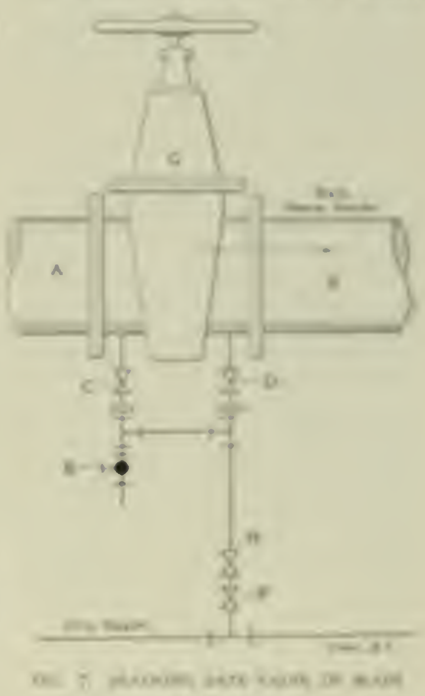

FIG. 7. PLACING GATE VALVE IN MAIN STEAM HEADER

Running Pump from Drip Header

A steam-driven pump for the purpose of boiler feeding, etc., will operate about as well on a mixture of steam and water as it will on dry steam; therefore the water which has been drained into a drip header may be directly beneath it, and the steam connection to the pump taken directly from the drip header. If the pumps are run continually while the main steam line is in service, they tend to keep up circulation and keep the line free of water. If the pumps are shut down, however, there should be another means of removing the water of condensation automatically, either through a trap, gravity return system, steam loop, pump and receiver or other suitable means.

Water drained off through the steam cylinder of a pump should not be again returned to the boilers unless filtered to remove the oil it contains. This holds good for all exhaust-steam drips after passing through an engine or pump cylinder where oil is present. A swinging check valve should be installed in each drip connection between the steam main and drip header, to prevent steam or water from backing up in any section of the steam main while out of service. Since the amount of condensation to be handled by drip pipes is practically an unknown factor, no general rule can be given for proportioning them. The designer must use his own judgment in this, as well as many other matters relating to the design of the piping system.

Draining Water Pockets

Fig. 1 shows a construction very often used in draining the end of a steam line where steam is taken from the top of the header. The line rises through a tee *A* vertically, with one end capped by a blind flange *B* drilled for a drip connection *C*. With this arrangement of the piping, the water of condensation is swept along the header at high velocity by the steam flow, and upon striking the back of the tee is suddenly arrested and broken up into fine particles or drops, some of which are caught up again by the steam and carried up past the elbow and into the engine cylinder unless stopped by a separator. Fig. 2 shows an arrangement of piping

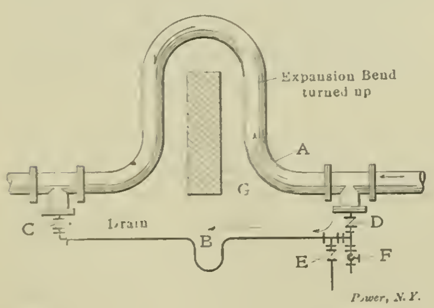

FIG. 9. DRAINING AN EXPANSION LOOP

much preferred to that shown in Fig. 1. The tee *A* is placed horizontally in the line, with the outlet looking up and a drip pocket *E* connected to the extreme end of the line through the elbow *D*. With this arrangement the water of condensation is swept along to the end of the line, falling through the elbow into the drip pocket *E*, where it is drained off through the drip line *C*.

In Fig. 3 is shown a section of a high-pressure steam line provided with a reducing tee. If the steam flow is in the direction of the arrows, a water pocket is formed in the line *A*. If the water which will collect here is not drained off as fast as it forms, a heavy flow of steam will sweep it over to the engine. Fig. 4 shows a line reduced on the run through a concentric reducer of the regular type. The results are the same as in the previous case. Figs. 5 and 6 show how this water pocket may be avoided by the use of an eccentric reducer, or an eccentric flange,

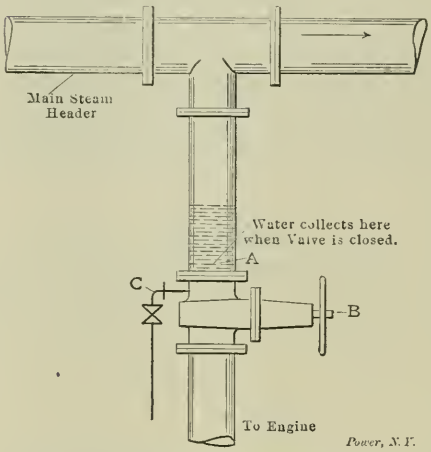

FIG. 8. WHEN STEAM IS TAKEN FROM BOTTOM OF HEADER

in place of the fittings shown in Figs. 3 and 4. The eccentric reducer is to be preferred to the flange in all cases, but the cost will be greater.

In cutting out a section of piping for repairs, or to renew gaskets, etc., workmen are sometimes scalded when breaking joints, due to some pressure still remaining in the line after the main valves are closed. When the bolts are loosened the water of condensation in the dead section gushes out, scalding the face or hands of the workman. The dead section should be well drained before opening the joints.

Fig. 7 shows a gate valve *G* placed in a steam main and dividing it up into sections *A* and *B*. This valve is dripped at each side of the gate or disk, through the drip valves *C, D* and *F*, and check valve *H* into the drip header. Globe valve *E* is for an open bleeder connection. If section *B* is shut down, the drip valve should be closed. The water of condensation forming in the live section *A* is drained off into the header through valves *C, H* and *F*, or if the steam were flowing in the opposite direction and section *A* cut out of service, drip valve *C* should be closed and section *B* drained through the valves *D, H* and *F* into the drip header.

With this arrangement of the drip piping and valves, the line may be used as a bypass around the main valve *G* to equalize the pressure in the dead section, or to warm it up gradually before opening the main valve, thus preventing knocking and pounding in the line due to water hammer. To use the piping as a bypass, valve *F* should be closed, and valves *C* and *D* opened to admit steam from one section to the other. When the main valve *G* is open and steam flowing, drip valves *C, D* and *F* should remain open to drain the line at this point.

When shutting down either section *A* or *B* for repairs, the dead section of the piping can be cleared of steam and water by opening the bleeder valve *E* and blowing out the pressure. For example, if section *A* were shut down, valves *D* and *F* should be closed, and drip valve *C* and bleeder valve *E* opened to the atmosphere, or *vice versa* with section *B* shut down. The check valve *H* is to prevent the water in the drip header from backing up into either section of the steam main when out of service, should the attendant forget to close the drip valves *C* and *D*. All the valves in the main line may be dripped in this manner satisfactorily.

When steam is taken from the bottom of a main, as shown in Fig. 8, the water of condensation collects at *A* when valve *B* is closed. The valve should be tapped above the seat for a drip connection at *C*. This drip line should be connected to a trap or into the drip header.

When installing an expansion loop or bend, it is sometimes impossible, for want of sufficient space, to place it horizontally as it should be, or, again, it is sometimes necessary to carry a steam line over an obstruction, as shown at *G*, Fig. 9. With

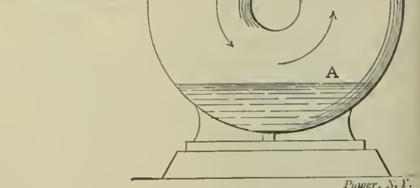

FIG. 10. CAST-IRON EXHAUST ENTRAINER

the bend turned up as shown, a water pocket is formed in the line at each end of the bend. A drip line should be placed as shown and bent at *B* to take up the expansion. The steam flowing in the direction of the arrows, travels up and over the expansion bend *A*, while the water travels along through the drip line below through valves *D* and *C*. A bleeder valve is provided at *F* and a connection to the main drip line or to a trap is made through the valve *E* in case it is required to drain the water off at this point. Valves

D and *C* should always remain open while the line is in service, to insure the water of condensation being carried on with the steam flow past the pocket at the inlet side of the bend at *A* in case the trap does not work properly or in case valve *E* is closed.

The drainage from any part of the steam-piping system is valuable on account of the water and the heat it contains, and should be returned to the boilers again by suitable means. Fuel is an important and expensive item of cost and any means of saving fuel is a means of increasing the earning capacity of a plant, large or small. Sometimes the saving due to returning high-pressure drips to the boilers in small plants is not sufficient to warrant the expenditure for the necessary apparatus to do so. This is a point to be determined by the engineer familiar with the existing conditions.

Low-pressure Drips

Condensation from exhaust-steam lines always contains more or less oil, and for this reason should be filtered before returning to the boilers, as the presence of oil in the boilers causes burning of the plates and sagging. As a general rule this condensation is collected in a drip line and led off to the sewer, trench, condenser overflow tunnel or other convenient points, as in most cases it does not pay to attempt returning these drips to the boiler.

Fig. 10 shows an exhaust entrainer for removing the water of condensation from exhaust pipes in condensing systems. It consists simply of a double elbow which provides a pocket at the foot of the riser into which the drip water from the engines may drain, and is so arranged that the exhaust steam must pass over the surface of the water at *A*. The action of the exhaust steam is to entrain or pick up minute particles of water and carry them upward to the condenser, whatever the hight of the latter. The particles are so infinitesimal that the loss of vacuum under any ordinary condition cannot be detected. These entrainers being provided with a substantial foot, serve as a support for the exhaust riser. They are chiefly used in connection with barometric condensers or condensers of a similar type.

Exhaust-steam mains under vacuum cannot be drained direct to the atmosphere while the condenser is in operation, as the minute a drip valve is opened, in place of the water flowing out, air rushes in and breaks the vacuum. There are several other methods, however, of draining exhaust-steam lines under vacuum, such as through a vacuum trap, tilt pump and receiver, etc., which it is not the writer's intention to discuss here.

Wet versus Dry Compression

By Joseph H. Hart

To the average operating engineer at the ammonia compression system the terms wet and dry compression are more or relative and have no special significance. He knows that there are several methods of operating refrigerating machines in regard to temperatures, load and back pressures and he has as a general thing his own little theory in regard to best conditions of operation. He also knows in a general way that various types of machines and various manufacturers are committed especially to the wet-compression, whereas others utilize the dry-compression type, and that in the wet-compression system the operation of compression is accomplished by carrying frost back on the suction pipe to the inlet valve of the compressor and in some cases completely covering the compressor with frost. The meaning of these two terms, however, and their significance from a scientific viewpoint, and the various factors which go to determine the relative efficiency of the two types are matters practically unknown.

Now, in order to understand what is meant by these relative terms, it can be said in a general way that all ordinary compression is dry compression and yet the two terms are often used with a more general significance. Thus, air compression can be either dry compression or wet compression depending upon the presence or suspension of water vapor in the air during compression. In the other significance air compression is always dry compression and wet compression is impossible with that material except under conditions only obtainable in the physical laboratory. It can be said [illegible] in ammonia compression that the terms wet and dry compression have to do with the latter significance and are [illegible] connected with the presence or absence of water vapor in the material.

Now, dry compression in this latter significance of the term is accomplished whenever a gas is compressed. Wet compression only [illegible] when a vapor is compressed. The difference in the meaning of the words gas and vapor is all important. A vapor is a gas near the temperature of condensation of the material. Another definition can be stated as follows: A gas is a vapor above the critical temperature. The critical temperature of a substance is the temperature above which a gas cannot be liquefied no matter to what [illegible] the compression; only [illegible] it will always remain a gas and possess all the properties of the [illegible]. A gas follows Boyle's law and Charles' law so [illegible] variation of pressure, volume and temperature [illegible]

[illegible] the product of the pressure and volume is a constant quantity and this constant according to Charles' law is directly proportional to the absolute temperature of the material. Thus keeping the pressure [illegible] constant the [illegible] in direct proportion to the absolute temperature of the gas. These laws do not hold for vapor, however. The product of the pressure and volume is not a constant [illegible] of either one in the case of vapors, even though the temperature is kept constant. It is this peculiar property of vapors and gases which is the ultimate basis of the relative efficiency of wet and dry compression.

Ammonia Compression Characteristics

Ammonia compression is complicated still more than the compression of an ordinary vapor by the fact that the compression [illegible] of a temperature immediately in the vicinity of the temperature of condensation and often passes through this temperature during the process of compression. In dry compression the work done on the gas in compression is at least evident in an increase in temperature. The quantity of heat produced is an exact equivalent to the work done on the gas [illegible] in this compression that the compressor often operates at its maximum efficiency with [illegible] indication of work, and the transformation of this work into heat lowers very greatly the efficiency of the compression, due to the rise of temperature of the gas with a resulting increase in the amount of effective pressure required for compression. Thus the object in compression is to compress the gas and remove the heat of compression as fast as produced. It is impossible to do this with any great facility and the result is that the heating effect is often cumulative. What is known as cylinder reheating is due to the fact that the cylinder walls become heated on the compression and upon the opening of the inlet valve again for a second charge the incoming gas is at once heated by contact with the hot cylinder walls. This reheating effect gives the result of an increase in the initial pressure of the gas during compression.

The same [illegible] a portion of the gas [illegible] back through [illegible] is a decrease in the density of the gas at constant pressure, or what is considered to be leakage [illegible] with a [illegible] in the capacity of the ammonia compressor [illegible] of a compressor [illegible] the capacity of an ammonia compressor [illegible] of ammonia gas compressed [illegible] operating [illegible] city of the compressor diminish greatly but the heating effect continues and results in an increase in average pressure throughout the stroke and a lower efficiency of compression as well.

The jacket of the average ammonia compressor is hopelessly inadequate in the performance of its duty in the cooling of this unit. The heating effect of compression is largely a skin phenomenon limited at high speeds to the intense heating of a thin layer on the interior of the cylinder walls and cooled by recharging before conduction to the water jacket has had time to get in its effect. The old De Lavergne type of compressor, utilizing an auxiliary oil circulation through the compressor, was designed for the purpose of producing an internal water jacket in its effect and for the elimination of clearance evils as well. That the net result was an increase in complexity in the operation of the compressor, with a loss rather than increase in efficiency, is now an accepted conclusion.

Today compressors in which this phenomenon occurs are the common existing type and are the factors which limit the speed of operation and are the greatest limitations on efficiency of the process. The average air compressor is essentially of this type and the evil effects due to reheating and clearance are merely augmented by the presence of water vapor as existing in normal air. Thus, the removal of the water vapor from air presents a form of dry compression, whereas its presence constitutes wet compression, and the effect of water vapor in its influence on efficiency is the determining factor in the two cases. Air and ammonia under these circumstances are two typical gases and dry compression is the resulting phenomenon which occurs in the operation of the compressor.

Now, in the operation of the ammonia compressor it was found possible by injecting a little ammonia liquid into the cylinder on each stroke to keep the material cool throughout the entire period of compression. This does not mean that the heat is not produced. The same, or at least a definite, amount of heat equivalent to the work done is produced on each stroke of the piston. This heat, however, does not result in an increase in operating pressure as it does in the case of gas compression, due to two reasons. One is that the resulting increase in pressure due to heating effect would not be as great in the case of a vapor as in a gas and the other is due to the fact that the heat as fast as produced is absorbed by the vaporization of a portion of the ammonia liquid present in the cylinder. Thus the utilization of this device results in the elimination of two evils, with the production of two additional ones.

Reheating Effect Eliminated

The reheating effect, with consequent diminution in density of the incoming charge and of capacity in the cylinder for the same, is totally eliminated by keeping the cylinder walls cold, but the capacity of the cylinder is reduced in turn by the volume of the ammonia liquid injected per stroke, and the work is increased by the fact that the piston operates against the vapor which is produced by vaporization from the ammonia liquid present in the cylinder when the latter is heated by the heat produced by compression. Thus, the saving is more imaginary than real and is a question of relative efficiencies merely. In dry compression every ounce of ammonia gas which passed through the cylinder was ultimately used for the production of available refrigeration. On the other hand, in wet compression a portion of the ammonia liquid available for the production of refrigeration becomes no longer available for this purpose, since it is evaporated in the cylinder and the heat of vaporization used to produce cooling in the compressional charge during compression rather than in commercial cooling where desired. Thus, the ammonia which passes through the compressor or through the condenser is no criterion or measure in the wet compression system of the amount of refrigeration produced.

While the preceding conditions represent the ideal phase of the wet compression it is not accomplished by any means in practice except under abnormal conditions and is not believed to be the most efficient process. The significance of wet compression is complicated by the fact that there is no real dividing line between the two types. The exact point where the vapor ceases to be a vapor and becomes a gas is dependent upon its critical temperature but this temperature does not enter in many developments. Thus, in air compression the critical temperature is so low that throughout the entire cycle of air changes the critical temperature is never even approached. On the other hand, the critical temperature of ammonia gas is relatively so high that almost throughout the entire stroke it is never approached from the other side.

Again, in ammonia compression matters are complicated by the introduction of what is known as saturated vapor. A saturated vapor is a vapor in contact with its own liquid. Increase in pressure or temperature on such a mixture results in variations in the amount of vapor present, since variations in pressure under such conditions results often in a variation in density without effect upon the pressure or apparent volume. Real wet compression in ammonia is the compression of a saturated vapor throughout the stroke; that is, ammonia liquid is present throughout the entire period of compression. The density of the vapor increases greatly on account of the further production of extra vapor from the liquid during the process. If the liquid injected at the beginning of the stroke is only sufficient to keep the vapor saturated throughout a portion of the stroke, that is, if the heat produced is more than enough to vaporize all the liquid present, then the stroke is no longer absolute wet compression. It is a mixture of wet and dry compression, with the variation between the two not occurring immediately at the complete evaporation of the liquid.

Thus, some wet-compression systems exist in which practically no liquid is injected. The vapor is practically at its condensation point and saturated at the beginning of the stroke, a fine mist of the liquid only being present. This explains the reason why there exists such a variation in possible compressions. In actual practice the conditions occurring inside the cylinder are largely evident from external conditions. The property of ammonia gas is largely a function of the temperature, especially at a given suction pressure. Hence the different phases of dry and wet compression can be readily attained by varying the temperatures of the charge. If the frost is carried back to the inlet valve of the cylinder practically partially wet compression is occurring. If the frost is carried completely over the cylinder so that the water jacket has a layer of ice on its surface, it can be assumed that a portion of liquid ammonia is injected on each stroke, or that the vapor is so saturated with ammonia mist that it behaves in this manner. However, it is possible, with extremely cold condenser water to have this compression occur under these conditions without normal wet compression in the strictest sense of the word. However, such temperatures of condenser water would be extremely abnormal.

The efficiency of a compressor is a function not only of temperatures but also of speed. The result is that the average operating engineer should attempt to get a maximum speed out of his compressor with minimum steam consumption and minimum temperatures on the ammonia gages. Available refrigeration is in every case directly proportional to the work done and hence the speed, if the pressures are the same in the two cases, and it is the generally accepted opinion today that ammonia compressors operate best under normal condenser-water temperatures when the frost is carried back on the suction pipe to within a few inches of the inlet valve of the compressor and the attempt made under these circumstances to speed up the compressor to the extent that the water jacket gets fairly hot or at least is warm to the touch. The frost will invariably slide in one direction or the other without regular attention but it represents undoubtedly the point of maximum efficiency in the operation of the plant.

Hydraulically Operated Valves for Curtis Steam Turbines

The speed of the steam turbine is controlled for different loads by successively opening and closing valves, thereby putting into use more nozzles which admit steam to the first wheel. These valves are of the poppet type, each being closed by a helical spring. The valves are all duplicates and are opened in rotation by cams mounted on a shaft, each cam having an angular lead over that preceding it. The cam shaft is actuated by the piston of an hydraulic cylinder, causing the valves to open so that throttling occurs on opening or closing a valve before the next one opens or closes, thereby regulating the amount of steam admitted for any load.

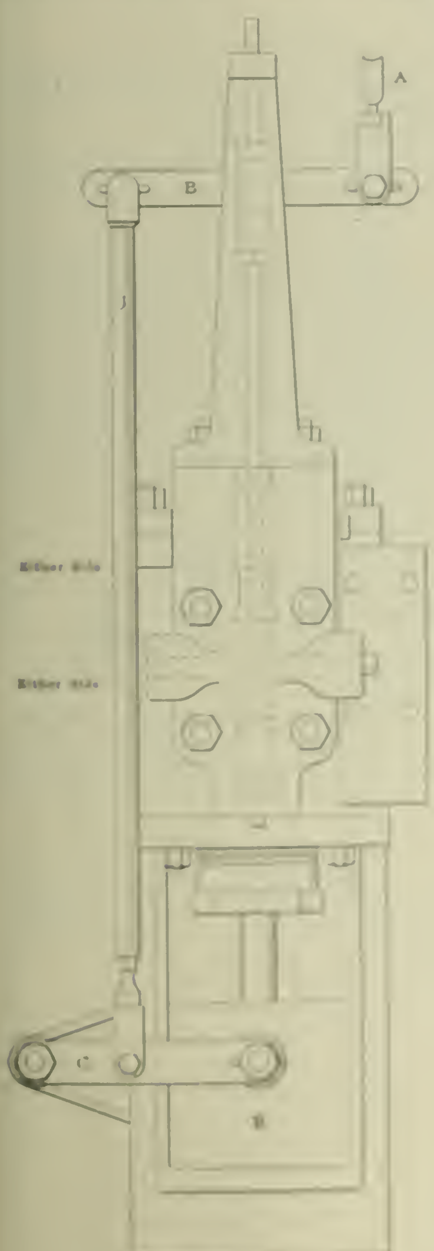

FIG. 1

FIG. 2

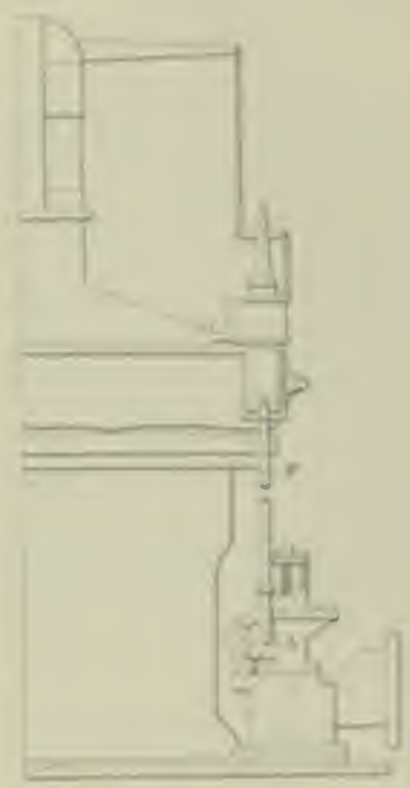

FIG. 3

Referring to Fig. 1, the rod A is actuated by the governor, the lever arms B and C being so arranged that the piston D, Fig. 3, will stay in a fixed position to correspond with any position of the rod A, Fig. 1, as the crosshead E, [illegible] connected through a connecting rod F, Fig. 3, to the cam shaft [illegible] therefore there will be a fixed position of valves open for any position of the governor. While the turbine is running at a fixed speed the piston valve will occupy a central position closing both ports, G and H, Fig. 2. If the speed decreases the governor will move the rod A, Fig. 1, down, opening the port G to the discharge port and port H to admit liquid under the piston, thus opening more valves and thereby increasing the speed. In turning, the piston [illegible] the rod J, Fig. 1, upward and moves the valve B to its central position again.

On a good working machine, a [illegible] valve will drop of its own weight to the [illegible] connecting the rods A and J from the lever B. I have experienced some trouble [illegible] this valve [illegible] thereby affecting its work. It is necessary that the connections between the valves and governor be free from friction and no binding at any joints, and the liquid must be clean and free from grit for good service.

William Butler.

Somerville, Mass.

Pressure Required to Lift a Check Valve

Referring to a letter appearing on page 201 of the January 26 number, entitled, "Pressure Required to Lift a Check Valve," I do not agree with Mr. Helms in the following respects:

For instance, Mr. Helms describes a conical poppet double-seat valve so proportioned that the pressure on the front of the valve may equal the pressure on the back of the valve at the moment of opening, the pressure per square inch being the same in each case. This valve, as illustrated by Mr. Helms, is shown in Fig. 1. A recess is cut or cast circumferentially around the valve disk at *a a*, and the fluid pressure is led into this recess through ports *b b*.

Mr. Helms states: "It is evident that if the area of this recess represented by 0.7854 $(d_1^2 - d_2^2)$ is equal to the projected area of the seat, 0.7854 $(d^2 - d_3^2)$, the valve will open when the pressure per unit area on the front is equal to the pressure per unit area on the back of the disk, since the areas exposed to the action of the fluid pressure are equal on both sides." The weight of the valve disk itself is, of course, neglected in this case.

The point I wish to make clear is this: By referring to Fig. 1 it will be seen that the fluid pressure acting vertically in the recess *a* on a circumferential strip of width *Y* acts up, and reacts down in the recess, and is thus balanced as shown by the arrows and their direction. This pressure, being balanced, has no tendency to lift the valve from its seat. In this case the tendency is to rupture the valve disk itself. Probably this can be better understood by referring to Fig. 2. Here the valve disk is represented as a piston *A* fitted into the cylinder *B*. The diameter of the piston D_4 equals D_4 in Fig. 1. The piston is recessed at *a a*. The dimensions D_4, *Y* and d_2 are equal in both cases.

As before, the fluid pressure is led into ports *b b*. Here it is quite evident that any pressure admitted to recess *a* through port *b* has no tendency to lift the piston, as the forces are balanced vertically. If this is true in both cases, Fig. 1 and 2, there is only the area of a circumferential strip of width *x*, Fig. 1, as the effective area of recess *a*.

The pressure acting up against the strip *x*, reacts down against the sides of the conical valve seat, tending to separate the two bodies. The projected area, or area of strip *x*, equals 0.7854 $(d_1^2 - D_4^2)$. This, it would appear, represents the effective area of the recess acted upon by the fluid pressure, and not the area 0.7854 $(d_1^2 - d_2^2)$, as given by Mr. Helms.

As the sum of the areas, 0.7854 $(d_1^2 - D_4^2)$ and 0.7854 d_3^2, does not equal the area 0.7854 d^2, or in other words, as the area of the front of the disk plus the area of the circumferential strip *x* does not equal the area of the back of the disk, the pressures per square inch will not be equal on both sides of the valve at the moment of opening. Thus, with a valve

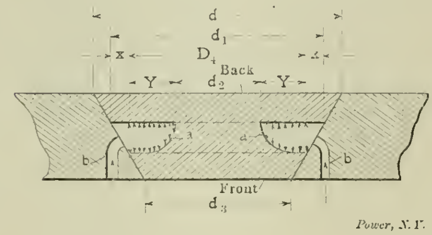

FIG. 1

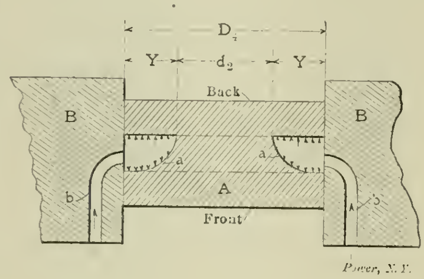

FIG. 2

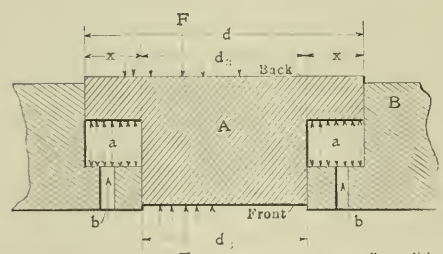

FIG. 3

of this type the pressure per square inch on the front, or under side, will necessarily have to be somewhat greater than the pressure per square inch on the back, or upper side, in order to raise the valve disk from its seat. This is, of course, providing the valve disk makes perfect contact, metal to metal, with the seat, and is not separated by a thin film of the fluid, in which case, neglecting the weight of the disk, the difference in pressure necessary to cause the liquid to flow through the opening should be sufficient to unseat the valve.

If the weight of the valve disk is taken into consideration, the pressure on the under side must necessarily be somewhat greater in order to hold the disk open. Ordinarily, the kinetic energy of the flowing liquid should be sufficient to do this if the disk is not of great weight.

If the valve was arranged as shown in Fig. 3, and the pressure per square inch equal, front and back, the total force *E*, acting up, will equal the total force *F*, acting down, as the areas acted upon by the fluid are equal, both front and back, inasmuch as $d_3 + 2x = d$.

Mr. Helms also makes the following statement: For valves having a circular cross-section the pressure will be equal on both sides at the moment of opening, neglecting the weight of the disk, when the valve is proportional as expressed by the following equation:

$$d_2 = d_1^2 + d_3^2 - d_2^2.$$

This is evidently an error, as the formula should read

$$d^2 = d_1^2 + d_3^2 - d_2^2$$

or

$$d = \sqrt{d_1^2 + d_3^2 - d_2^2}\ .$$

However, if the foregoing reasoning is correct, this formula will not hold good for the valve in question.

William F. Fischer.

New York, N. Y.

Under the above caption, F. C. Helms, on page 201 of the January 26 number, says: "It is evident that if the area of this annular recess, represented by 0.7854 $(d_1^2 - d_2^2)$, is equal to the area of the seat, 0.7854 $(d^2 - d_3^2)$, the valve will open when the pressure per unit area on the front is equal to the pressure per unit area on the back, since the areas exposed to the action of the fluid pressure are equal on both sides. For valves having a circular cross-section, the pressures will be equal on both sides at the moment of opening (neglecting the weight of the valve), when the valve is proportioned as expressed by the following equation: $d_2 = d_1^2 + d_3^2 - d_2^2$."

The letters refer to the dimensions shown in Mr. Helm's article. The above equation is evidently a misprint, and from the previous discussion I judge it should read: $d^2 = d_1^2 + d_3^2 - d_2^2$.

What I take exception to is his statement regarding the annular recess. He evidently expects to balance the poppet valve by this recess. Mr. Helms falls into an error when he says the valve is balanced when $d_1^2 - d_2^2 = d^2 - d_3^2$.

To explain this, I have enlarged that part of his illustration, as shown in Fig. 1. This shows the recess when pressure is admitted to the recess through the port *B*. The effective area of the recess that helps to lift the valve is 0.7854 $(d_1^2 - d_4^2)$.

To make this clear I have drawn reacting forces at *C* that include all forces in the effective area given above. At *A* I have drawn reacting forces that include all that do not fall in the effective area. As will be seen, the forces at *C* will react and help lift the valve, while those at A will neutralize each other and act as so much dead water.

It will be seen, then, that to fully balance the poppet valve by Mr. Helms' method would require $d_1 = d$ and $d_4 = d_3$ which is a condition not to be considered.

Partially balanced valves have been built on the double-beat principle, see Fig. 2, which is a modification of the idea suggested by Mr. Helms. Let D_1 and D_2 be the diameters of the larger and smaller seats of a double-beat valve, and P the effective pressure of the fluid in pounds per square inch. Then the force required to open the valve equals $0.7854\ (D_1^2 - D_2^2)\ P$, neglecting the width of the seats and the weight of the valve.

FIG. 1

From this it is evident that by making the difference between D_1 and D_2 small, the force required to open the valve will be small, and consequently the extra pressure required to open the valve will also be small.

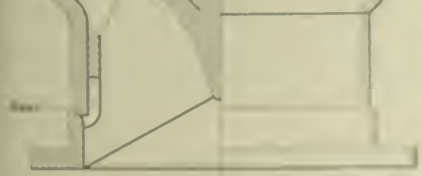

FIG. 2

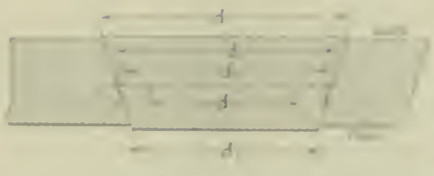
The double-beat valve shown in Fig. 2 was designed by A. F. Nagle, and is now pumping water under an effective pressure of 52 pounds per square inch. The valve is worked automatically by the water. The seats have a [illegible]-inch bearing surface, and are made of bronze.

JOHN B. SPERRY.

Aurora, Ill.

On page [illegible] of the January 26 number is shown a sketch of poppet double-seated balancing valve which I think would fail to balance in actual practice. To illustrate the point I take exception to I submit a sketch similar to the one mentioned.

Mr. Helms states that "it is evident that if the area of the annular recess represented by $0.7854\ (d^2 - d_1^2)$, is equal to the area of the seat, $0.7854\ (d_2^2 - d_3^2)$, the valve will open when the pressure per unit area on the front is equal to the pressure per unit area on the back, since the areas exposed to the action of the fluid pressure are equal on both sides." This statement is wrong, as he has not taken into consideration the effect of the pressure acting on the area of the surface represented by $0.7854\ (d_4^2 - d^2)$, see sketch, which acts in a downward direction opposing the pressure tending to lift the valve. The pressure acting toward lifting the valve should be obtained by $0.7854\ (d_1^2 - D^2)$, and is shown graphically by the open triangle in the sketch herewith presented.



MR. CAREY'S SKETCH

T. CAREY.

Albany, N. Y.

Repairing a Crank Disk

Our main [illegible] Watertown simple engine, running at [illegible] revolutions per minute, began to pound badly and I lost no time in shutting down. When the engine came to a stop I found the crank disk cracked across its face, the crack passing through the lower part of the crank-pin hole and extending to within [illegible] inch of the outside edge of the crank disk.

As it would require a week or ten days to obtain a new disk, we decided to shrink on a band. A piece of [illegible]-inch steel was rolled and welded into a band and turned up in a lathe [illegible] inch smaller than the disk. After heating the band in an open [illegible] fire to expand it, we forced it on the disk, and as it cooled it drew the crack together so it could hardly be noticed.

After connecting the crank pin we started up, and the engine ran for [illegible] a week, when the crank pin showed signs of being loose in the disk. I took the pin out and [illegible] punched it all around and drove it in again. I put it in the [illegible] [illegible] [illegible] [illegible] of [illegible] any signs of loosening.

[illegible] but [illegible] the company decided to have a new disk put on. I had a new one cast [illegible] inches larger in diameter than the old disk, and as the old disk had a hole of [illegible] size in the center [illegible] a shaft hole, it allowed the new disk to be used. I [illegible] [illegible] than the old one.

When the new disk was ready I went [illegible] engine from the boiler and heated the disk as hot as possible with steam, which so expanded it that with the aid of four [illegible]-inch rods running back over the hub of the driving wheel it was pulled on [illegible].

SHOWING THE CRACK IN THE CRANK DISK

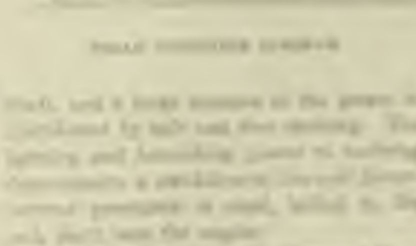
H. T. [illegible].

[illegible], Me.

Freak Indicator Diagram

The accompanying diagram is from an engine of a type sold by the C. H. Brown company about [illegible] years ago. The cylinder diameter is [illegible] inches, stroke [illegible] inches, revolutions per minute [illegible] and the steam pressure [illegible] pounds.

The engine is belted to [illegible] line shaft,



FREAK INDICATOR DIAGRAM

shaft, and a large amount of the power is distributed by belt and line shafting. The lighting and [illegible] ... [illegible] ... the engine.

It was [illegible] by other diagrams from the engine [illegible] [illegible] [illegible], but it was one of the [illegible] [illegible]. The engineer [illegible] all the [illegible] for a moment so that I could get my diagrams quickly, and then throw the generator on again before the motors had stopped. I got the crank-end diagram, but took the head-end just as he threw in the main switch and blew several fuses. I suppose there is some connection between the short-circuited generator and the freak diagram, but have been unable to decide where it lies.

EARL R. FILKINS.

Chicago, Ill.

An Obscure Electric Circuit Trouble

Not having seen any suggestion as to the cause of the arc-circuit trouble of Mr. Minton I would like to make a suggestion as to the probable cause and also explain some of the conditions which probably exist. To begin with, the arrangement of stepping down the voltage from the high-tension lines is not to be recommended, as the arc circuit is electrically connected with them, and the trouble in this case seems to be on that account. It is more advisable to have a transformer with a 11,500-volt primary and an 8000-volt secondary. This would insulate the transmission lines from the arc circuits. The arrangement now is an auto-transformer with an 8000-volt tap.

What I think caused the trouble was a ground on the one leg of the high-tension lines which the auto-transformer is not connected to, and also the high-resistance ground in the underground wires where the lead cable is split and the rubber insulation is deteriorated. As noted, when the stab switch on the regulator side of the arc circuit was inserted, the regulator moved to its extreme position; this could only be expected, as there were but forty lamps burning. It had to act that way to hold the current down. On inserting the stab switch on the opposite side of the circuit, the meter reading there was only four amperes, and to account for this, I think that the current divided at the ground in the underground wire, taking two circuits to the generator; the one circuit which took four amperes went by the way of the lamps and the 2000-volt tap of the auto-transformer, and the remainder of the current went by the way of the grounded arc circuit to the grounded high-tension leg.

It was said that the resistance to ground on the arc circuit was one megohm, but although this ohmic resistance is high, the dielectric strength of the insulation may have been very low, so that when the arc circuit was thrown on the current kept arcing through the small holes in the rubber to the ground, this enabling the ground circuit to form. The discharge of the lightning arrester at the instant of the closing of the arc circuit was due to the ground leg of the high-tension line and also the surge of current through the regulator and the forty lamps. This, of course, happened before the regulator or lamps had a chance to act, thus practically causing an instantaneous short-circuit on the transmission line.

The reason the circuit acted the same way when transferred to the switches of No. 2 circuit was on account of the cause of the trouble not being removed. But when the transformer was changed to a different source of supply, the circuit acted O. K. This proved that the former supply circuit was grounded. An arc circuit can be operated if only one ground exists on the circuit, but it is advisable to get rid of it as soon as possible.

It was not necessary to put a solid ground on the circuit where the cable was grounded to find out if there was a ground between the last lamp and the transformer, because if there was one, it would soon burn itself free or burn up the primary of the transformer, for in a case such as this the 2000-volt primary would be placed across a 11,500-volt circuit. But the solid ground helped out in such a way that it caused two good circuits through the lamps, and instead of the load being on one phase it was thrown across two of the three phases. The circuits formed were as follows: One circuit flowing through the regulator and the forty lamps to ground, the regulator holding the current down so that the lamps would burn; the other circuit was through the primary of the transformer and the other seventy lamps, the voltage per lamp in the latter circuit being greater than normal by about 20 volts at least. If this circuit burned all right, it is probable that the high-tension voltage is less than stated in the sketch. The reason the regulator started to burn after placing a solid ground on the lamps, was because the resistance of the first circuit through the regulator, forty lamps, the solid ground and the grounded high-tension leg was reduced considerably, this overloading the regulator more in this case than before the circuit was solidly grounded.

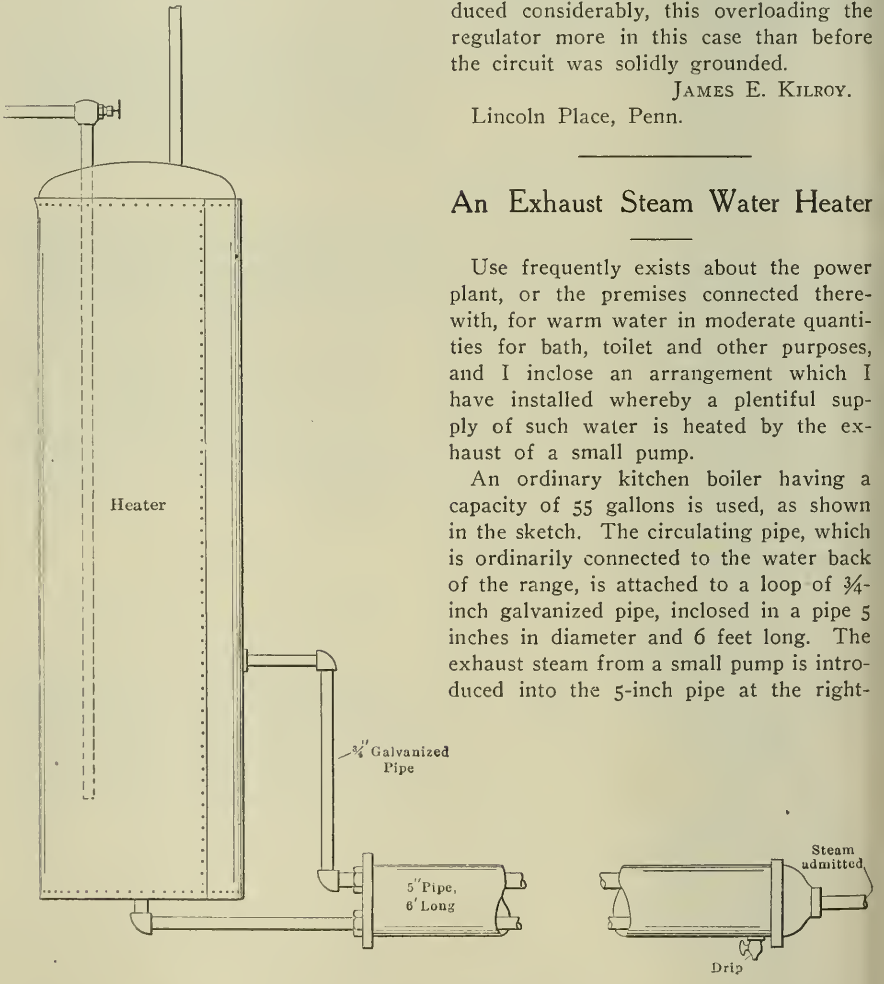
JAMES E. KILROY.

Lincoln Place, Penn.

An Exhaust Steam Water Heater

Use frequently exists about the power plant, or the premises connected therewith, for warm water in moderate quantities for bath, toilet and other purposes, and I inclose an arrangement which I have installed whereby a plentiful supply of such water is heated by the exhaust of a small pump.

An ordinary kitchen boiler having a capacity of 55 gallons is used, as shown in the sketch. The circulating pipe, which is ordinarily connected to the water back of the range, is attached to a loop of ¾-inch galvanized pipe, inclosed in a pipe 5 inches in diameter and 6 feet long. The exhaust steam from a small pump is introduced into the 5-inch pipe at the right-hand end and escapes from a pipe at the other end, as shown, a drip being provided at the lowest point to carry off the water of condensation. The loop is thus always surrounded with exhaust steam, which by heating the water inside produces a circulation, keeping the contents of the boiler sufficiently warm. However little may be drawn from the boiler, its temperature can never rise above the boiling point at atmospheric pressure, and hot water and not steam will come when the tap is opened.



AN EXHAUST-STEAM WATER HEATER

J. A. LOYER.

Montreal, Can.

An Engine Turning Device

The sketch shows an engine-turning device I used in one of my plants. It is simple and works well. When one lifts up the lever the link will slide down and grip the rim for a new pull. The illustration shows its construction.

AN ENGINE-TURNING DEVICE

More Frequent Internal Inspection

The editorial under the caption "More Frequent Internal Inspection" deserves more than passing notice. In considering the value of a boiler inspection two facts should always be borne in mind: First, there are boiler inspectors and boiler inspectors, and they are not by any means all alike. The personal equation plays a very important part in their work; second, the boiler inspector sees the thing from a different viewpoint. He is interested in risks, the boiler owner is interested in economy. It was with the thought of recouping possible loss that the owner in the first place took out a policy. So there you are.

The man who places too much reliance in the boiler-inspector's report is very likely to wake up some morning a sorry man. And this does not presuppose that the inspector did not do his work conscientiously, either. Perhaps he has. Perhaps he has discovered that the tubes are coated with scale, and so states in the report. But the risk is good, and he is not particularly concerned whether you are burning a wee bit more coal because of the scale, and so he says: "Oh, there isn't enough to bother with." Take his word for it, and you'll pay for it in hard cash. But it is to be remembered that there are plenty of cases where scale is present and the inspection has not revealed it. A few concrete cases may be cited.

About four years ago a boiler-tube cleaner was sent on trial to the Petersburg electric-light plant, Petersburg, Ill. The cleaner was tried, ten wheelbarrow loads of scale were taken out "and the boilers were considered by the inspectors to be in good shape," the president reported.

In the May 7, 1908, issue of *Electric Traction Weekly* there was published a paper by A. M. Allen, a consulting engineer. Following is an excerpt:

"As an example, the writer knows of a plant having four 150-horsepower return-tubular boilers, operating twenty-four hours per day, which were pushed to their utmost to furnish the necessary steam, and the insurance inspector's after their examination reported the boilers as being clean. At about this time an enterprising salesman arrived with a tube cleaner which he induced the management to try. This was put through the tubes and scale taken out by the bushel, the result being that they are now operating their plant on only three of the boilers."

Take another case: Last July, a boiler-tube cleaner was sent to the Clinton prison, Dannemora, N. Y., for trial. Among other things, Mr. Gilbert, superintendent of industries of the institution, in his report stated: "I removed [illegible] pounds of scale from our No. 1 boiler, and directly after an inspector's report of 'clean boiler' I took out [illegible] pounds of scale from our No. 2 boiler."

These concrete cases prove nothing if they don't prove that it pays to investigate boiler conditions yourself regardless of what the inspector's report is. You have done a distinct service by touching on this matter.

H. E. GARSWORTH.

Buffalo, N. Y.

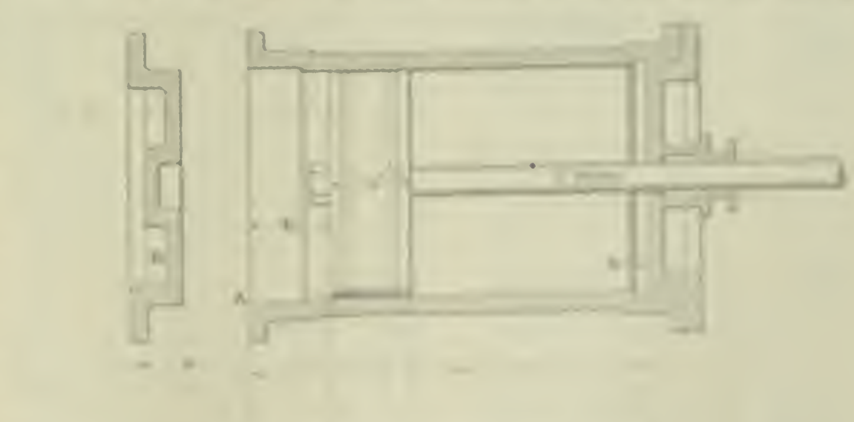
Method of Adjusting Pistons

To adjust a piston for clearance in a large engine requires considerable hard work. The following is an idea I picked up some time ago that makes it an easy job:

Presuming the piston is out of the cylinder, take a 2x1½-inch stick a little longer than the cylinder and, placing it inside against the front head, make a mark at the end of the cylinder at *A*. Say we have an engine with a 27-inch stroke, piston head 12 inches thick, false head 5 inches thick and the cylinder from *A* to *B* 44½ inches. Lay off these measurements on the stick and you have ½ inch *b-b*, which represents ½ inch clearance on each end. When putting the piston in place, adjust it so that the distance from *A* to *C* is [illegible] and clearance will be equal on both ends of the cylinder.

CHARLES J. [illegible].

[illegible], Mass.



METHOD OF PISTON ADJUSTMENT

Two Loose Nuts

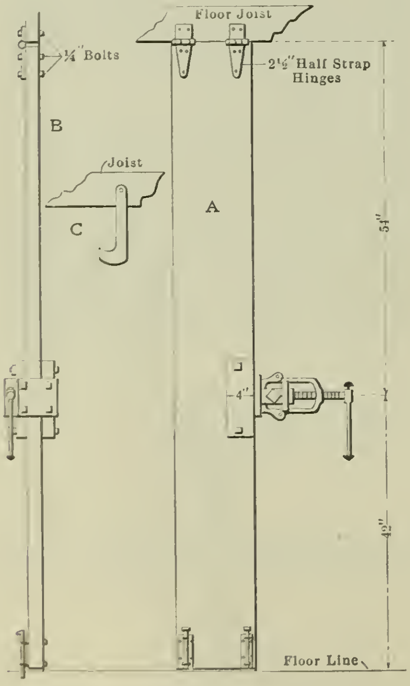
On page 306 of the February 9 number, Mr. Wakeman has a sketch of a Corliss engine, showing the exhaust valves covering the port leading from the cylinder to the valve. This is not correct, as the pressure would force the valve from its seat, resulting in a leaky engine. The valve should cover the port leading to the exhaust chamber; then the pressure would have a tendency to force the valve to seat tight. Also, where will the cylinder head go to when the crank reaches the dead center?

E. L. Dean.

North Wilbraham, Mass.

Movable Pipe Vise Support

At *A* is shown a front elevation of the device complete; *B* is a side elevation and *C* a detail of the hook for holding the support out of the way when not in use.



A MOVABLE PIPE-VISE SUPPORT

In *A* it will be seen that the pipe vise is mounted on an ordinary 2x12-inch plank, 8 feet long, and at a suitable hight to be convenient to work at. The plank is hinged at the top by means of two ordinary half-strap hinges to the floor joist or an overhead timber. At the bottom of the plank are two 6-inch door bolts which enter plates inserted in the floor and hold the device firmly in a working position.

The vise is bolted to two pieces of 2x4-inch stock, 12 inches long, which are in turn through-bolted to the upright 2x12-inch plank, thus forming a very firm support for the vise with comparatively light material.

The hook shown at *C* is a simple piece of flat steel suitably bent or forged and attached to any suitable overhead support.

When the vise is not in use the floor bolts are raised and the plank lifted until the hook catches it, thus leaving the floor entirely clear for any purpose desired.

Edwin Kilburn.

Spring Valley, Minn.

Lighting Problem

In the issue of February 2, under the head of "Lighting Problem," F. L. Rolph asks for criticism and remarks on a wiring diagram. The connections shown are feasible. Care, however, must be taken to make the leg of the incandescent circuit, which is also a part of the arc-light circuit, of sufficient capacity so that there is no material drop of potential, thereby lowering the drop on the incandescent circuit. Each incandescent lamp should have a shunt box or coil, so that the burning out of one lamp will not put out the others, nor increase the voltage across the others; or some other device must be used so that when the lamp burns out the circuit will not be interrupted and additional resistance will be introduced in the circuit to make up for the loss of this lamp.

With reference to commercial circuits, unless it is possible to divide the load fairly evenly between the circuits, I should recommend the use of three wires on each side in order to make this division of load possible, and thereby keep the regulation fairly close.

Henry D. Jackson.

Boston, Mass.

Why Some Engineers Do Not Read

When I read a letter recently under the above heading it directed my thoughts back to my first experience in engineering, under a chief. Being deeply interested along engineering lines, I procured some books and began to study at home. Then I enrolled as a student in a correspondence school. Finally I secured a job as fireman in a light and power plant in a town of about 13,000 inhabitants.

Thinking that I was now fairly on my way for advancement, I studied harder than ever and began to read technical papers, and could see the benefit gained by so doing. But unfortunately I was under a chief who condemned books and papers and claimed that there was nothing in them. He said that he "had a head that told him things," etc., but I went ahead just the same, received a promotion and finally secured the management of a municipal plant in a neighboring town, a position I never could have held without study. I still read Power and The Engineer, especially the practical letters, and derive much benefit from it.

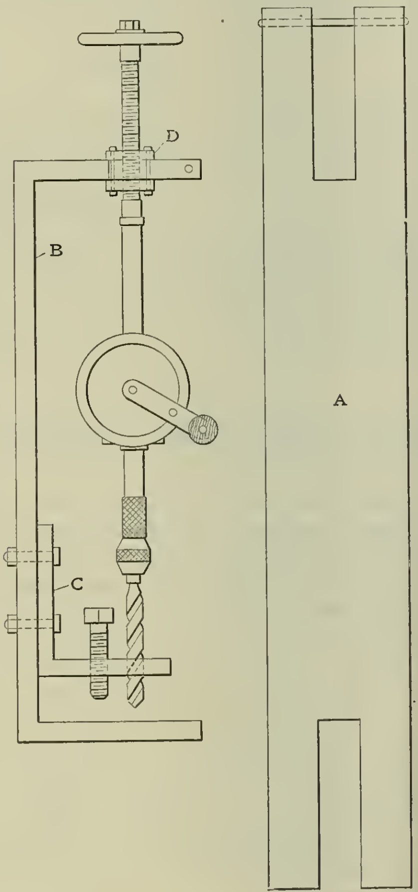
After a few inexcusable delays our friend, whose head told him everything, was asked to resign. He then got into a little plant in a town of about 600, but after a few months he had that plant shut down, and he was looking for another position. It pays to read technical papers.

E. H. Cavanaugh.

Altamont, Ill.

Using a Breast Drill

The accompanying sketch shows how a breast drill can be used to good advantage. Having to drill a great many holes, I fitted up the drill in the manner shown.



USING A BREAST DRILL TO ADVANTAGE

I took a piece of ⅜x2-inch cold-rolled steel *A*, and after sawing slots in both ends, bent it as shown at *B*. Next I took a piece of the same stock and sawed a slot in it and then bent it at right angles, as shown at *C*, and bolted it to the frame piece. A couple of set screws were provided to clamp it to the work to be drilled. I then took two ½-inch nuts and sawed them out to fit the slot, as shown at *D C*.

A 1-inch shaft was then turned out with a head and one end threaded to fit the nuts. The other end was turned down to fit a collar, which in turn fitted the shoulder of the breast drill. A pin prevents the nuts from sliding out of the frame.

Flue Gas Sampler

Sampling tubes for collecting the flue gases for analysis with the CO_2 automatic recorder, or with other analyzing instruments, have always given more or less worry to the operator. If they do not become stopped up with soot, there is always the question as to whether an average sample is being obtained.

After using the American Society of Mechanical Engineers' flue-gas sampler, as described in volume 21 of the *Transactions*, page [illegible], for some time, it was discarded on account of soot and small particles of ash collecting in the small tubes and solidifying to such an extent that they could not be removed by blowing through with steam, thus closing the openings, the advantage of this design being thereby destroyed, as the sample was no longer an average one.

While we had better success with a single ½-inch pipe, reaching across the stack, with a number of ⅛-inch holes drilled in the under side, throughout its length, with the end capped, there was always the doubt as to whether a proper sample of the gas was being taken.

The line sketch herewith shows the design of sampler now in use. This sampler is made up entirely of pipe and standard fittings, and is so constructed as to collect gases from all parts of the stack and mix them in a mixing chamber before going to the recorder, the sampler being placed in the stack just below the damper.

The mixing chamber is a [illegible]-inch sleeve coupling, with a plug in its bottom having a [illegible]-inch hole in its center. In the top of this sleeve is a [illegible]-inch bushing and a ½-inch nipple to which the sampling tube is connected by means of a tee. The sampling tube extends across the stack, forming a hanger for the entire apparatus, and at the same time giving an opening in which a [illegible] thermometer can be inserted. Six holes are drilled in the mixing chamber and tapped for ½-inch pipe, to which are attached six legs, as shown. The pipes forming the legs have a slotted opening on the under side, decreasing in width toward the mixing chamber, making a slot the width of which at any point is proportional to the distance from the center.

This sampler has given good results after nine months' use, and up to the present shows no signs of clogging with soot and ash. The line on the chart is much more regular than the line obtained from the use of the single-tube sampler and resembles the line obtained from the use of the A. S. M. E. "[illegible]" sampler.

DETAILS OF A FLUE-GAS SAMPLER

Rope Drive for Governor

In the issue of January 26, E. McLaren comments on the governor drive mentioned in a previous number. Answering his letter, I would say that the rope drive previously mentioned not only reduces the liability of losing the driving power due to a possible break but, what is more important, there is much less liability of slippage, even should the ropes become oily. Each rope as it passes over the sheave is firmly held, or I might say wedged, into a V-shaped groove, and each rope is alone capable of driving the governor, so that the slippage, even under very unfavorable conditions for a belt drive, is almost negligible with the rope drive.

Mr. McLaren mentions "[illegible]," which I take to mean gripping of the governor spindle due to heating caused by friction. In a properly built governor the fits are made such that this is almost impossible. The friction of the governor is very small and if it is properly oiled it can easily be turned by hand. Under ordinary conditions the small belt is a more than sufficient drive, though far less reliable than the rope drive.

[illegible] bearings are not necessary in a properly designed governor. Most modern governors support the spindle on two hardened steel [illegible], or on a brass bushing between the steel bottoms. In the latter case a lot [illegible] is provided [illegible] to take up the wear of the brass.

One of the objects of my [illegible] letter was to point out the "safety-stop" [illegible]. The term "safety stop" is a [illegible] [illegible]; the attachment is a "[illegible] [illegible]" with a [illegible] [illegible]. [illegible] would be [illegible] [illegible] [illegible], especially where there is [illegible] [illegible] [illegible]. [illegible] [illegible] and the right side of the belt [illegible] [illegible] [illegible] McLaren's suggestion [illegible] [illegible] [illegible] [illegible] would [illegible] [illegible] [illegible].

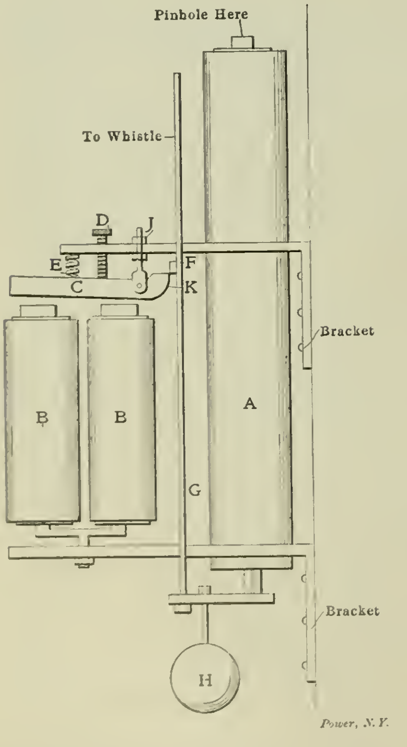
Automatic Device for Sounding Whistle Alarm

The accompanying sketch illustrates a device which is connected in series with an annunciator on the battery side of our fire-alarm system for the purpose of automatically sounding the whistle in case of fire. The magnets *B B* are connected in series with the annunciator, and in case an alarm is turned in from any station about the works the armature *C* is drawn downward, thus operating the catch *K* and releasing the rod *G*, which is drawn down by the weight *H*, the weight being sufficient to pull the whistle.

The descent of the rod is regulated by the dashpot *A*, which prevents it from descending with a jerk. When the circuit is opened again the armature is lifted by the spring *E*, which is just strong enough to raise and support the weight of the armature. The rod and weight are then raised by hand ready for the next call. The air gap between the armature and the magnets is regulated by the set screw *D* and hanger *J*.



DEVICE FOR SOUNDING WHISTLE ALARM

The parts *F* and *K* are made of hardened steel, the armature of soft iron, and the rod and hook, at the bottom, are made of steel; the dashpot, hangers, set screw and brackets are made of brass. The magnets were taken from an old alarm bell. This device works very well and is substantial. The system is tested at regular intervals to insure its being in working order.

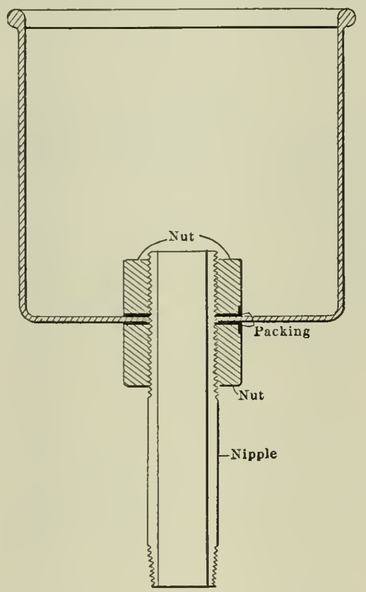
Piping Vessels Without Threading or Soldering

Following is a kink in piping vessels that cannot be tapped or soldered: A hole is cut in the vessel, through which a piece of pipe of the size to be used is passed. A long screw nipple is secured by two locknuts. One nut is removed and the other screwed down to the shoulder of the long screw, with the counter-



PIPING A PAN, BUCKET OR OTHER VESSEL

bored side facing the long screw end of the nipple. After passing the long screw end of the nipple through the hole in the vessel from the outside, screw the other locknut on with the counterbored side toward the bottom of the vessel. Then wind a piece of lampwick or other packing around the nipple on both sides of the vessel, between it and the locknuts, and screw them up tight.

Piping can be run from the end of the nipple to any desired place. We use this joint in running pipes from oil tanks to various parts of machines and engines, and find it very satisfactory.

Transformer Connections

In the issue of February 2, under the head of "Transformer Connections," R. S. Carroll asks if, having two transformers connected in open delta across phases *1* and *2*, it would be necessary to install the lighting transformer across phase *3*; also what effect it would have on the regulation.

Since without the lighting transformer the circuit would be balanced, it would make no difference on which phase the lighting transformer was installed, as this would be the only unbalancing feature of the circuit. The effect on the regulation, therefore, would be dependent on the size of the wire used on the phase on which the lighting transformer was installed, and the loss in this wire. Since the lights are used when the motors are not, the regulation would be entirely dependent on the regulation of the transformer and the size of the wire. The motor-circuit regulation would be dependent, also, on the same conditions.

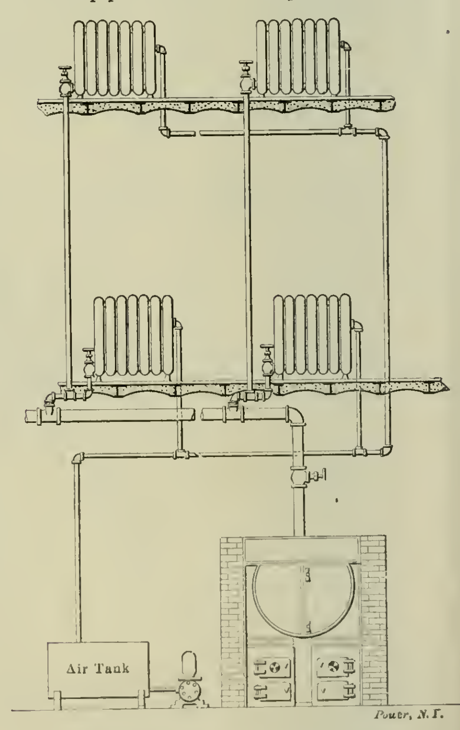
Substitute for Air Valves

The accompanying illustration shows the arrangement of my heating plant and my method of preventing water hammering in the pipes and radiators. All air valves have been removed and instead I have connected a small ⅜-inch air pipe running parallel with the steam pipe. This air pipe extends from the various radiators to the basement and connects to an air tank after combining in one 1-inch pipe.

In the morning I open the valve on the 1-inch pipe and leave it open until I get



ARRANGEMENT OF HEATING PLANT

4 or 5 pounds of steam on the boiler, when the valve is closed. I keep up steam until about 11 a.m., by which time there is considerable condensed water in the air pipe at the lower end, and there has also formed a strong vacuum between this water and the radiator. The vacuum in the air pipes will draw the vapor out of the boiler and the radiators will remain hot all day. I can steam up any time during the day and there is absolutely no water hammering. I have 82 radiators in

the building, and in cold weather the air valves would generally freeze, keeping me running around opening up air valves instead of attending to the boiler. I put in 1736 feet of air pipes, arranged as shown. At the air tank is a belt-connected pump driven by a gasoline engine for removing the condensed water.

Sleepy Eye, Minn.

Babbitting a Large Main Bearing

In response to a hurry-up call, a machinist was sent to babbitt a main bearing. The engineer had neglected the bearing during the night run and from some cause or other, the babbitt had melted, so that the shaft was wearing down into the iron of the bottom box before the engine was stopped.

A piece of sheet iron a little longer than the bottom box was bent, as shown at *A*, Fig. 1, and fastened to the box by means of clamps, leaving an opening of ½ to ¾ inch for the babbitt. Another piece was bent as shown at *B* and fastened to the quarter box, allowing room for the babbitt metal. The boxes were stood on end on an iron plate and the bottom well sealed with clay to hold the babbitt. A little tallow from a candle was scraped into the cavity to prevent an explosion, and the boxes poured. When cool, the sheet-iron forms were removed and the babbitt well hammered with a ball-peen hammer.

The boxes were then assembled as shown in Fig. 2 (end view) and Fig. 3 (side view). The pieces *C C* are of hardwood, the bottom ones being of the required thickness to bring the center of the box to the same hight as the center of a lathe. The bolts *D D* hold the bearing together and also clamp it to the lathe carriage. The pieces *E E* were made of hardwood, and high enough to enable the cutter to clear the pieces *C C*. Care was taken to have the distance across from the outside faces of the wedges *F F* the width of the opening in the frame. A boring bar was placed in the lathe. The boxes were then set, bored out, oil grooves cut, and the surface scraped.

FIG. 3

Dashpot Does Not Seat

In endeavoring to answer the query of Elsworth Davis under the above caption, on page 200 of the January 26 number, I will say that it is very difficult to suggest the cause of the trouble from the meager particulars given. Requests for information in reference to matters of this kind should be accompanied with some details, such as type of dashpot, the make of engine, whether of old or late design, etc. For instance, the dashpot and plunger of the old Hamilton-Corliss, and the later engines of this same make, are entirely dissimilar.

The old Hamilton, as well as other Corliss engines made at this time, employs a type having two plungers in one, the smaller having a cup leather on it, and this has for its office the formation of the vacuum for pulling down the plunger after the knock-off cam has caused the release of the die from the block. The upper plunger is much larger, and has a leather riveted on its under side. This leather has a small flap valve working over a small port bored in the plunger. The object of this plunger is to cushion the plunger on its descent to prevent it from slamming or striking the bottom of the dashpot. As the plunger rises this little flap valve opens and allows the air chamber to fill with air, and in the air chamber of the dashpot proper there is an air-exhaust regulating valve. When this is properly set it will allow all of the air to escape except just enough to cushion the drop of the plunger. When the plunger has risen and the block is released, allowing the plunger to drop, the little flap valve closes, so that the air admitted through it cannot escape through it, and hence can escape only through the regulating valve.

Now the trouble may be caused by the cup leather having become worn out, or having become defective from any other cause, so that the necessary vacuum is not formed under it. Or, what is more likely, the leather on the cushioning plunger, or the plunger itself, may have become worn and defective, or the little flap valve may be defective. This last is the most frequent cause of the trouble. If it has become defective it makes it impossible to regulate the [illegible].

I have had this trouble when the dashpot would work all right when using the starting bar, and would work good and bad by turns when running. The only sure way to locate the trouble is to dismantle the dashpot, having acquired a knowledge of the functions of each part and the conditions each part must be in to perform its functions properly. If this does not lead Mr. Davis to a solution of the problem, my advice would be to take it up with the builders of the engine, giving full particulars. The times I have been helped by the builders of engines are many. They are the best friends of the ambitious engineer.

WILLIAM W[illegible].

Lincoln, Neb.

On page 200 of the January 26 number, Elsworth Davis tells of his trouble with a dashpot not seating with a light load on the engine. If he had stated what kind of dashpot it was, whether leather packed or otherwise, what kind of engine and what load and how fast the engine ran, perhaps readers would more clearly understand the nature of the trouble.

I have had the same kind of trouble, but the dashpots were of the leather-packed type. Every time the leather got the least bit worn he would leak in and partially destroy the vacuum in the dashpot, and the dashpot would not seat until the load forced it down.

There are several things that will cause this trouble: low [illegible] compression, too high speed with low boiler pressure, too high [illegible] pressure, or [illegible] causing the dashpot to [illegible]. The latter usually caused the trouble I had.

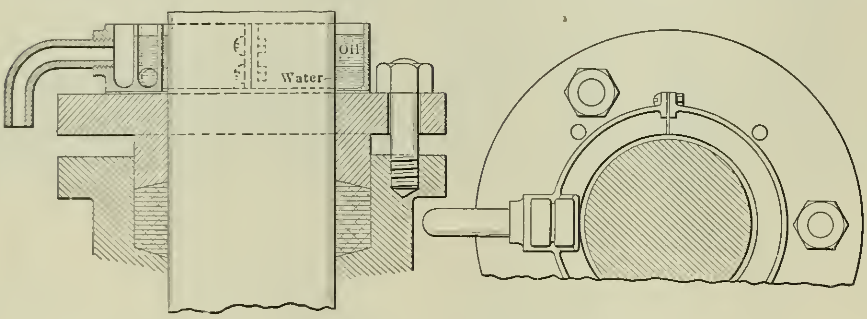
Mr. Davis says that he working the [illegible] by hand the dashpot works easily. Perhaps he does not move the [illegible] as far as it would when the engine is running. That will make a great difference, as the governor and knockoff cams are not in the same position when worked as they would be while running.

C[illegible] W. [illegible].

[illegible], Neb.

Method of Lubricating Elevator Plungers

While the plunger elevator is being discussed in the columns of Power, I submit a sketch showing a method I have used to lubricate the plungers of elevators, pumps, accumulators, etc. I found that oil keeps a plunger in better condition than grease, but is easily washed away by leakage from the stuffing box. To prevent this, I attach a collar to the plunger and gland, which retains the oil and acts as a separator, permitting the water to escape through the drip. The plunger in moving up or down carries the oil on its surface, thus keeping the plunger free from gum or corrosion and also preserving the packing. Should any water leak by the packing, it will pass through the opening near the bottom of the ring and overflow to the drip pipe. The sketch shows the ring made in two pieces to facilitate its application.



METHOD OF LUBRICATING ELEVATOR PLUNGERS

The "Contraflo" Condenser

In the article on "Development of the Surface Condenser," in the February 16 number, at the bottom of page 347 the statement is made: "In order that the air pump may extract the greatest quantity of air from the condenser, it is necessary to remove the vapor with which the air is mixed." A clearer statement would be as follows: In order that an air pump may extract the greatest quantity of air from a condenser its temperature must be low relatively to the temperature in the condenser, for to remove a given weight of air it is also necessary to remove the vapor with which it is mixed.

On page 348, in the first column, it is stated that "The sealing water, after passing through the air pump, is returned to the cooler, so that the same water is used over and over again." This statement is true as applicable to a dry system, where the water of condensation is not dealt with by the air pump, but by a separate pump. It does not apply to the design illustrated in the article, however.

Although the Contraflo Condenser Company, of London, is the manufacturer of this condenser, the Elwood Company is not the selling agent in the United States, but the representative to authorize the manufacture of the "Contraflo" condenser, under license, by any reputable builder of this class of machinery in the United States.

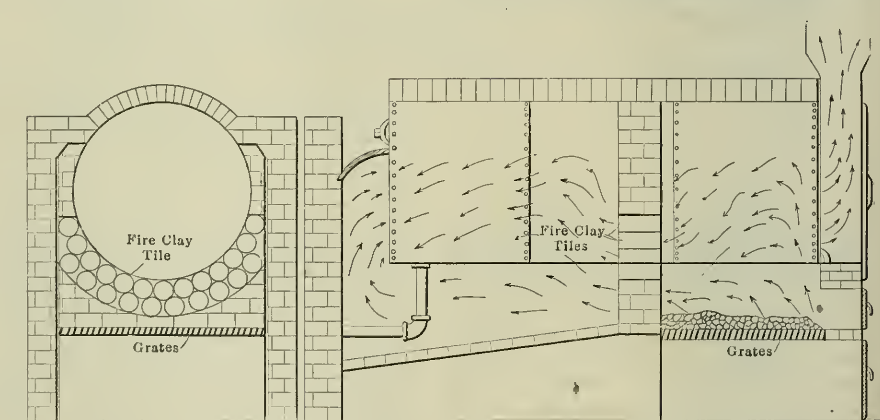
The Elwold Company,
W. R. Molinard, Manager.

Philadelphia, Penn.

Getting Complete Combustion

It seems to be the general opinion of most all authorities on smoke-consuming devices that the gases must be brought into contact with a white-hot arch of fire-brick before passing onto the shell and tubes, in order to get complete combustion.

In the ordinary boiler setting the main body of the gases passes directly from the grates over the bridgewall, along the comparatively cool surface of the shell and into the tubes, without any direct contact with the furnace walls, naturally resulting in a rapid cooling of the gases. These pass off in the form of smoke, which could be consumed if the proper amount of air was admitted to the furnace and divided into small streams, coming in contact with a surface hot enough to ignite the mixture.



END AND SIDE VIEWS OF FURNACE PROPOSED TO SECURE BETTER COMBUSTION

The sketch illustrates a method that could be applied with very little change or expense to any ordinary boiler setting to get this result. End and side views of the furnace are shown. The space over the original bridgewall is filled in to about the center line of the boiler shell, with fire-clay tile, the bridgewall being round to conform with the boiler curvature. This causes all gases to pass through the tile, which is at a white heat, before reaching the combustion chamber.

If necessary, in order to get the proper mixture of air before the gases enter the tile, air jets could be placed in the front of the bridgewall and a steam jet used to inject the proper quantity of air, although I think sufficient air could be admitted through the furnace doors and over the fire to get proper results, at the same time keeping the temperature of the door and surrounding wall down. The space between the bridgewall and boiler should be made large enough not to restrict the draft by the space taken up by the tile.

S. Kirlin.

Fort Smith, Ark.

Fixing Loose Crank Pins

I have read at different times how engineers have fixed loose crank pins by riveting the end over, center punching the pin around the end near the outside, or driving in dowel pins. One may in this town cut a keyseat in the pin and drive in a key.

Professor Sweet's scheme is, in my opinion, the best, that of drilling a hole in the center of the pin and driving in a taper tool-steel pin.

My scheme to cure a loose crank pin is to put in a new one. It is not much of a job to make a new pin, and if an engineer has not the ability to do it he has no business with a job of any importance. If a pin is loose in the fit, center punching, etc., will not make it tight.

John Dunn.

Streator, Ill.

Some Useful Lessons of Limewater

The Gases in the Air and the Part They Play in Combustion; Interesting Experiments to Prove That When Coal Burns It Forms an Acid

BY CHARLES S. PALMER

All that we have studied thus far is only an introduction to what that barrel of quicklime has to tell. We have seen that lime-like substances are found in hard water and that, sometimes, it is one of these same lime-like things which may be used to overcome this hardness; as though one should make one hand wash the other; or, following the old proverb, healing by "a hair of the dog that bit him." But this subject of hard water, while very real and practical, is not a separate thing by itself; it is connected with many other chemical facts and theories. We will make short excursions into some of these other fields, such as that of fire or water, or that of acids or alkalies.

Fire

In making our clearing before our imaginary cabin home, in the forest of ignorance and prejudice, one of the first things which we should know something about is the air, or the atmosphere, as it is also called. We know that the air has everything to do with burning, for if we want to make a fire burn in a stove or furnace all that is necessary is to keep the grate free from ashes, supply it with fuel, light it and give it free draft. Indeed, in some forms of power maker one can almost control the engine by regulating the doors and dampers. So it is almost self-evident that burning, in the common meaning, is dependent on the air draft.

Moreover, when coal or fuel burns there is some great change in the fuel. Most of it goes up the stack, except some 5 or 10, or, perhaps, 15 or 20 per cent. of ashes, but usually from 80 to 90 per cent. of the fuel vanishes in the work of furnishing heat and power. If one should look only at the fuel and the remaining ashes he would suppose that burning is a subtraction; and there was once common among scientific men a theory which called itself "phlogiston," that is, "fire stuff," and which supposed that burning is a subtraction, because they looked only at the fuel and ashes. But if we look with one eye at the fuel and the ashes and save the other eye for the waste gases which go up the chimney, then we find that burning is an *addition*, and not a small addition but a great addition. This is proved by burning fuel in closed apparatus and weighing everything which comes off it. In this way it is found that one ton of hard coal will send up the chimney, when well burned, between three and four tons of burnt gas, to say nothing of wasting heat on some nine or ten tons of a gas (nitrogen) which is in the air as neutral "filler."

If your attention has never been called to these curious facts, you have a good right to be skeptical as to the correctness of the figures. They are only general, but they are approximately correct; and you begin to think that our eyes must be half blind to let such vast quantities of substances slip by us unnoticed. There are many ways of getting at these interesting things, but one of the easiest ways is to ask this simple question: Is the air about us composed of one thing or of several things? You have heard all your life that the air is mostly made up of the two gases, nitrogen and oxygen; but if

FIG. 1

you have not taken this statement to the [illegible] of your careful attention, if you have not tested this statement with your own chemical apparatus, you can have but a faint notion of the wonderful meaning and the good business value which lie hidden behind the simple statement that the air is made up of nitrogen and oxygen. You know that there is more of the nitrogen than the oxygen, and yet that the oxygen is the active thing so far as burning is concerned; but you need to prove at least a part of this for yourself, in order to see what the fact is worth to you.

Two Things in the Air

Take a common wash or dish pan as shown in Figs. 1 and 2. By the way, you will be flattered to know that your wash dish is serving for what the books call a "pneumatic trough," which means a convenience for handling gases, a simple but great invention. Put an inch or two of common water into the dish. Get a wide-mouthed jar, say a common fruit jar. Find a wide, flat cork, which will easily pass through the mouth of the jar, without touching the sides, and float the cork on the water in the wash dish. Now find a little saucer-shaped dish to ride on the cork and to hold some easily combustible stuff, such as match ends, sulphur or phosphorus. The cork must be flat and well balanced with its cargo of stuff to burn, and sometimes it will be more stable if the wider end of the cork is at the bottom. You will find that you must get this point well fixed, as you have got to place the jar mouth downward over the cork and its cargo without disturbing the latter. Any saucer-shaped piece of tin or iron, as the round cover of a spice box, will do for the little dish; sometimes the saucers and plates of a doll's tea set serve first rate for such purposes, or the little dishes in a common box of water paints. You want to get the cork and its load well balanced, so you can slip the wide-mouthed bottle down over the cork. Then light the phosphorus or match ends, or what ever else you wish burned, and neatly put the bottle mouth downward into the water and over the burning cargo on the floating cork. As it burns, there will be an escape of several bubbles of air from the bottle, and you can explain this by the sudden heating of the air shut up in the bottle. But pretty soon the fire in the dish on the cork will burn more slowly, and finally it will go out. Meanwhile the cork with its cargo has risen up and into the jar as the watery [illegible] and inside the jar to take the [illegible].

Now note the air in the inside of the jar or bottle. If it is [illegible] some [illegible] will be partly absorbed by the water in the bottle, [illegible] the water will rise part way up the inside of bottle (Fig. 2). You must be patient [illegible] this experiment, [illegible] you will get [illegible] in handling [illegible]. You will [illegible] phosphorus from match [illegible].

drops of kerosene, you will not get as much absorption of the burnt fumes by the water. But in every case, with the burning of phosphorus you will get an absorption of the air in the bottle by the burning amounting to from one-fifth to one-third. The correct figure is about one-fifth; but you may drive off too much air at the start from the expansion from heating, before the real burning has gone very far; and this error in the experiment will show up as an apparent absorption of the original air greater than the real absorption and disappearance of the air in the bottle.

There are several sides to this experiment, and we will mention them here, so that you can be on the lookout for them:

First, the strong burning of the stuff in the little saucer, and the placing of the jar over this.

Second, as soon as the fire has gone out in the saucer and the water in the jar has finished absorbing the fumes from the burning, lift the jar quickly out of the water, first slipping a piece of cardboard over the mouth to keep the water that is in it from flowing out. Shake violently, using the cardboard cover, and set the jar right side up on the table. Note the amount of absorption of the original air in the jar.

Third, light a splinter of wood and thrust it quickly down into the air left in the upper part of the jar; the splinter is put out, as anybody should know it would be, because if the fire of phosphorus went out, wood or paper would not burn well in this same residual air. All the same, it is not a foolish thing to do, to test this same residual air with your splinter of wood. It sets you to thinking what it all means and you begin to note that there must be different kinds of gas as regards their ability to help burning. The gas oxygen that has gone off (it has gone into the water) helped the burning), and it amounted to only about one-fifth by volume of the whole air. The part of the air that is left will not help common burning, although it makes up some four-fifths by volume of the air; this remaining part is nearly all nitrogen. Just to set your mind at rest, you may like to know that there are three other things in the air in small quantities. These are some water vapor, some of your old friend carbonic-acid gas and a strange newcomer, called argon, the "lazy element," because it does not do anything but exist; that is, it does not make any definite compound with anything, but sometimes pretends to be like nitrogen as it is found in the air, about one part in a hundred by volume.

Fourth, put some litmus into the water at the bottom of the jar and note the action. Of course, you know enough by this time never to take one piece of litmus paper, nor one color, but *two* pieces; or, at least, one piece colored red at one end and blue at the other. You can take a bit of red litmus and let one-half touch a piece of soap to blue one-half. With both red and blue litmus you can catch both alkalies and acids. You will find that the water in the bottom of your jar turns the litmus red; that means that the burning has made something which went into the water and which has acid properties. If you used mostly phosphorus then the burning of the phosphorus has made one kind of phosphoric acid. If you used mostly sulphur in burning in the little dish on the cork, then the burning mostly made sulphurous acid, with some sulphuric acid. But in both cases, the burning with the oxygen of the air made things that are essentially acids. It was the great French chemist, Lavoisier, who found this out some hundred and forty or fifty years ago, about the time of the Revolutionary war; he showed that burning was an *addition,* and that the adding of the "burn-helping" gas (oxygen) in

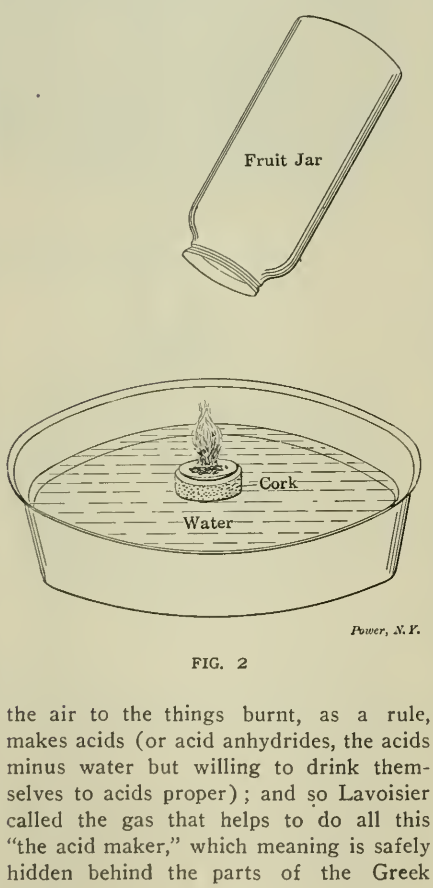


FIG. 2

the air to the things burnt, as a rule, makes acids (or acid anhydrides, the acids minus water but willing to drink themselves to acids proper); and so Lavoisier called the gas that helps to do all this "the acid maker," which meaning is safely hidden behind the parts of the Greek makeup, "oxy-gen." You will find out later that this claim of oxygen to make all acids, is not quite exact, but that there are acids which have no oxygen in them; but in every such case the acids have something which plays proxy for oxygen, so that in its broadest sense the name "oxygen," "acid maker," is not so bad for the "burn helper" in the air.

Repeat the Experiment Often

You must try this fundamental experiment of attacking the composition of the air over and over again and in every shape and method that your ingenuity can devise. Perhaps you can get some of the pure phosphorus to use, the kind that comes in yellow sticks and which must be kept under water to save it from burning up; or perhaps you can get a pinch of the so-called "red" phosphorus, a dark brownish-red powder, which is real phosphorus baked in a close vessel until it goes temporarily into this curious, sleepy form where it does not have to be kept under water to save it from burning; perhaps you can get some of this, to put in your little dish; but, whatever you do use, make it burn and make it take out all of the active oxygen from the air that it will, about one-fifth by volume at any rate. Usually you will get a larger apparent absorption, due to the aforesaid escape of some bubbles by heating.

You must keep your eye fixed on the several points: The good burning; the closing-in of the little saucer by the inverting of the jar; the absorption of part of the air in the jar and the testing of the remaining air; the testing of the water in the bottom of the jar. It all makes a part of the story of the composition of the air, but you will wonder how our friend limewater can help us out here. Well, that is an interesting question; and, in this chapter, we can only begin to show how limewater may have a great deal to do with the problems of burning.

Your thoughts will run somewhat as follows: It is all right to test such things as sulphur and phosphorus and match ends; but common coal is the thing which makes the bulk of fuel burnt, and we want to see what the air does to that, and how it does it.

The point which we are going to study is this: that coal burns first to carbon monoxide, CO, and this burns farther to carbon dioxide, your friend carbonic-acid gas, CO_2, or carbonic anhydride, the anhydride of true carbonic acid proper, H_2CO_3. Now the acids of phosphorus and sulphur and those strong-smelling things made from burning in the air, are readily absorbed by water; and they readily turn litmus red. But carbonic-acid gas is only feebly absorbed by water: it has not much taste and it does not act strongly on litmus; and so we are up against the question of trying to prove that when coal, or carbon, burns in the air, it does make its own form of acid, or acid anhydride, just as sulphur and phosphorus make theirs. You can begin to see how we are going to do this with the help of limewater; for you have already sucked the gases from glowing coal through some limewater, and you are fairly familiar with the acid properties of the gas from burning coal. But that special point will wait for another lesson: we want to get this point clinched, of the approximate amount of active "burn helper," oxygen, in the air.

There are one or two questions which may come up to your mind at this time.

One of them is this: What would happen if the air were pure oxygen? That is an interesting question, and you will make some experiments later with pure oxygen to show what would happen. But there are two forms to that question. One form is, what would happen if the nitrogen were taken out from the air and only the oxygen were left? That is one thing, but it would be quite another affair if the nitrogen were taken out from the air, and if its place were taken by so much more oxygen, that would be a condition of frightful possibilities, as you will see when you come to make pure oxygen.

One more question that I want you to think over between now and the reading of the next lesson is this: Why do you have to *light* a fire? Why doesn't it light itself? There is the fuel, there is the air, which you cannot see, but which you can feel, and it is waiting to take hold of your coal. But why does it wait until you kindle it, with all sorts of coaxing, from the match, through the shavings or paper, through the kindling wood, to the hard fuel; why all this preparation for what seems all ready to take place of and by itself? This question is worth some attention, the right answer will open your eyes to some things which no one can see, but which we must all believe to be true; it is the story of the chemical units, noted by those initial letters, and the groups into which those chemical units unite, groups which make up all kinds of material things which you see and feel every day. You are getting near the top of one of the foothills of science, and one of these days you will see the main range, and you can see all this from the window of your boiler room.

Credit for Low Pressure Turbines

In the February 2 number, page 241, L. Battu gives the credit of the conception and working out of the low-pressure turbine to Professor Rateau, mentioning J. W. Kirkland in a very complimentary way, but entirely ignoring W. L. R. Emmet, who at the International Electrical Congress, at St. Louis, in September, 1904, only a few months after Professor Rateau had presented at the Chicago meeting of the American Society of Mechanical Engineers the paper to which Mr. Battu refers, presented a paper containing the following, which shows that he had at that time a comprehensive idea of the advantages of the steam turbine for low pressure work:

Portion of Paper Read in St. Louis, in September, 1904, at a Meeting of the International Electrical Congress

Since, as has been stated, the best steam turbines so far developed give degrees of economy about equal to those of the best steam engines, and since the turbine, as explained, works in a larger field of available energy, it may naturally be inferred that the steam engine within its own range of action is more efficient than the steam turbine, and that to a certain extent is true. This fact naturally suggests a combination which undoubtedly has a large field of application, namely, the use of low-pressure steam turbines taking exhaust steam from existing reciprocating engines. It is probable that such combinations will only be a phase of the steam-turbine development, since it is highly probable that efficiencies as high as the best steam-engine efficiencies will soon be attained by turbines under all ranges of pressure and that it will become desirable for many economic reasons to discard reciprocating engines altogether.

The most advantageous conditions for the combined use of reciprocating engines and steam turbines will be found in existing steam plants where reciprocating engines are used to operate electric generators separately or in parallel. In such plants low pressure steam turbines can be installed and can be arranged to take steam directly from the exhaust pipe of engines without valves or governing mechanism. The turbines would be designed to give a very high efficiency with highly expanded steam and a condensing plant should be installed adapted to the highest degree of vacuum. The low-pressure valve stems and rod packings of the engines should be sealed with steam and other provisions should be made for the exclusion of air. The steam turbine should operate a generator adapted to connection in parallel with that driven by the engine.

A turbine designed for operation under these conditions would be an ideally simple affair and its maintenance and care would add little or nothing to the cost of station operation. There are many large stations in which the introduction of such turbines with proper condensing facilities would increase the output as much as 30 per cent., without any increase of the fuel consumption or change in the boiler plant. There are probably very few stations operated with reciprocating engines where the introduction in this manner of properly designed turbines would not increase the output as much as 20 per cent. In one case recently considered, 25 per cent. could be added to the output of the station without diminishing at all the work being done by the engines, that is, such an amount of work could be obtained with degrees of vacuum pressure entirely below those from which the engines are capable of deriving any benefit.

In such cases it would generally be desirable to design the turbine that under full load conditions it would take steam at a pressure of about 8 pounds absolute, corresponding approximately to the exhaust point in the low-pressure cylinder of the engine. The engine would then handle all the power which it could handle with maximum efficiency, and its own output would be only slightly reduced. The turbine would handle the power to which the engine was not well adapted. Under conditions of light load some economy might be effected by changing the cutoff conditions on the engine, but it would probably be better to leave all the conditions fixed and to allow the pressure on the turbine to vary as the load changed.

Such low pressure turbines would occupy a small space and there are probably few existing engine plants in which room could not be provided for their installation. The cost of installing such turbines with complete condensing facilities should not exceed $30 per kilowatt of capacity added to the station. This in itself is a small expenditure for an additional plant, even if we do not consider the fact that the use of this additional plant does not call for any increase in fuel consumption or in steam-generating apparatus.

The following table shows the approximate increase of output which can be obtained by using a low-pressure turbine with good vacuum worked in series with a good Corliss engine over that which could be obtained from the engine alone when used with the best vacuum. The engine considered would consume with atmospheric exhaust 18 pounds per indicated horsepower, and with a vacuum of 27 inches or better 14.7 pounds per indicated horsepower. In the turbine an efficiency is assumed which is justified by actual experiments, and which can easily be obtained in a simple machine of this kind.

Pressure of Steam Entering Engine, [illegible] Inches of Vacuum.	Per Cent. Gain Over Output of Engine When Worked with High Vacuum; The Turbine Exhausting to a Vacuum of 28 Inches.
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

These figures show an important possibility which should be realized in many existing plants, and they also illustrate forcibly the value of good vacuum in turbine work, since it shows the large amount of work available in these low pressure ranges by the use of turbines.

One square foot of heating surface is needed in a boiler for every 200 cubic feet of space in a church or hall. In a dwelling house, every 100 cubic feet of space requires 1 square foot of heating surface. Radiators should have 1 square foot of superficial area to every 8 square feet of glass in windows and 1 square foot for every 80 cubic feet of space to be heated. One horsepower in a boiler is generally sufficient for [illegible]

Safety Valves

The Mechanical Engineers Devote an Evening to Their Discussion; Lift as a Factor of Valve Capacity, and as Experimentally Determined

The February meeting of the American Society of Mechanical Engineers was devoted to the consideration of safety valves. Frederic M. Whyte, General Mechanical Engineer of the New York Central lines, introduced the subject, speaking particularly of the safety valve as related to locomotive boilers:

Frederic M. Whyte

The general practice in locomotive work has been to determine the size and number of valves to be used in an offhand way, and former practice has guided these determinations entirely. The capacity is indicated in an indifferent way expressed as a "size" referring to the diameter of something more or less certain, while the other dimension, the lift, which is necessary to give an indication of the capacity, is entirely ignored.

It will be comparatively easy to determine the capacities of valves, if the elaborate tests which have been already made, data from which will be presented in this discussion, have not already solved this part of the problem. More difficulty will be experienced in determining the quantity of steam to be discharged and the rate of release. Instead of indicating the capacity of the valve in a very rough way by the diameter of some opening, the method should be adopted of expressing the capacity in pounds of steam which the valve is capable of delivering at certain pressures. The capacity of the muffler need not be questioned except in extreme designs, but the indicated capacity should be that of the valve complete, with or without muffler according to the intended use of the valve.

In any kind of generating plant it ought to be quite sufficient if those immediately responsible for the quantity of steam produced know what is available. In stationary and marine work this is generally true and steam gages can be placed within view of those who should know what the pressure is at any time. Unfortunately, in locomotive work it has become perhaps desirable that others than those within view of the gage of the cab know something about the steam pressure, and inasmuch as the fireman is willing and sometimes anxious that they should know, he takes the only means at hand to inform them when he thinks that the results of his labors are good, and fires "against the pop" so that everybody within hearing or sight of the valve knows by the escaping steam that the fireman is doing his duty.

Assuming that such an indication of steaming conditions has grown to be a necessity, how can it be produced at the least expense? Two devices at least are available, the simmering valve, which will open slightly for two or three pounds about the normal maximum and then open full, just reversing this in seating, and the small pilot valve, which will open at two or three pounds pressure below the working valve. For the simmering valve, a seat must be used which will not cut under the wiredrawing action of the steam.

In locomotive practice it is not necessary that the valve capacity shall be equal to the maximum steaming capacity of the boilers, because the maximum steaming capacity is only at a time when steam is being used through the cylinders or blower to make the draft. Having fixed upon the per cent. of the generating capacity to be provided for in the valve, it will be necessary to determine the desirable unit capacity of the valves. Some States require that each locomotive boiler shall have at least two valves. Maintenance considerations indicate that these should be duplicates and therefore each has a capacity equal to one-half the required discharge capacity. If a number of boilers of different capacities are to be considered then the smaller ones will probably be provided with the same valves as the larger ones, for the purpose of duplication. There are some large boilers for which three valves may be necessary because the necessary capacity in two units might make the valves abnormally large for construction purposes. It is worth while also to consider whether undesirable results would come about from opening almost instantaneously an escape of steam from the boiler to the atmosphere. No suggestions are offered on this, but it is hoped that something bearing on the subject may be developed in the discussion.

L. D. Lovekin,

Chief Engineer of the New York Shipbuilding Company, said in part:

During 1903 I was asked to look into the rules and regulations as prescribed by the Board of Supervising Inspectors of the United States Steamboat Inspection Service concerning safety valves. This rule was established on grate surface without regard to the amount of coal burned thereon in a given time.

The rule as originally made served its purpose without trouble, but it must be remembered that this rule was made when such things as forced draft were almost unknown. Having in view the difference in the amount of coal now burned per square foot of grate surface, I prepared a new rule based on the well-known formula of Napier for the flow of steam through an orifice. The derivation of the formula is shown on page 473.

It will be noted that in preparing this work, the lift was based on 1/32 of the diameter of the valves, and while I consider this to be within good practical limits, I have found a number of safety-valve manufacturers who differ with me in regard to the lift. There is one thing certain, however, that whether the valve is restricted to 1/32 of its diameter or not, the net area of the opening should in my mind be at least equal to the tabled result indicated by the formula referred to.

I am not in favor of what might be termed an excessive lift of valve, such as one-fourth of the diameter, although some of our best recognized authorities in connection with the inspection of steamships still adhere to that list, the British Board of Trade being one of the foremost in this connection.

Unfortunately, when I presented the formula and table of safety valves to the board of supervising inspectors of steam vessels, they failed to state in their rules and regulations that the sizes of these valves were based upon the lift of the valve being equal to 1/32 of its diameter, and consequently left out a most important element. Under the rules of the board as they now exist in their printed forms it is quite possible to have a valve of the proper size in inches by said rules and yet be far below the actual requirements.

Having settled upon the proper diameter of a safety valve according to the formula, it will be evident that the clear area between the valve and its seat, due to having a lift equal to 1/32 of its diameter, is only about 1/11 of the area of the nominal diameter found by the formula. Therefore, it would seem that the inlet from the boiler to the safety valve should be equal in area only to the free area between the safety valve and its seat. This would reduce the opening in the boiler to about 1/11 of the area used at the present time.

Experiments in this line, however, have shown that a free entrance from the boiler to the safety valve is absolutely necessary to prevent chattering. Just exactly what relation this is I have not determined; in fact, it would depend entirely on the length of the nozzle or pipe connecting the safety valve to the boiler. In most cases safety valves are bolted either directly to the boiler or to a casting bolted directly to the boiler and which forms a seat for both the safety and stop valves, so that there would be very little to gain in reducing the inlet nozzle to a safety valve.

While dealing with the inlet side of a safety valve, I think it might be proper to bring out a feature seldom if ever discussed in connection with safety valves,

DERIVATION OF THE UNITED STATES BOARD OF SUPERVISING INSPECTORS' RULE FOR AREAS OF SAFETY VALVES

Napier's Rule for flow of steam through orifices.

Flow in pounds per second =

$$\frac{\textit{Absolute pressure} \times \textit{area}}{70}$$

(This corroborated by Peabody's experiments.)

P = Absolute pressure = gage pressure + 15
W = Pounds discharged per hour
A = Area of valve opening or orifice

Hence

$$W = \frac{P \times A}{70} \times 60 \times 60 = \frac{360 \times A \times P}{7}$$

For safety valve practice, cut this amount down 25 per cent., leaving 75 per cent.

Thus

$$W = 0.75 \times \frac{360}{7} \times A \times P = \frac{270 \times A \times P}{7}$$

Restrict the lift of valve to $\frac{1}{32}$ of its diameter = $\frac{d}{32}$

then

$$A = \frac{d}{32} \times \pi \times d = \textit{lift} \times \textit{circumference} = \frac{\pi \times d^2}{32}$$

Substituting this value for A as area of orifice

$$W = \frac{270}{7} \times P \times \frac{\pi d^2}{32}.$$

In a valve of diameter d the area =

$$\frac{\pi d^2}{4} = a.$$

To get W in terms of area of valve, substitute for d^2 its value in terms of a

$$d^2 = \frac{4a}{\pi}$$

$$W = \frac{270}{7} \times P \times \frac{\pi}{32} \times \frac{4a}{\pi} = 4.82 \times P \times a$$

In which value position W will represent the pounds of steam that must escape per hour, which must be equal to the pounds of water that the boiler can evaporate per hour.

To reduce this to a working basis consider these quantities per square foot of grate surface per hour.

W = Pounds of water evaporated per square foot of grate surface per hour.

P = Absolute pressure per square inch.

A = Area of safety valve per square foot of grate surface.

Hence

$W = 4.82 \times P \times a$, and $a = [illegible] \times \frac{W}{P}$.

From which a table of areas required per square foot of grate surface may be found by assuming the different values of W and P.

and that is the placing of safety valves upon the outlet end of dry pipes in boilers. These dry pipes, as is well known, usually consist of a pipe running along the upper part of a boiler and having slots cut into it so as to give an area equal to the full area of the pipe. In some cases which have come under my notice I have found the steam pressure within the boiler itself to be 200 pounds per square inch, while that of the outlet of the pipe was only 180 pounds, a drop of 20 pounds of pressure taking place due to wiredrawing the steam through the slots in the dry pipe. I have known of other cases where we have had 200 pounds of boiler pressure in connection with water-tube boilers and have purposely restricted the flow of steam through the dry pipe so as to cause a reduction in pressure of 10 pounds and thus obtain a slight degree of superheat. In this case, however, the valves were applied to the boiler drum and not to the dry pipe.

Some rules insist on the outlet area being equivalent to the full bore of the safety valve. This appears both unnecessary and unreasonable, for if we have only 1/11 of the area for the steam to pass through at the valve seat, we certainly do not require the full area in the outlet to pass on to the atmosphere. I would suggest that the area at the outlet from a safety valve should be equal to one-half the nominal area of the valve itself.

In the test on the United States cruiser "Tennessee," where we tried this scheme, we [illegible] with capped outlets [illegible] with one of the connecting ends [illegible] valves without [illegible] and although the steam pressure went up 20 pounds above the popping point, no trouble was experienced as a result of this outlet stoppage, thus proving beyond doubt that a combined area of outlet equal to one-half of the area of the safety valve, which is the way in which most of the United States battleships are equipped, is sufficient to prevent an excess of accumulation of pressure.

Philip G. Darling.

Mechanical Engineer of Manning, Maxwell and Moore, submitted a paper on "Safety Valve Capacity," the purpose of which is to show an apparatus and method devised to determine safety valve lifts, giving the results of tests made with this apparatus upon different valves, to compare a few of the existing rules or formulas governing valve size and to propose a rule giving the weight of a series of discharge of steam [illegible] based on experiments [illegible] special requirements, and results as indicate its general bearing upon valve requirements.

Two factors have mainly had a prominent part [illegible] determining the area of discharge and hence the relieving capacity; the diameter of the inlet opening at the seat and the valve lift. The former is the nominal valve size, the latter is the amount the valve disk lifts vertically from the seat when in action. In calculating the sizes of valves to be placed on boilers, rules which do not include a term for this valve lift, or an equivalent, such as a term for the *effective* area of discharge, assume in their derivation a lift for each size of valve. Nearly all existing rules and formulas are of this kind which rate all valves of a given nominal size as of the same capacity.

To find what lifts valves of standard make actually have in practice, and thus test the truth or error of this assumption that they are approximately the same for valves of the same size, an apparatus has been devised and tests upon different makes of valves conducted. With this apparatus not only can the valve lift be read at any moment to one-thousandth of an inch, but an exact permanent record of the lift during the blowing of the valve is obtained somewhat similar to a steam-engine indicator diagram in appearance and of a quite similar use and value in analyzing the action of the valve. See Fig. 1.

As appears in Figs. 2 and 3, the valve under test is mounted upon the boiler in the regular manner, and a small rod is tapped into the top end of its spindle, which rod connects the lifting parts of the valve directly with a circular micrometer gage, the reading hand of which indicates the lift upon a large circular scale or dial. The rod through this gage case is solid, maintaining a direct connection to the pencil movement of the recording gage above. This is a modified Edson recording gage with a multiplication in the pencil movement of about 8 to 1 and, with the chart drum driven by an electric motor, giving a horizontal time element to the record. The steam pressures are noted and read from a large test gage graduated in pounds per square inch, and an electric-spark device makes it possible to spot the chart at any moment, which is done as the different even pound pressures during the blowing of the valve are reached. The actual lift equivalents of the pencil hights upon the chart are carefully calibrated so that the record may be accurately measured to thousandths of an inch.

In testing, the motor driving the paper drum is started and the pressure in the boiler raised. The valve being mounted directly upon the boiler, then pops, blows down and closes under the exact conditions of service, the pencil recording on the chart the history of its action.

With this apparatus, investigations and tests were started upon seven different makes of 4-inch stationary safety valve and these tests were followed with similar ones upon nine makes of muffler locomotive valve, six of which were 3½-inch

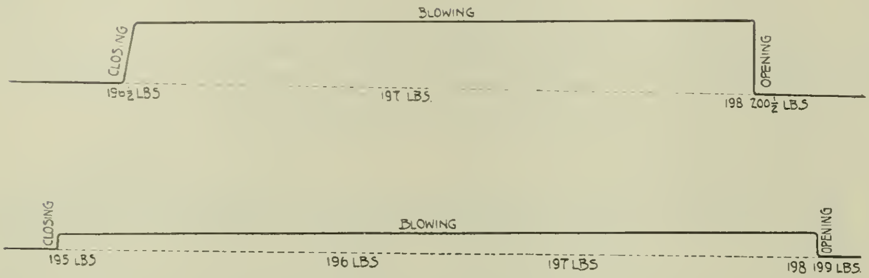

FIG. 1. TYPICAL HIGH- AND LOW-LIFT SAFETY-VALVE DIAGRAMS

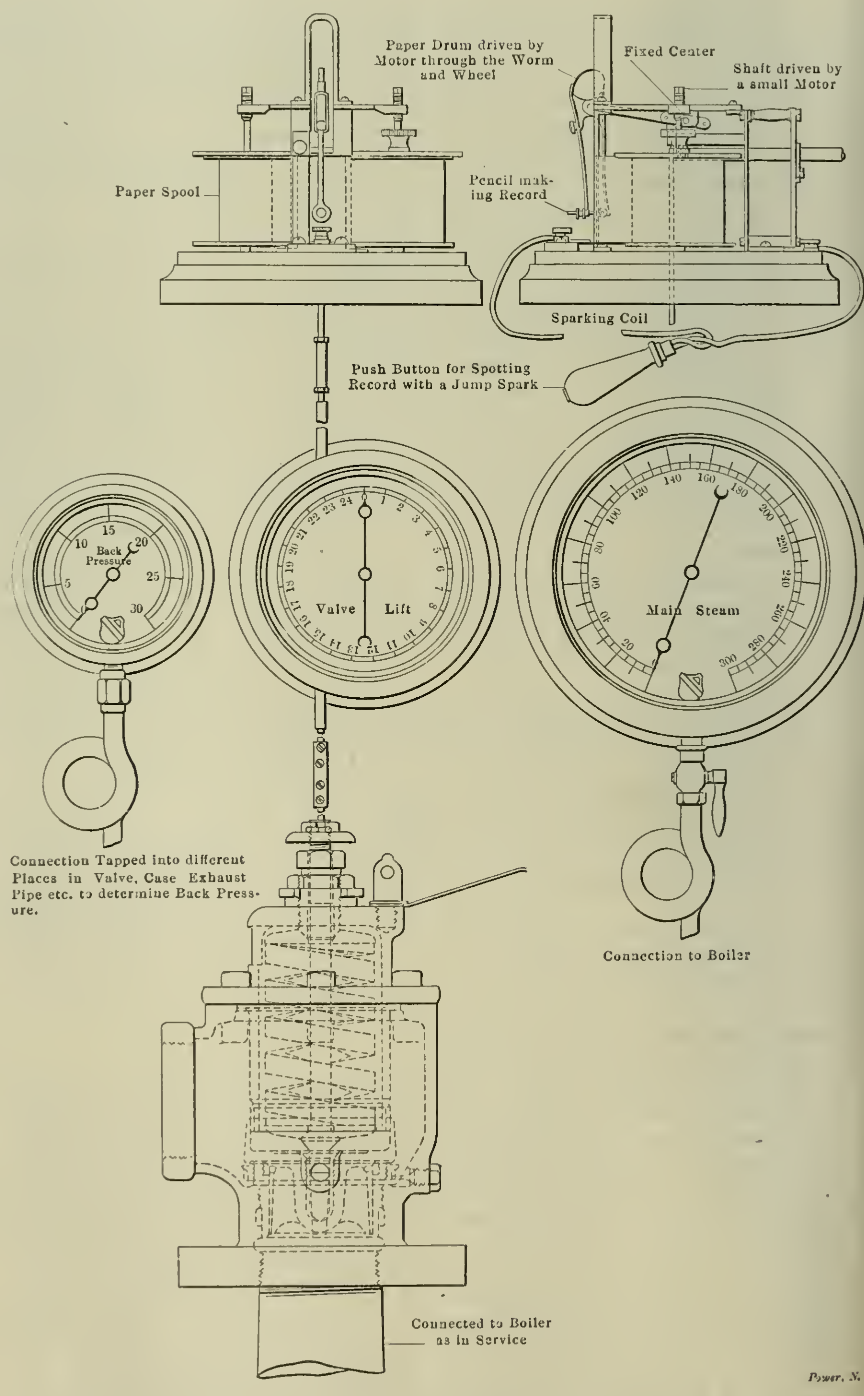

FIG. 2. OUTLINE DRAWING OF THE SAFETY-VALVE TESTING APPARATUS

l of the valves being designed for and sted at 200 pounds. The stationary-alve tests were made upon a 94 horse-ower water-tube boiler made by the abcock & Wilcox Company. The loco-otive-valve tests were made upon loco-otive No. 800 of the Illinois Central ailroad, the valve being mounted di-ectly upon the top of the main steam ome. This locomotive is a consolida-on type, having 50 square feet of grate rea and 2953 square feet of heating sur-

The results of the 4-inch iron-body stationary valve tests summarized are as follows: Of the seven valves the average lift at opening was 0.079-inch and at closing 0.044-inch, or, excluding the valve with the highest lifts, the averages were 0.07-inch at opening and 0.037-inch at closing. The valve with the lowest lifts had 0.031-inch at opening and 0.017-inch at closing, while that with the highest had 0.137-inch and 0.088-inch. Expressing the opening lifts as percentages of the

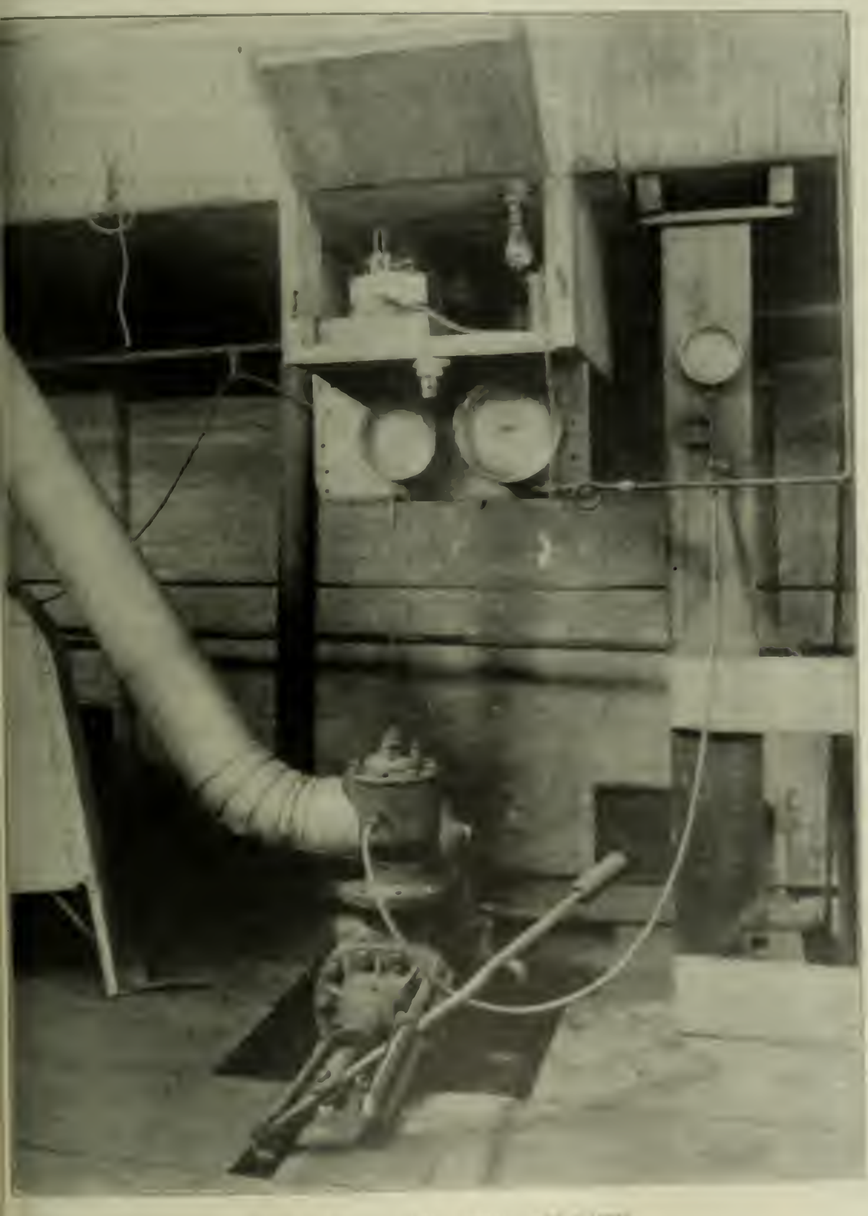

FIG. 3. PHOTOGRAPH OF THE APPARATUS

face. Although a great amount of additional experimenting has been done, only the results of the foregoing will be quoted in this paper. These lift records show (with the exception of a small preliminary simmer which some of the valves have) an abrupt opening to full lift and an almost equally abrupt closing when a certain lower lift is reached. Both the opening and closing lifts are significant of the action of the valves.

highest, the lowest had [illegible] per cent., the next larger [illegible] per cent., and the next [illegible] per cent. Of the [illegible]-inch [illegible] locomotive valves the summarized [illegible] are as follows: Average of the [illegible] valves [illegible]-inch at opening and [illegible]-inch at closing. Average, excluding the highest, [illegible]-inch at opening and [illegible]-inch at closing. The lowest lift valve had [illegible] inch opening and [illegible]-inch closing, the highest [illegible] [illegible] [illegible]

closing. As percentages of the highest the lowest lift valve was 36.4 per cent., the next larger 30.8 per cent., and the next 36.4 per cent.

The great variation—300 per cent.—in the lifts of these standard valves of the same size is startling and its real significance is apparent when it is realized that under existing official safety-valve rules these valves, some of them with less than one-third the lift and capacity of others, receive the same rating and are listed as of equal relieving value.

[After explaining the rule of the board of supervising inspectors, the derivation of which is explained in Mr. Lowden's remarks, Mr. Darling says:]

In the valves to which this rule is applied the following lifts are assumed to exist: 1-inch valve, 0.03; 2-inch valve, 0.06-inch; 3-inch valve, 0.09-inch; 4-inch valve, 0.13-inch; 5-inch valve, 0.15-inch; 6-inch valve, 0.19-inch.

Referring back to the valve lifts found by test, it is seen that the highest lift agrees very closely with the lift assumed in the rule and if the valve lifts of the different designs were more uniformly of this value or if the rule expressly stipulated either that the lift of 1/32 of the valve diameter actually obtains in valves qualifying under it or that an equivalent discharge area be obtained by the use of larger valves, the rule would apply satisfactorily to that size of valve. However, the lowest-lift valve actually has but ¼, the next larger less than ½ and the average lift of all but the highest-lift valve, which average is 0.07-inch, is but 50 per cent. of the lift assumed in the rule for these 4-inch valves.

Massachusetts Rule of 1909

$$A = \frac{W \times 70}{P} \times 11,$$

where

A = Total area of safety valve or valves in square inches.

W = Pounds of water evaporated per square foot of grate surface per second.

P = Boiler pressure (absolute).

One of the most recently issued rules is that contained in the pamphlet of the new Massachusetts Board of Boiler Rules, issued March 22, 1908. This rule is merely the United States rule given herewith with a [illegible] per cent. larger constant and therefore requiring that amount larger valves. The evaporation term is expressed in pounds per second instead of per hour, and the constants are given instead of [illegible] [illegible] when reduced to the form of the United States rule it gives:

$$A = 0.2074 \, W \, \frac{W}{P}$$

[illegible] [illegible] [illegible] [illegible] [illegible] [illegible] the United States rule [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] done, shows that this rule assumes a valve lift of 1/33 of the valve diameter instead of 1/32 of the United States rule. This changing of the assumed lift from 1/32 to 1/33 of the valve diameter being the only difference between the two rules, the inadequacy of the United States rule just referred to applies to this more recent rule of the Massachusetts Board.

Philadelphia Rule:

$$A = \frac{22.5\,G}{P \times 8.62},$$

where

A = Area of safety valve in square inches per square foot of grate,
G = Grate area in square feet,
P = Boiler pressure (gage).

The Philadelphia rule now in use came from France in 1868, being the official rule there at that time, and was adopted and recommended to the City of Philadelphia by a specially appointed committee of the Franklin Institute; although this committee frankly acknowledged in its report that it "had not found the reasoning upon which the rule had been based." The area A of this rule is the effective valve opening, or, as stated in the Philadelphia ordinance of July 13, 1868, "the least sectional area for the discharge of steam." Consequently, if this rule were to be applied as its derivation by the French requires, the lift of the valve must be known and considered whenever it is used. However, the example of its application given in the ordinance, as well as that given in the original report of the Franklin Institute committee which recommended it, show the area A applied to the nominal valve opening. In the light of its derivation this method of using it takes as the effective discharge area the valve opening itself, the error of which is very great. Such use, as specifically stated in the report of the committee referred to, assumes a valve lift at least ¼ of the valve diameter, i.e., the practically impossible lift of 1-inch in a 4-inch valve.

The principal defect of these rules in the light of the preceding tests is that they assume that valves of the same nominal size have the same capacity and they rate them the same without distinction in spite of the fact that *in actual practice some have but one-third of the capacity of the others*. There are other defects as have been shown, such as varying the assumed lift as the valve diameter, while in reality with a given design the lifts are more nearly the same in the different sizes, not varying nearly as rapidly as the diameters. And further than this, the actual lifts assumed for the larger valves are nearly double the actual average obtained in practice.

The elements of a better rule for determining safety-valve size exist in Napier's formula for the flow of steam, combined with the actual discharge area of the valve as determined by its lift. In "Steam Boilers," by Peabody and Miller, this method of determining the discharge of a safety valve is used. The uncertainty of the coefficient of flow, that is, of the constant to be used in Napier's formula when applied to the irregular steam discharge passages of safety valves has probably been largely responsible for the fact that this method of obtaining valve capacities

SAFETY VALVE CAPACITY TESTS.

Note No. 1.—The valves all having 45° bevel seats, these areas are obtained from formula: $a = 2.22 \times D \times l + 1.11 \times l^2$ except where as in tests Nos. 8, 18, 23, 25, the valve lift is greater than the depth of the valve seat, where the following formula is used: $a = 2.22 \times D \times d + 1.11 \times d^2 + \pi \times D \times (l - d)$. a = discharge area (sq.in.). D = valve dia. (in.). l = valve lift (in.). d = depth of valve seat (in.).

Note No. 2.—The four wings of the valve feather or disk probably reduce the flow slightly, but as these are cut away at the seat a definite correction of the exit areas for them is impossible. Further, the formula constants are desired for the valves as made.

has not been more generally used. To determine what this constant or coefficient of flow is and how it is affected by variations in valve design and adjustment, an extended series of tests have recently been conducted at the Stirling department of the Babcock & Wilcox Company, at Barberton, Ohio.

A 373-horsepower class K No. 20 Stirling boiler, fired with a Stirling chain grate, with a total grate area of 101 square feet, was used. This boiler contained a U-type of superheater designed for a superheat of 50 degrees Fahrenheit.

The valves tested consisted of a 3-, 3½- and a 4-inch iron stationary valve, and a 1½-, 3- and 3½-inch locomotive valve, the latter with and without mufflers. These six valves were all previously tested and adjusted on steam. Without changing the position of the valve disk and ring the springs of these valves were then removed and solid spindles, threaded (with a 10-pitch thread), inserted through the valve casing above. Upon the top ends of these spindles were placed handwheels graduated with 100 divisions, shown in Fig. 4 as applied to the locomotive valves, the spindle and graduated wheel being similar to that used with the stationary valves. By this means the valve lift to thousandths of an inch was definitely set for each test and the necessity for constant valve-lift readings with that source of error eliminated. In all 29 tests were run, fifteen were 3 hours long, four 2½ hours, three 2 hours and seven of shorter duration.

Tests numbered 1 to 5 were preliminary runs of but one hour or less apiece, and the records of them are thus omitted in the accompanying table which gives the lifts, discharge areas, average pressure and superheat, and the steam discharge in pounds per hour of each of the other tests. The discharge areas have been figured for 45-degree seats from the formula

$$a = 2.22 \times d \times L + 1.11 \times L^2,$$

where a equals the effective area in square inches, d the valve diameter in inches and L the valve lift in inches.

In tests 8 and 21, where the width of valve seat was 0.225-inch and 0.185-inch, respectively, and the valve was thus slightly above the depth of the valve seat the area was figured for this condition.

As previously stated the application of these results is in fixing a constant for the flow of Napier's formula as applied to safety valves. This formula (given in the derivation of the board of supervising inspectors' rule) may be stated as

$$E = C \times a \times P,$$

in which E equals the pounds of steam discharged per hour and C is a constant; E, a and P being given for the tests, C is directly obtainable.

Figuring and plotting the values of this constant indicates the following conclusions:

(1) Increasing or altering the steam pressure from approximately 95 to 150 pounds per square inch (tests 14 and 20) does not affect the constant, this merely checking the applicability of Napier's formula in that respect.

(2) Radically changing the shape of the valve disk outside of the seat at the huddling or throttling chamber, so-called, does not affect the constant or discharge. In test No. 15 the valve had a downward projecting lip, resulting in deflecting the steam flow through nearly 90 degrees, yet the discharge was practically the same as in tests 10 and 14, where the lip was cut entirely away, as in Fig. 4, giving a comparatively unobstructed flow to the discharging steam.

(3) Moving the valve-adjusting ring

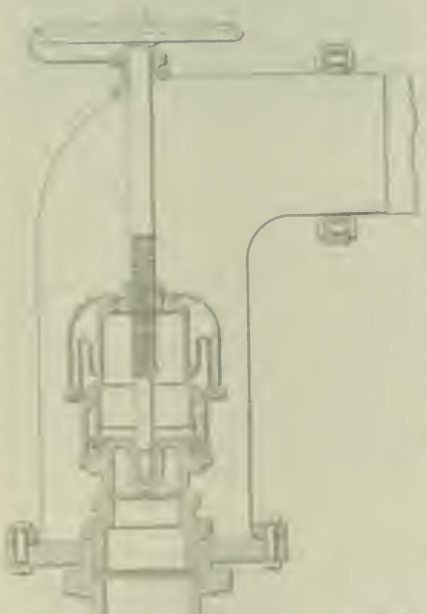

FIG. 4. VALVE DEVICES

through much more than its complete adjustment range does not affect the constant or discharge (tests 16 and 17).

(4) The addition of the muffler to a locomotive valve does not materially alter the constant of discharge. There is less than 2 per cent. difference between tests 10 and 13.

(5) Disregarding the rather unsatisfactory 1½-inch and 3-inch locomotive valve tests, the different sizes of valves tested show a variation in the constant when plotted to given lifts of about 3 per cent.

(6) There is a slight uniform decrease of the constant when increasing the valve lifts.

The variations indicated in the last two conditions are not large enough, however, materially to impair the value of a single constant obtained by averaging the constants of all the tests from those given. The selection of such a constant is necessary to correct with the other [illegible] conditions mentioned. The average constant is 47.5, giving as the formula

$$E = 47.5 \times a \times P.$$

The theoretical value for the constant of Napier's formula is 51.4, of which the above is 92½ per cent.

To make this formula more generally serviceable, it should be expressed in terms of the valve diameter and lift, and can be still further simplified in its application by expressing the area E (steam discharged or boiler evaporation per hour) in terms of the boiler heating surface or grate area. For the flat seated [illegible] 45-degree seats the effective discharge area is, with a slight approximation,

$$a = L \times \cos 45 \times \pi \times D,$$

in which L equals the valve lift, vertically, in inches and D the valve diameter in inches. Substituting this in the foregoing formula gives

$$E = 47.5 \times L \times \cos 45 \times \pi \times D \times P$$

or

$$E = 105.5 \times L \times D \times P.$$

The slight mathematical approximation referred to consists in multiplying the $L \times \cos 45$ by $\pi \times D$ instead of by the exact value $\pi \times D$ [illegible] L. To find directly the effect of this approximation upon the constant, the values for E, L, D and P from the tests have been substituted in the formula and the average constant redetermined, which is 105.1. The average lift of all the tests is 0.110-inch. Plotting the constants obtained from the formula in each test, as ordinates, to valve lifts as abscissas, allowing for the slight inclination referred to in condition (6), and plotting a line with this inclination through the obtained average constant, 105.1, shown at the 0.110 average lift, gives a line which at a maximum lift of 0.1-inch gives a constant of about 106. At lower lifts this is slightly larger. Therefore, 106 would seem to be the conservative figure to adopt as a constant in this formula for general use, giving

$$E = 106 \times L \times D \times P.$$

This transposed for D gives:

$$D = 0.00943 \times \frac{E}{L \times P}.$$

[illegible]

[illegible]

exists, place these constants on the safe side. The capacities of the stationary and locomotive valves, the lift-test results of which are summarized in the foregoing, have been figured from this formula, taking the valve lifts at opening and in pounds of steam per hour, and are as follows:

Of the seven 4-inch iron-body stationary valves, the average capacity at 200 pounds pressure is 7370 pounds per hour, the smallest capacity valve (figured for a flat seat) has a capacity of 3960 pounds, the largest 12,400 pounds; and of the six 3½-inch muffler locomotive valves at 200 pounds pressure, the average capacity is 6060 pounds per hour, the smallest 4020 pounds, the largest 11,050 pounds.

To make the use of the rule more direct where the evaporation of the boiler is only indirectly known it may be expressed in terms of the boiler-heating surface or grate area. This modification consists merely in substituting for the term E (pounds of total evaporation per hour) a term H (square feet of total heating surface) multiplied by pounds of water per square foot of heating surface per hour which the boiler will evaporate. Evidently the value of these modified forms of the formula depends upon the proper selection of average boiler evaporation figures for different types of boiler and also upon the possibility of so grouping these boiler types that average figures can be thus selected. This modified form of the formula is

$$D = C \times \frac{H}{L \times P},$$

in which H equals the total boiler heating surface in square feet and C is a constant.

Values of the constant for different types of boiler and service have been selected. These constants are susceptible, of course, to endless discussion among manufacturers and it is undoubtedly more satisfactory where any question arises to use the form containing the term E itself. Nevertheless the form containing the term H is more direct in its application and it is believed that the values given in the following for the constant will prove serviceable. In applying the formula in this form rather than the original one containing the evaporation term E, it should be remembered that these constants are based upon average proportions and, therefore, should not be used for boilers in which any abnormal proportions or relations between grate area, heating surface, etc., exist.

For cylindrical multitubular, vertical and water-tube stationary boilers a constant of 0.068 is suggested. This is based upon an average evaporation of 3½ pounds of water per square foot of heating surface per hour, with an overload capacity of 100 per cent., giving 7 pounds per square foot of heating surface, the figure used in obtaining the constant.

For water-tube marine and Scotch marine boilers, the suggested constant is 0.095. This is based upon an overload or maximum evaporation of 10 pounds of water per square foot of heating surface per hour.

For locomotive valves the constant is 0.055, determined experimentally as explained in what follows: In locomotive practice there are special conditions to be considered which separate it from regular stationary and marine work. In the first place the maximum evaporation of a locomotive is only possible with the maximum draft obtained when the cylinders are exhausting up the stack, at which time the throttle is necessarily open. The throttle being open is drawing some of the steam and, therefore, the safety valves on a locomotive can never receive the full maximum evaporation of the boiler. Just what per cent. of this maximum evaporation the valve must be able to relieve under the most severe conditions can only be determined experimentally. Evidently the severest conditions obtain when an engineman, after a long, hard, uphill haul, with a full glass of water and full pressure, reaches the top of the hill and suddenly shuts off his throttle and injectors. The work on the hill has got the engine steaming to its maximum and the sudden closing of throttle and injectors forces all the steam through the safety valves. Of course, the minute the throttle is closed the steaming quickly falls off and it is at just that moment that the severest test upon the valves comes.

A large number of service tests have been conducted to determine this constant. The size of the valves upon a locomotive has been increased or decreased until one valve would just handle the maximum steam generation and, the locomotive heating surface being known, the formula was figured back to obtain the constant. Other special conditions were considered, such as the liability in locomotive practice to a not infrequent occurrence of the most severe conditions; the exceptionally severe service which locomotive safety valves receive; and the advisability on locomotives to provide a substantial excess valve capacity.

As to the method of applying the proposed safety-valve capacity rule in practice, manufacturers could be asked to specify the capacities of their valves, stamping them upon them as the opening and closing pressures are now done. This would necessitate no extra work, only the time required in the stamping, because for valves of the same size and design giving practically the same lift this would have to be determined but once, which of itself is but a moment's work with the small portable lift gage now available. The specifying of safety valves by a designing engineer could then be as definite a problem as is that of other pieces of apparatus. Whatever views are held, as to the advantages of high or low lifts, there can be no question, it would seem, as to the advantage of knowing what this lift actually is, as would be shown in this specifying by manufacturers of the capacities of their valves. Further, as to the feasibility of adopting such a rule (which incorporates the valve lift) in statutes governing valve sizes, this would involve the granting and obtaining by manufacturers of a legal rating for valve designs based upon their demonstrated lifts.

Wrought Pipe

By H. E. Schuler

At one time I worked in the pipe shop of a large manufacturing concern and became more or less familiar with the mistakes made by engineers and others in ordering pipe.

Standard pipe is always measured on the inside (that is 2-inch pipe measures 2 inches inside diameter, etc.) up to and including 12-inch pipe. Above 12-inch, pipe is always measured on the outside and is called "O.D.," or outside-diameter pipe. Extra-strong and double-extra-strong pipe are very nearly of the same outside diameter as standard pipe, the extra thickness being on the inside, thereby decreasing the inside diameter or area of the pipe. For this reason no special die is required to thread them.

In ordering pipe always remember that standard pipe comes threaded, with a coupling on one end, up to and including 12-inch pipe, and above this size, or all "O.D." pipe, the pipe comes with plain ends and an extra charge is made for threads and couplings. The thickness of "O.D." pipe must be specified if you wish it threaded, as it is impractical to thread this pipe when less than 5/16 inch in thickness. Extra-strong and double-extra-strong pipe also come with plain ends and an extra charge is made for threads and couplings.

A great many engineers in ordering pipe simply specify a certain number of feet of wrought pipe of certain size and labor under the delusion that they are getting wrought-iron pipe when they are really getting wrought-steel pipe.

If you wish wrought-iron pipe you must specify: "This pipe must be strictly wrought-iron." Wrought-iron pipe costs a little more than wrought-steel pipe and the bursting pressure is considerably less.

A great many engineers claim that wrought-iron pipe is more durable than and not as susceptible to corrosion as wrought-steel pipe and are willing to pay a little more for it. Of course, the safe working pressure of any pipe varies with the inside diameter and the thickness; also the weld, which is always an uncertain factor. From 1/8- to 3-inch pipe can be secured in the butt weld and from 1½-inch up in the lap weld.

Pipe from 1/8- to 3-inch is tested at from 600 to 1000 pounds, and 3-inch to 15-inch at from 500 to 1000 pounds, before leaving the factory. Several lengths of 8- and 10-inch standard pipe were tested and burst at from 1800 to 3200 pounds pressure, but of course there are factors, such as expansion, joints, strains due to improperly hanging threads, etc., which should be taken into consideration when installing pipe. Pieces of pipe 12 inches or under in length are called nipples and are measured from end to end the same as pipe and not between the threads, as thought by some people.

Some of the defects to look for in wrought pipe are poor threads, brittleness, defective welds, flat places and hard spots. The most common complaint is of poor threads, and nine times in ten this complaint would not be registered if a little judgment were used by the engineer or steamfitter. Quite often the end of pipe is jammed against something which pushes the first thread back against the second, making it impossible to start the fitting on the pipe. A few minutes' work with the hammer and cold chisel repairs this and the fitting goes on all right. Sometimes a thread or two are slightly broken, but if one or two threads are completely stripped from the pipe it will not spoil a properly made joint.

When the pipe breaks off in layers just ahead of or between the cutting points of the dies it is defective and should be returned. There are several good dies in the market for threading pipe, also several poor ones, and some judgment should be used in purchasing a set. Personally I always buy an adjustable die so that in cutting pipe 1½-inch or over I can take two cuts, thereby decreasing the labor. Adjustable dies are also very handy in cutting special threads for any purpose.

Dr. Frederick W. Taylor, past president of the American Society of Mechanical Engineers, gave an address before the College of Engineering of the University of Illinois, on Thursday, February 18, along general engineering lines supplemented by anecdotes from the early part of the careers of successful engineers.

A movement has been set on foot by the English Ceramic Society for a conference of representatives of the various technical institutes and societies, to consider ways and means of arranging for the "grading" and standardizing, as far as possible, of the refractory materials, such as fireclay, magnesite, etc., used in the construction of furnaces, kilns and ovens.

Square Plaited Ropes

Square plaited ropes, which are, we believe, of German origin, are much more extensively used abroad than in this country. Quite recently, however, Venhardt & Co., Limited, of 26 and 27 Bush lane, Cannon street, E. C., has taken up the agency here and has already supplied several factories with this type of rope. From what we can gather it appears to

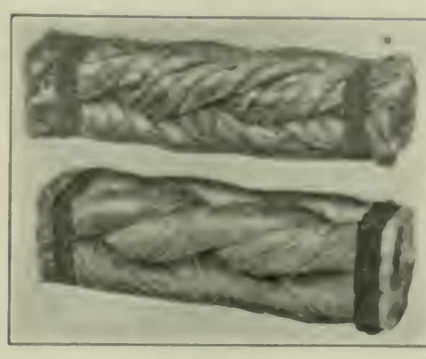

FIG. 1. SQUARE ROPE

give excellent results and to be very durable. The accompanying engraving shows two forms of this rope. They are designed specially for driving and not for cable work, as it is recognized that they will not turn and are, therefore, unsuitable for the latter use. The severest work to which any form of rope may be submitted is probably the driving of

FIG. 2. SQUARE ROPE IN GROOVE

rolling mills. Yet many such mills are now being satisfactorily driven with square plaited ropes. For this purpose a cabled construction is used, its form being shown in the top view of Fig. 1. Each strand is twisted before use into an independent rope, and each strand comprises several threads. The lower view of Fig. 1 shows the plaiting of an ordinary standard construction rope. The ropes are made of hemp or cotton, and the firm guarantees a hemp rope, although stronger, to outlast a cotton rope. No special pulleys are required, as the rope lies into an ordinary groove in the manner shown in Fig. 2. The ropes each comprise eight strands, two sets of four strands each are so to speak opposed to each other, by which means it is claimed that the rope follows an even and uniform course, while it is free from any tendency to twist or turn. High pliability is another advantage claimed for this form of rope, and pulleys of very moderate diameter may be used, which is small compared with what is required for round ropes. We were told that special attention is paid to the treatment of the rope while under construction to take as much of the stretch out of it as possible. Each strand is stretched before use, and the special manner of plaiting permits of stretching the ropes to the maximum limit. To render these waterproof they are impregnated with a special solution, no tar being used.

With regard to the properties of the square plaited rope, we were informed that the 1¾-inch size will replace and give the same power as a 2-inch round rope and that it is from 10 to 15 per cent. lighter than the round rope which it displaces. The square ropes which have been impregnated as a protection against the influence of the weather are naturally heavier than those which have not been so treated. The following table by the maker gives some interesting data relating to the square ropes which will enable a comparison to be made with the better known round rope drives.

Square Plaited Ropes			[illegible]	[illegible]
[illegible]	[illegible]	[illegible]		
[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

The load is generally assumed to be from 85 to 115 pounds per square inch of section, the latter being the general practice with these ropes. The square plaited ropes appear to have a long life, and to be free from the normal amount of stretching. We were assured that there are cases where the ropes have been working for eight and nine years in running belts without re-splicing being necessary.—The Engineer, London.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for February, 1909, was (weekly and monthly) 151,000.

March 2............... 42,000
March 9............... 37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents PAGE

Progressiveness and Asininity

There is really a very narrow line of separation between real, commendable progressiveness and a stupid belief in one's ability to upset natural laws. The same underlying spirit produces both the brilliant investigator and discoverer and the pitiable dupe of his own ignorance who firmly believes in perpetual motion and the creation of energy—that is, unwillingness to accept as final the dicta of other seekers after knowledge. If we all were content with the fruits of investigations made by dead and gone physicists and engineers there would be no more progress in applied physics and engineering; neither would there be the perennial crop of perpetual-motion and similar misguided inventors.

There is one supreme test, however, which invariably differentiates an intelligent investigator from a self-centered fool: the application of established natural laws to his ideas. The work of the former type of man is always in conformity with the fundamental laws of nature which have been proved to be sound, while that of the false prophet is always based on a violent distortion or total disregard of all physical laws applying to his problem; the former never tries to upset the laws of gravity and of the conservation of energy, whereas the latter invariably manifests a lofty contempt for theory and a valiant determination to force tribute from Nature without giving up an equivalent.

Safety Valves

For years the rule of the Board of Supervising Inspectors of the Steamboat Inspection Service of the United States, which was our principal if not our only official expression upon the subject of safety-valve capacity, was one square inch of safety-valve area for each three square feet of grate surface. Gradually it became apparent that the grate surface, apart from the rate of combustion, was no measure of the steam-making capacity of a boiler, and that a given orifice would discharge more steam at a higher than at a lower pressure, in fact, that the weight discharged per unit of time was in direct proportion to the absolute pressure.

Five years ago the board adopted the following formula devised by L. D. Lovekin, chief engineer of the New York Shipbuilding Company:

$$Area = 0.2074 \frac{\text{Weight of steam per hour}}{\text{Absolute pressure}}.$$

The derivation of this formula is explained on page 473. It is based upon Napier's approximate formula for the flow of steam through an orifice:

$$W = \frac{A\ P}{70},$$

where the weight, W, is in pounds per second, the area A in square inches and pressure P in pounds absolute.

Mr. Lovekin's formula is based upon the assumption that the valve lifts one-thirty-second of its diameter, i.e., that a one-inch valve will lift one-thirty-second of an inch and a six-inch six-thirty-seconds, or three-sixteenths; and the coefficient 0.2074 comes by multiplying the 70 of Napier's formula by 32 and dividing by 3600, to reduce the area required to release the given weight in a second to that required to release it in an hour, by 0.75 chosen arbitrarily "for safety" and by 4, which is the 4 of the common expression for area:

$$Area = d^2 \frac{\pi}{4} = d^2\ 0.7854,$$

the π canceling out. If the weight W is taken as per square foot of grate surface the area must, of course, be multiplied by the number of square feet of grate surface involved, and this may be an excuse for striving for accuracy in the coefficient, for any inaccuracy would be multiplied in proportion; but it is difficult to see the necessity or sense, in a formula based upon Napier's confessed approximation, involving an assumed lift, which the valve will hit only by accident, including an arbitrarily chosen factor of safety, and used to indicate the next larger size of valve commercially available, of carrying the coefficient out to four places of decimals. If the formula had been written:

$$A = 0.2 \frac{W}{P},$$

it would have been more simple and sensible and would have indicated the same size of valve in any case except where the present rule falls just above an available size.

But the experiments made by Mr. Darling and reported on pages 473 +, as well as the discussion at the meeting at which the paper was presented, brought out the fact that safety valves do not lift in proportion to their diameters; that the lift is practically the same for a large, as for a small valve, smaller for the larger valve if anything, and is around three-thirty-seconds of an inch for all valves in normal condition. The recognition of this fact makes a beautifully simple formula possible.

The area available for the discharge of steam with a flat-seated valve is the product of the circumference and the lift, or with a beveled seat, the above product multiplied by the sine of the angle which the seat makes with the vertical axis. If the Napier formula,

$$W = \frac{A\ P}{70},$$

be multiplied by 3600 to express W in pounds of steam to be discharged per hour instead of per second, and transposed to indicate the area required, it will read:

$$A = \frac{70\ W}{3600\ P}.$$

If A be taken as the product of the circumference and the lift ($d \times 3.1416 \times l$), and the lift be assumed as one-sixteenth of an inch,

$$\frac{d \times 3.1416}{16} = \frac{70\ W}{3600\ P}$$

or

$$d = \frac{16 \times 70 \times W}{3.1416 \times 3600\ P},$$

and

$$d = 0.1\ \frac{W}{P},$$

almost exactly.

Dividing the weight of steam to be delivered per hour by the absolute pressure of that steam and moving the decimal point one place to the left would give the diameter of valve required directly, without any reference to tables of areas and, the available area varying directly as the diameter, the result can be proportioned among a number of valves, if too large for one, by simple division. If the rule indicated 12 inches of diameter two 6-inch, or three 4-inch valves could be used.

For the common 45-degree beveled seat the constant would become 1.4; but if the lift be assumed to be 0.0714 instead of one-sixteenth or 0.0625 the constant will return to 0.1. This is less than $\frac{5}{64}$. Mr. Lovekin's rule has been assuming that a three-inch valve lifts $\frac{3}{32}$ or $\frac{6}{64}$, and any maker will guarantee a valve of any size to lift three thirty-seconds, when the valve pops, and to stand at that hight so long as the pressure is maintained. Should the pressure increase the valve is free to open farther, and more of the higher pressure steam will escape through the same area due to its greater density so that there is an ample margin of safety. Mr. Lovekin's rule has proved ample and the proposed rule gives the same results for valves 2 5/4 inches in diameter, requires less diameter of valve below this and more than his formula does for diameters greater than 2 5/4 inches.

The purpose of a rule for safety valves is not to determine with mathematical precision the exact area required to discharge a given amount of steam per second, but to indicate a size of valve which will be ample for that service without being so large as to discharge the boiler too quickly or to be extravagant in cost. The proposed rule is simpler and safer than the present, is more consistent with the governing facts, if, as it appears, the lift is practically the same for all sizes of valves, and will, we believe, indicate valves ample to discharge the assumed amount of steam, but not needlessly large.

In estimating the quantity of steam which the valve may be called upon to discharge it should be borne in mind that the maximum rate of evaporation for a few minutes is apt to considerably exceed the average rate. The performance of a boiler for an hour is the aggregate result of varying conditions of fire, draft, rate of feed, etc. The momentary evaporation under favorable conditions may be considerably more than the average evaporation for the hour.

The establishment by Mr. Darling of the fact that Napier's formula applies so closely to the discharge from a safety valve is very gratifying. It remains to be determined if any allowance is required for superheated steam within the limits of ordinary practice.

Be Exact

In all professions it pays to be exact in thought and statement, oral or written, and more especially does this apply to engineering. Although a great many engineers are, perhaps, exact enough in thought, there is a general tendency to be careless in the expression of the thought. To a certain extent this is only natural, for back of the statement, in the mind of the writer, is the idea, and the meaning to him is perfectly plain, but to the reader, who sees only the expression, the statement not only may not be clear, but is often misleading. Long-continued carelessness in this regard will surely leave its mark, and in time the careless writer becomes the careless thinker; and the same characteristic will creep into the solution and computation of the problems which enter into the everyday life of the engineer.

Many errors have been caused by the careless use of the word "pressure," or failure to specify what pressure is meant. Customary use of the word in connection with steam practice refers to pressure per square inch above the pressure of the atmosphere, as indicated by an ordinary gage. But many calculations require the pressure to be taken in pounds absolute, i.e., as the quantity indicated by an ordinary pressure gage plus the pressure of the atmosphere. In other calculations the pressures must be taken per square foot; and other situations which should be taken in millimeters of mercury or kilograms per square centimeter are [illegible] taken in the customary pounds per square inch.

Other words, such as work, power, energy and force, are often confused. To know the proper definitions and how to use each word in its right place requires but a few moments and is plainly worth the effort.

Another error of common occurrence is found in the expression of the number of heat units in water at a certain temperature; that is, if the water is at a temperature of [illegible] degrees Fahrenheit, it is not uncommon to be informed that it contains [illegible] B.t.u., when as a matter of fact it contains only [illegible] B.t.u., the starting point of 32 degrees Fahrenheit, from which the amount of heat is reckoned, being entirely overlooked. A designation should always be made as to what thermometrical scale the temperature applies. There are a great many other things along this line requiring the same attention.

The Care of Commutators

Several times we have heard of operating engineers who [illegible] to use emery habitually for smoothing off commutators, and with no bad results. One well known contributor to our columns says he has used it for years without any trouble whatever, and we do not question his veracity in the slightest degree. The number of men who have reported favorable experience with emery, however, is small; the number who have brought trouble upon themselves is large. In a practical operating experience of [illegible] years the present writer has never but once seen emery used for the purpose mentioned without producing worse trouble than that which it was intended to cure; the exception was explained by the facts that no lubricant was used on the commutator and the mica between the bars was unusually thick and of just the quality to match the copper in its rate of wear. Whenever a commutator is lubricated, the use of emery is very likely to be followed by "leaks" across the mica strips which separate the commutator bars. Of course there may be cases where this does not happen. There have been many cases of recovery by persons who have [illegible] doses of deadly [illegible], but this does not prove that [illegible] is a safe habit to form.

The more progressive city libraries of the country are paying increased attention to engineering and technical subjects in their work with the public. Among those which are especially active in this field is the Public Library of Washington, D. C., as shown by the annual report for [illegible] just issued. This institution has organized a special department, the Useful Arts Department, to meet the demands of its readers for books on the engineering trades, and [illegible] [illegible]

"Schutte" Electric Motor Operated Gate Valve

The "Schutte" precision electric motor-operated gate valve is illustrated in Figs. 1 and 2. The loose-fitting handwheel has a vertical movement on the upper end of the yokenut to which it is clutch-connected only when in its lowest or hand-operating position; this step-clutch is formed on the handwheel hub, around which there is a continuous rim, the latter engaging with the two extensions of a pivoted or hinged-gear clutch lever, the heavy end of which, when lowered, engages with a narrow lug on the inside of the rim of the large spur gear also loosely mounted on the yokenut below the clutch collar that carries the aforesaid hinged lever. As this hinged clutch lever and the lug on the inside rim of the gear are both narrow, the gear can make about ⅞ of a revolution for impact and for the purpose of allowing the motor to acquire speed.

When the valve is used for motor operation the handwheel is prevented from revolving and held in its highest or out-of-gear position by the two vertical lever-supported rods resting against the under side of the handwheel rim. From this it will be seen that the handwheel is entirely cut out when the valve is being operated by a motor and can therefore exert no jamming action at the end of travel due to the stored-up inertia, nor does power have to be exerted to set it in motion even frictionally.

The handwheel and gearing as described interlock so that both cannot be out of action at the same time, nor can both be in action at the same time. When the handwheel is in use the motor gearing is disengaged and *vice versa*.

As these valves are intended for operation from a distance, such as from a different floor where the operator at the reversing controller is unable to see in what position the gearing has been left, an instruction plate is provided on each arm of the yoke, so as to insure that the gearing is left ready for emergency use. It is placed on the side opposite to that shown in the illustration and reads: "Always leave valve ready for motor operation with handwheel in highest position;" the raising and lowering of the wheel being accomplished by means of a screw spindle attached to a central lever on the rock-shaft carrying the side levers that raise and lower the supporting rods.

To cut the motor out at the proper time, two travel-limit switches are provided, one for the upward and one for the downward stroke; these close the circuit on a shunt trip coil in the controller so that the latter will be thrown to its off position, thereby informing the operator that the valve has made its complete upward or downward travel, as the case may be. In addition to this a double-pole circuit-breaker is used to guard against burning out of the motor or controller from overload.

These valves find special application as an emergency shutoff on steam mains between boiler and engine, or in turbine rooms. They are fitted with motors for either direct or alternating current of any standard voltage.

To guard the threaded valve spindle from grit or dirt, and to insure a clean, oiled surface, a protecting sleeve is screwed to the upper end of the handwheel hub.

The motor is of special construction, fully incased, provided with self-oiling bearings, of large overload capacity and capable of standing the heat of high-temperature steam to which the valves are subjected.

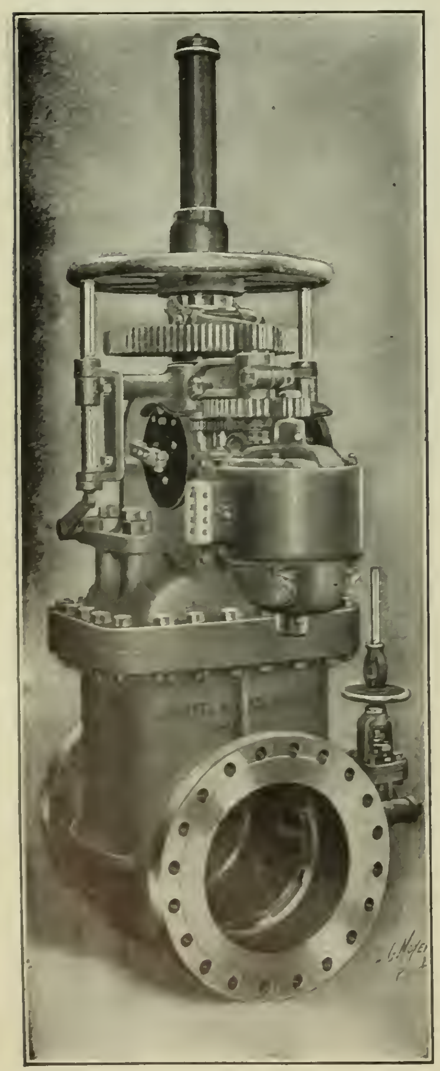

FIG. 1

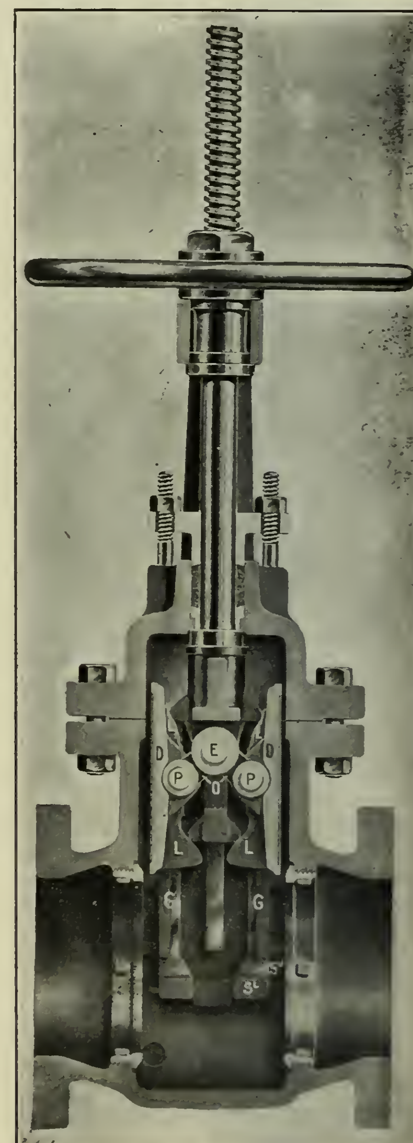

FIG. 2

As gravity is used to engage and disengage the motor gearing and keep the handwheel in its lowest position, these valves must be used with the spindle vertical and with mechanism on the top as shown. They can, however, be fitted with a spring so that the spindle may be used in a horizontal position and the valve may be used inverted.

Fig. 2 is a sectional view of the valve proper, *G G* being the guides which keep the valve disks *D D* in place, the whole being made tight by means of the leverage due to the arrangement shown at *P*, *E* and *L*.

This valve is manufactured by the Schutte & Koerting Company, Twelfth and Thompson streets, Philadelphia, Penn.

Westinghouse Large Direct Current Motors

The accompanying engravings illustrate a line of direct-current motors recently brought out by the Westinghouse Electric and Manufacturing Company in order to meet a growing demand for machines of larger size than the ordinary direct-current lines supply. These machines, known as Type E.M., are built in capacities ranging from 90 horsepower upward

FIG. 1. WESTINGHOUSE HEAVY-DUTY MOTOR

FIG. 2. MAGNET YOKE OF WESTINGHOUSE MOTOR

FIG. 3. WESTINGHOUSE ARMATURE AND COMMUTATOR

FIG. 4. BRUSH AND HOLDER OF WESTINGHOUSE MOTOR

and for all standard direct-current voltages. They are supplied with a standard bed frame and pedestals, as illustrated in Fig. 1, or without bed and pedestals, for direct mounting.

The field magnet consists of a cast-iron yoke ring with laminated magnet poles bolted to the ring. The magnet poles are built up of relatively thick sheets of steel; one pole-tip corner of each sheet is cut off and the sheets are assembled with the remaining tips staggered, as close inspection

of Fig. 2 will reveal. This gives [illegible] possible high magnetic density at the tips, tending to stability of field at the edges of the air gap, of course, and [illegible] improvement in commutation. The field winding is shunt, series or compound, according to the requirements. All three classes of winding are standardized, so that no special construction is necessary in order to [illegible]. The field-magnet coils are wound on heavy

paper tubes or bobbins and treated with a waterproof insulating compound, but they are not wrapped with tape; better radiation is obtained by leaving the surfaces unwrapped.

The armature is of the familiar slotted-core type, with a bar-connected winding of individually insulated coils. The core disks and commutator are mounted on a shell or drum with a smooth spider into which the shaft fits. This construction permits the shaft to be removed and replaced without disturbing the armature-core disks or the commutator connections. The armature winding is equipped with equalizing connections housed in the rear "overhang" of the winding, which is protected against centrifugal force by a band of binding wire, as shown in Fig. 3. This engraving illustrates the general construction of the armature and commutator; the end of the spider into which the shaft fits is just visible within the commutator core. The armature winding is held in the core slots by wooden wedges.

The brush holders are of the simple box type shown in Fig. 4. The brush is pressed on the commutator by a flat spring coiled about an adjustable spindle and a finger loop is riveted to the spring for convenience in lifting the spring away from the brush. The latter is a rectangular carbon block with a flat flexible "pigtail" attached to its upper end by means of a strap and a bolt; the nut on the end of this bolt is held in place by a lock washer. The commutator construction is along the well known standard lines of Westinghouse practice, as is also that of the self-oiling bearings and pedestals.

"Faultless" Metallic Packing

"Faultless" metallic packing is manufactured by the Hoyt Metal Company, [illegible] Locust street, St. Louis, Mo. The metal used in this packing is said to be of a special mixture, made in the form of rings turned [illegible] in the diameter of the rod and cut into [illegible] sections. The sections are held together by wire springs. The rings are in [illegible], with the flat sides together. [illegible] rings with [illegible] hold the packing rings to the rod with a [illegible] and makes [illegible]. The construction is shown in the illustration.

SECTION AND COMPLETE RING OF FAULTLESS METALLIC PACKING

The rubber section of the ring is of especially prepared stock, which is said to be unaffected by steam, oil or ammonia. The rubber does not come in contact with the rod, but acts as a cushion to take up vibration, there being a continuous metal surface beyond the rod.

Obituary

Francis H. Boyer, 64 years old, died at his home in Somerville, Mass., Sunday, February 21. Mr. Boyer was a widely known mechanical engineer and architect, at one time superintendent of the refrigeration department of the De La Vergne company and later master mechanic for the John P. Squire Company. He was a member of the A. S. M. E., and once served on its board of managers for three years. He also belonged to the N. A. S. E., and other engineering organizations. Latterly Mr. Boyer was in business with his son, Charles W. Boyer, manufacturing refrigerating and ice-making machinery, designing abattoirs, building water-cooling towers and coal-handling and conveying machinery.

Business Items

Richard Thompson has opened an office at 123 Liberty street, New York, for the sale of steam specialties.

The York Manufacturing Company, York, Penn., manufacturer of ice and refrigerating machinery, reports 28 recent orders aggregating 1350 tons of refrigeration.

E. J. DuBois, son of William J. DuBois, in charge of the engineering of the fleet of the United Fruit Company, and prominent in M. E. B. A. circles has accepted a position with the sales department of the William B. McVicker Company. His especial attention will be given to marine business.

The "Selden and Zena" packing has just been furnished for use on the plungers of the pumping engines at the waterworks in St. Petersburg, Russia. These packings are made by Randolph Brandt, 72 Cortlandt street, New York, who also advises us that a number of pump manufacturers use these packings for outside-packed plungers, this packing being specified by many chief engineers.

The Hughson Steam Specialty Company, 60 South Halstead street, Chicago, Ill., has succeeded the John Davis Company, of Chicago, in the manufacture of the "Eclipse" steam specialties. George F. Hughson, who is president of the new company, was the original owner and inventor of these specialties, which include regulating, back-pressure relief and blowoff valves, pump regulators, steam traps and separators. All of the former agents of the John Davis Company will continue to handle these goods.

G. J. Burrer, proprietor of the Sunbury Flour Mill and electric-light plant at Sunbury, Ohio, in a letter to the Buckeye Boiler Skimmer Company, South End, Toledo, Ohio, says: "I find the skimmer all right. My boiler has not foamed since I put the skimmer in. When I put the device in there was ⅛ inch of scale on the tubes, and in three weeks they were as clean as could be. I opened the boiler again on Monday and there was not a particle of dirt or mud in the back head, but I took out two gallons of scale from the front head.

"Aid to Shippers" is the title of a 72-page book containing a quantity of information of value to all engaged in the export or import trade. The book is issued by Oelriches & Company, of New York, for more than forty years the American representatives of the North German Lloyd Steamship Company, who, by reason of long experience, are qualified to advise. The table of foreign moneys with United States equivalents, together with weights, measurements, tariffs, customs requirements, etc., will be found of value. A copy of this book will be sent, postpaid, on request to Oelrichs & Company, Forwarding Department, 5 Greenwich street, New York.

Among the recent orders taken by the Crocker-Wheeler Company, of Ampere, N. J., is one for a 250-kilowatt, motor-generator set for the Tennessee Coal, Iron and Railroad Company, at Ensley, Ala. It will consist of a 250-kilowatt 275-volt direct-current generator driven by a 6600-volt 3-phase 25-cycle synchronous motor, and will be used as an exciter. Another order is one for about 50 horsepower of small elevator motors purchased by the Haughton Elevator and Machine Company, Toledo, Ohio. Yawman & Erbe, of Rochester, New York, have also placed orders for a number of 2/5-horsepower motors for use on some of their specialties.

The Missouri Valley Milling Company, Mandan, North Dakota, has given contract to the Minneapolis Steel and Machinery Company, for furnishing and installing the complete power plant for a new mill being built at Dickinson, North Dakota. The contract includes one 12 and 26x36 heavy-duty cross-compound Twin City Corliss engine, with evaporative surface condenser, a 300-horsepower feed-water heater and purifier, a boiler-feed pump, pumps for fire service, a 50-kilowatt direct-current generator, switchboard and motor, one 5000-gallon wooden water tank, oil and steam separators, miscellaneous transmission machinery and all piping, valves and fittings.

J. E. Lonergan Company has been incorporated in Pennsylvania, with a paid-in capital of $200,000, to succeed to the business of J. E. Lonergan & Company, 211 and 213 Race street, Philadelphia, Penn. The new company will have the following officers: John E. Lonergan, president; M. A. Hudson, vice-president; H. S. Whitney, secretary; W. E. Crofton, treasurer; directors, John E. Lonergan, M. A. Hudson, H. S. Whitney, W. E. Crofton, James F. Lonergan. H. S. Whitney and M. A. Hudson were connected for many years at New York and Chicago with Manning, Maxwell & Moore. W. E. Crofton, for the past 26 years, has been cashier and head bookkeeper for J. E. Lonergan & Company.

The International Acheson Graphite Company, of Niagara Falls, advises us that it is the only maker of graphite in the world. It operates the electric-furnace process, and thus the company is in full control of every ounce of raw material that enters its furnaces, while it also controls the application of the furnaces during the entire period of their operation. Because of these facts and the thorough scientific skill applied, this company makes what it calls, "grade 1340 Acheson-Graphite," guaranteed to be at least 99 per cent. pure, very fine, soft, lusterless and unctuous. The company's claim is that this is the best lubricating agent now known, as it is not tough, and has those spreading qualities so necessary to ideal lubrication.

The Keystone Lubricating Company, Philadelphia, manufacturer of Keystone grease, has recently been advised of the efficiency and economy of this product in the lubrication of governor pins of an installation of Westinghouse high-speed engines at the plant of the Electric Storage Battery Company, Philadelphia. In this type of flywheel governor the conditions of safe and effective lubrication are severe, as the governor pin carries a pair of heavy weights and oscillates through a short arc only for its maximum travel between light load and full load on the engine. The chief engineer, reporting on the performance of Keystone grease, states that it gives perfect satisfaction, with a consumption of four to six ounces of No. 2 density grease on each engine per week of thirteen consecutive shifts.

Typical Low-Pressure Steam Turbine Plant

Double-flow Turbine Utilizing the Exhaust of Two 750-Kilowatt Corliss Engines. No Governor, and Capacity Varies with Initial Pressure

BY J. R. BIBBINS

Probably the first application of the low-pressure type of steam turbine to commercial work in connection with American mining properties is to be found in the power plant of the U. S. Coal and Coke Company, Gary, W. Va. Considerable progress has been made in this country in the low-pressure turbines in connection with light and power plants, and this installation will serve as an illustration of the possibilities of this type, not only in mining properties, but also in other industrial work where similar conditions of power service are encountered.

Power Plant

The Gary plant was installed in [illegible] with an equipment of two [illegible]-kilowatt generators, each driven by two simple Harrisburg engines which were later changed to cross-compound engines. In 1904, a 750-kilowatt cross-compound Corliss engine driven unit was added, and in 1905 a duplicate unit, aggregating 2300 kilowatts in engine-type units. On account of installing some new machinery, a low pressure turbine was added in 1907 to utilize the exhaust from the Corliss engines—also a complete expansion turbine, both of standard Westinghouse construction. Each of these drives a 1000-kilowatt generator.

The property at Gary, W. Va., consists of eight coke plants and four coal mines, all electrically driven with the exception of the hoisting engines and fan at one of the mines, which is a shaft; hence the plant is subject to a combination load from a large number of rotary converters which furnish direct current for mine locomotives, pumps, coal-cutting machinery, larries and coke-drawing machines, and for a large number of induction motors which drive fans, [illegible], crushers, picking tables, compressors, conveyors, etc.

The present equipment consists of two 400-kilowatt generators driven by [illegible]-inch Harrisburg engines; two 750-kilowatt generators, each driven by [illegible]-inch Corliss steam engines; one 1000-kilowatt Westinghouse single-flow steam turbine, and one 1000-kilowatt Westinghouse double-flow low-pressure turbine.

This equipment occupies a building [illegible] feet, with an additional 18-foot longitudinal bay for auxiliaries, etc. The 2000-kilowatt capacity in turbines occupies about one-third of the building, and the [illegible]-kilowatt engine-driven units occupy about two-thirds of the building.

It would be noted that the low-pressure turbine receives steam only from the two Corliss engines. The Harrisburg engines, although exhausting into the common header, are [illegible]

FIG. 4. LOW-PRESSURE TURBINE WITH THROTTLE VALVE IN FOREGROUND

ing the day. This exhaust steam is all sent to heaters in the boiler room and a valve in the exhaust header is provided to separate these engines from the remainder of the system, so that the low-pressure plant at Gary is only concerned with the 1500-kilowatt capacity in Corliss engines.

Turbine Types

An interesting comparison of the two types of turbine unit is afforded by these two machines which are of equal capacity. It will be noted from the accompanying table that the low-pressure turbine is one-third shorter than the high-pressure machine, but the hight and width are about the same, the exhaust area of the high being 2.5 times greater. The generators both deliver three-phase power at 6600 volts and each revolves 1500 revolutions per minute. The fields are strap-wound and the armatures form-wound with coils

held in place by overhanging lips of the laminated mold. A puncture test of 15,000 volts was made on the armature winding and 1000 volts on the field. The generators will not exceed 40 degrees rise at continuous full load with a power factor ranging from 90 to 100 per cent., and at full load will give an efficiency of 94 per cent., including iron and copper losses.

The complete-expansion turbine unit has an overload capacity of 50 per cent., but the low-pressure turbine unit, being dependent upon a fixed initial pressure of 15 pounds absolute, can have no overload unless the initial pressure is raised. But with 18 pounds initial pressure, an overload of 25 per cent. would be realized; with longer cutoff on the engines, an initial pressure of perhaps 25 pounds would be obtained with correspondingly greater overload.

Governing

Owing to the service conditions arising in this plant, the simplest system of gov-

FIG. 5. [illegible]

erning has been adopted for the low-pressure unit. In fact, the turbine has no governor at all, but delivers its current to the same busbars as do the two engine units supplying it with exhaust steam. Under this condition, then, the low-pressure turbine is equivalent to the third cylinder of a triple-expansion steam-engine system, and instead of the turbine generator being directly driven by mechanical means from the engine shaft, it is held in perfect step by electrical means; i.e., by connecting with the same bus. It therefore occurs that with the turbine throttle valve open, the load on the turbine and engines will rise and fall together, depending upon the variations in external load, which accordingly varies the amount of exhaust steam supplied to the turbine. By reason of this arrangement, the pressure in the exhaust main varies according to the load on the entire plant, just as the receiver pressure of a compound engine varies.

The low-pressure turbine may be considered as an engine with a fixed cutoff. As the blade proportions are constant, the ability of the turbine to carry load depends entirely upon the initial pressure available; and consequently, as the load on the engine increases, the volume of steam passed per minute increases, the exhaust pressure rises and the low-pressure turbine is enabled to pass the extra quantity of steam required to generate the additional power. Thus it will be seen that this combination of prime movers presents simplicity and flexibility of operation. Under other conditions of service, where the turbine would be able to utilize but a small proportion of the exhaust steam available, it would be necessary to install a governor of the standard type which would convert the turbine into a constant-pressure instead of a variable-pressure machine, as here installed.

Turbine Construction

The construction of the turbine is clearly shown in the accompanying photographs and section. A low-pressure machine is characterized by the large steam passages necessary. Referring again to the accompanying table, the steam-supply mains to the high-pressure and low-pressure machines were 6 and 22 inches respectively; exhausts, 30 and 48 inches. It would be expected that this large difference would increase the bulk of the low-pressure machine beyond reasonable proportions, but through the adaptation of the Westinghouse double-flow design, the machine itself does not occupy even as much space as the single-flow complete-expansion turbine installed in the same power house.

On the other hand, the condenser serving the low-pressure turbine is twice as large as that serving the high-pressure machine; for the reason that in expanding the steam from boiler pressure, 150 pounds gage, down to atmosphere in the Corliss engine, nearly half of its internal work has already been expended, and twice as much steam must, therefore, pass through the low-pressure machine to do the same work as through the high-pressure turbine. The low-pressure turbine condenser at Gary, to be sure, serves 2500 kilowatts combined generating capacity, but owing to the superior economy of the combined plant, the work actually done by the condenser is much less than if serving a straight engine or turbine.

Referring to the sectional view of the turbine, it will be noted that the rotor is of simple construction and reasonable blade lengths, no balancing pistons, and a stator symmetrical in proportions. The disadvantage of excessively large exhaust areas is overcome by dividing the flow in its passage through the machine, combining the two halves in the bedplate into a single discharge to the condenser. In the foreground, Fig. 4, will be observed the automatic, quick-closing throttle which is operated by a centrifugal safety stop at the end of the turbine spindle. This is an important guarantee of the safety of the plant, for should the machine isolate itself electrically from the busbar either by short-circuiting or by an open circuit in the cable leads, the machine would be taking full steam without load. This safety stop operates at a predetermined overspeed, under 10 per cent., and closes the automatic throttle to shut down the machine. As a further precaution, a vacuum breaker may easily be operated instantly to lower the vacuum by the admission of air when the safety stop operates. Owing to the higher density, the turbine would then come to rest much more quickly than if it still were revolving in a high vacuum.

The remaining parts of the turbine conform to Westinghouse high-pressure turbine construction. One distinctive detail, however, is the rotary oil pump driven by worm gear from the turbine shaft. The wing pump is exceptionally simple and durable in construction, and requires little attention. It is located below the floor level at the base of the vertical housing surrounding the gear drive. This pump simply suffices to keep the journals flushed with oil. A complete system of strainer and intercooler provides for continuous return of the oil to the bearings. This apparatus, together with the steam strainer, is located beneath the steel floor plates at the side of the machine.

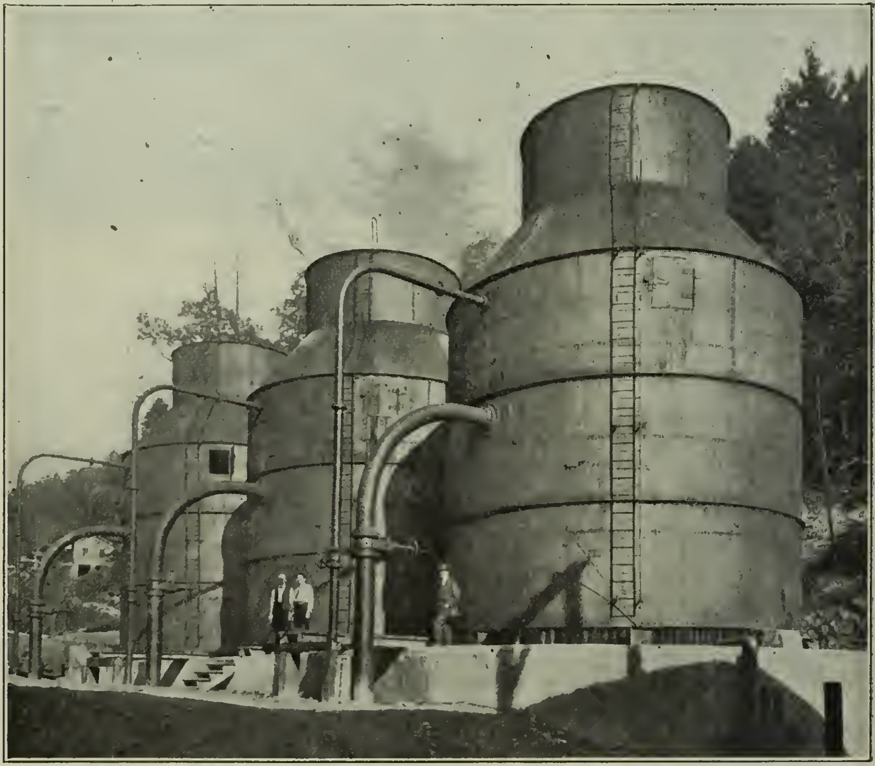

FIG. 6. BATTERY OF THREE ALBERGER COOLING TOWERS

Piping

Reverting to the plant arrangement, Fig. 2 shows in plan and elevation the general piping layout. It will be noted that all turbine-plant auxiliaries exhaust into the main low-pressure line in common with the steam engines. They do not appear to be affected by the variable back pressure of the exhaust system. A 22-inch separator on the side of the low-pressure turbine intake serves to abstract most of the suspended water of condensation, which, if passed through the turbine, would simply be detrimental in increasing the fluid friction. The piping is arranged so that feed water may be drawn either from the condenser hotwell, or the water-service main. In any event the feed would all pass through a Cochrane heater, where the oil coming over from the engines and pumps would be largely removed. Since the low-pressure plant went into com mission, a 3-inch live-steam connection has been made to the exhaust main through a reducing valve set at seven pounds. This is intended for emergencies only, to provide for either one or both Corliss engines being inoperative. It has been of service on several occasions to provide considerable overload capacity on the turbine during a deficiency of engine steam.

Condenser Plant

Both condensers are of the Alberger centrifugal jet type provided with individual turbine driven circulating pumps and engine-driven dry-vacuum pumps. All of the circulating water is cooled by a battery of Alberger cooling towers located a short distance away, each measuring 24 feet in diameter by 34 feet high. These are of a recent type, but standard in regard to the cooling surface employed. A distributor of the "Barker's Mill" type delivers the hot water at the top of the tower. But the draft fan, instead of being located as is ordinarily the case, at the base of the tower, is here installed horizontally in the contracted stack, the fan blades covering the entire area of the stack, which is 11 feet in diameter. This fan is driven at a speed of 175 revolutions per minute by a small Pelton waterwheel which, in turn, is supplied by a small turbo-pump located in the power house. With this arrangement the tower operates upon the induced-draft principle, and it is permissible to lower the shell some 5 or 6 feet below the standard type of tower with base fans, thus effecting a considerable saving in the hight to which the water must be elevated. Of the three towers installed, two were normally employed to serve the combined engine and low-pressure turbine plant, and the third, the high-pressure turbine. Thus far, good service has been obtained from this plant. Considering the combined plant only, with the two engines running and an engine load of 1400 kilowatts, the low-pressure turbine carried 1200 kilowatts with an inlet pressure of 16 pounds absolute and a vacuum of 25.8 inches, due to the high temperature of the injection water, 88 degrees, at the time. These observations were taken during hot weather, and with an increased vacuum, 28 inches, as in colder weather, the turbine would carry loads up to 1500 kilowatts.

E. O'Toole is general superintendent of the plant, and Howard N. Eavenson, chief engineer. The latter reports that with the relief valve set at 16 pounds absolute and the two Corliss engines running, a great deal more steam is obtained than is needed by the low-pressure turbine, even when running at its full load of 1500 kilowatts. This, then, makes the interesting combination of a low-pressure turbine without a governor running on a system of fixed back pressure and excess steam, which virtually amounts to no control on the turbine other than the throttle; i.e., the turbine carries a steady load as long as there is an excess supply of steam.

Gas Engines and Engineers

By F. L. Johnson

One day not long ago a friend, who had spent a great deal of time during the past few years attempting to design a noiseless gas engine, called to explain why more or less noise was necessary in the operation of a gas engine. Just as he had made it plain (to himself, if not to me) that the valve cams, gears and the mushroom-headed valves were of necessity more noisy in their action when used on a gas engine than when employed in the same way on a steam engine, my young friend Sawyer was shown into the room. Introductions followed, and the conversation was resumed.

"It has been found," said the designer, "that machinists and handy men make much better gas-engine operators than regular steam engineers."

Sawyer, who has a settled conviction that it is a steam engineer's business to know more about the theory and practice of operating moving machinery than anyone else, at once became interested and asked for an explanation.

To make his point clear, the designer said:

"The machinist's one real advantage over the steam engineer is that he does not know how to run a steam engine, and because of his ignorance of the steam engine or of any type of engine he will naturally be more inclined to accept advice and instruction.

"Steam engineers expect engines to run quietly. Machinists do not know whether they should be noisy or not, and the usual noises which accompany gas-engine operation do not annoy him. Not expecting any particular sounds, he accepts the noises as he finds them as a matter of course and attempts no adjustments until he knows what to adjust and why it needs adjustment."

"In other words," broke in Sawyer, "the machinist-operator handles a gas engine just as he does a lathe, a planer or a countershaft. He oils the [illegible] parts in the morning and [illegible]. The countershaft gets attention when it squeaks and he runs the machine until something fails. Then he reports to the foreman and a mechanic is called in to fix things.

"I have never known an engineer who would not give an engine a chance to prove what it could do before starting in to make changes, and I do not believe one would treat a gas engine differently from what he would a steam engine. Of course, he does not like the everlasting clatter of cams and gears, because he has known these things to operate noiselessly in other places and does not understand why they need to be noisy here."

As the designer saw that my young friend was getting in earnest, he said, in a conciliatory manner:

"If the steam engineer will not demand of the gas engine that which it cannot give, and will leave all adjustments alone until he understands what the effects of making them will be, he will be able to hold his own against all comers."

Soft words and superior smiles in this case did not produce the desired effect, and my friend Sawyer, trying to conceal as much as possible his earnestness, said:

"I was present at a meeting of mechanical engineers where the alleged unfitness of the steam engineer successfully to operate suction producers and gas engines was dwelt upon and the present and prospective owner gravely cautioned against employing an attendant whose previous condition of servitude had been in the boiler room or otherwise connected with the operation of a steam engine. And I wish to say that I know that the steam engineer will have little or no difficulty in demonstrating his fitness for the work of operating gas engines and producers should any of your superior class of thinkers ever succeed in designing a machine of nearly enough correct thermal and mechanical principles to be operated by anybody, not to mention the intelligent teamster taken from his seat on the wagon box, or the laborer drafted from the dirt pile and its attendant pick and [illegible].

"Your remarks remind me of the time when a whole lot of college electrical engineers condemned the Corliss engine as unfit for driving electrical generators because of the impossibility of satisfactory speed regulation. Most of these men have lived to see most of the electric current used for power and light come from generators driven by Corliss engines. It is the same class of professionals who to-day demand that a gas-engine operator shall be different from the steam engineer. Just how you want him different you do not say, but you leave it to be inferred that those characteristics which are the making of the successful steam engineer are handicaps on the other.

"It is perhaps possible that in the course of evolution from some of the masses of cast iron, steel and brass assembled by the cut-and-try process, with inaccessible moving parts mounted by [illegible] and [illegible] engines, a machine will be produced that, like the brush, will go on forever, requiring little or no skilled attention and no mental effort on the part of the operator. The steam engineer whose trade it is to operate and care for moving machinery will be found the most successful in overcoming the difficulties of gas-engine operation and maintenance."

Inaccuracies of Indicator Diagrams

Distortion of Pencil Motion Due to Inertia, Pressure Lag or Inaccuracies in Mechanism and Spring. Calibration of Indicator Diagrams

BY JULIAN C. SMALLWOOD*

Drum-motion distortion has been discussed in a previous article, and it has been observed that the errors inherent to the indicator emanate from the untruth of its drum motion and from the faultiness of its straight-line mechanism and spring. The former causes inaccuracy in the abscissas and the latter in the ordinates of the diagram. There is still another source of error in the abscissas, namely, the imperfection of the mechanism reducing the motion of the engine crosshead, but this is external to the indicator.

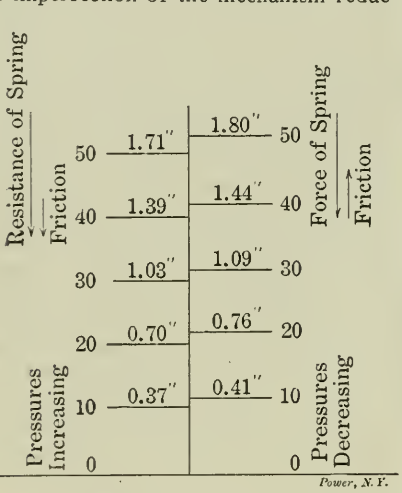

FIG. 1. CALIBRATION OF A 30-POUND SPRING

Distortion of Pencil Motion

Analysis of the pencil motion indicates that its distortion may be due to any or all of four causes: First, when applied to high-speed engines, the inertia of the indicator piston and attached linkage causes it to travel beyond its normal position. This results in a peaked admission line and a wavy expansion curve. Second, under the same conditions, the pressure in the indicator cylinder lags behind that operating on the piston of the engine because of the inability of the steam immediately to traverse the passages to the indicator. The error resulting is most considerable at about mid-stroke where the velocity of the reciprocating parts of the engine is greatest. The general effect is to increase the area of the diagram, cutoff and compression being represented later than they actually occur. Third, the mechanism actuating the pencil may incorrectly magnify the piston motion, and, fourth, the indicator spring almost invariably fails to exemplify the principle upon which its truth depends, that the contraction or extension of the spring is proportional to the force causing it.

Inertia—Of these four possibilities of error the first is troublesome only at high piston speeds. It may be obviated by the use of special indicators or by using stiff springs. Concerning the ordinary types, Professor Reynolds** has pointed out that the effect of inertia of the indicator piston and the attached moving parts can be expressed by two equations, one of which gives the probable distortion in per cent. during one cycle of the mechanism, and the other gives the number of oscillations of the pencil arm during that cycle. The same authority states that the former should be kept within 1 per cent. and the latter within the number 30. Using these figures the following values may be obtained from his equations:

$$s = \frac{0.00563\ W R^2}{a\ r}$$

and

$$s = \frac{0.0252\ W}{a\ r\ R^4},$$

where

s = Spring scale,
R = Revolutions per minute,
a = Area of indicator piston in square inches,
r = Ratio of piston to pencil motion,
W = Sum of the products of the weights in pounds of the separate moving parts and the squares of the ratios of such parts' motions to that of the indicator piston, respectively.

These equations may be reduced for any particular indicator to the form,

$$s = K R^2 \quad \text{and} \quad s = \frac{K'}{R^4},$$

in which K and K' are the constants combined. The greatest value of s resulting from their solution will give the lowest spring scale to be used for a given number of revolutions per minute.

Pressure Lag—The second cause of distortion of the pressure line, named above, cannot well be avoided at high speeds, nor can the resulting error be easily corrected. The disturbance is aggravated by long or tortuous pipe connections and may be considerable on this account even at low piston speeds. A comparison of diagrams taken with long and short connections shows that such piping should always be as short and direct as possible. The consequent error in mean effective pressure may be as high as 25 per cent.

Mechanism and Spring—Of the remaining sources of inaccuracy in the diagram's ordinates, that due to faulty pencil motion is in good indicators so small as to be unmeasurable. But the untruth of the spring not only may be very marked in a particular specimen, but may change with its use and age. Professor Carpenter, in a paper† discussing a lengthy series of calibration tests upon indicator springs, states that their "errors are of such magnitude that they cannot in general be neglected." Because of this fact it is the chief purpose of this article to tell how indicator springs may be tested and calibrated. It will be noted in the following that the corrections provide for error of the pencil linkage as well as of the spring.

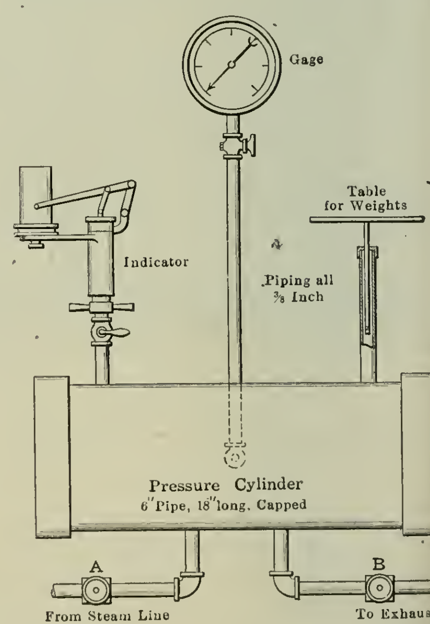

FIG. 2. TESTING BY STEAM PRESSURE

Calibration of Indicator Springs

It is first necessary to apply known pressures to an indicator which is fitted with the spring to be tested. Horizontal

*Instructor in mechanical engineering at the University of Pennsylvania.

***Proceedings*, Institution of C. E., Volume LXXXIII.

†*Transactions*, A. S. M. E., Volume 15, page 454.

lines should then be drawn on a card to correspond to these pressures. The vertical distances between the separate lines and the bottom one may now be used to obtain a value of the actual spring scale. Referring to Fig. 1, five horizontals corresponding to pressures of equal increments are shown on the left, the pressure increasing. On the right the same is shown with the pressure decreasing. It will be noted that these lines do not coincide. The reason for this is that the friction between the piston and the cylinder walls and in the moving parts aids the resistance of the spring when the pressure is rising, but acts against it when falling, as is represented by the arrows. The conclusion will therefore be reached that to calibrate accurately an indicator spring, steam pressure should be used so as to reproduce exactly the conditions of friction, temperature, etc., met with in practice. This, however, is not always convenient and, when it is not, pressure may be applied mechanically to obtain a reasonably accurate calibration.

Steam Pressure—Fig. 2 shows an apparatus for obtaining steam pressure of any desired amount up to that of the line. The drawing will be readily understood when it is explained that by adjusting the valves *A* and *B* the pressure is varied, and that the "table" is for the purpose of measuring it. An accurate gage would serve the purpose as well but because of the unreliability of gages, this device is preferable. The table is of known weight and is integral with a rod which terminates in a plunger of small cross-section. The steam pressure within the cylinder may be measured by balancing it with standard weights placed on the table.

Mechanical Pressure—For the purpose of applying mechanical pressure to the indicator piston, the author suggests the simple lever shown in Fig. 3. This is of oak, with metal strips *S* screwed to the short arm of such weight as to maintain equilibrium in the position shown. A weight equal to that of *A* and *B* may be hung at *E* when balancing. The detail of the piece *A* will be noted. It is a piece of rubber which fits into the lower side of the piston, and is backed by a special washer fastened to it. The rod *B* is made of ¼-inch round iron rounded at one end and filed to a knife edge at the other. The purpose of the combination is to transmit the load from a precise lever arm uniformly to the piston. In the position shown in Fig. 3, a one-pound weight on the weight pan *P* will effect a load of five pounds on the piston, which is equivalent to a steam pressure of ten pounds to the square inch, as the area of the ordinary indicator piston is one-half of one square inch. Thus, with 10 one-pound weights a 50-pound spring may be tested to 100 pounds. To test a lighter spring the weight pan may be placed nearer the fulcrum with a consequent reduction of force at the piston, the jockey weight *J* being employed to compensate for this change of position of the pan.

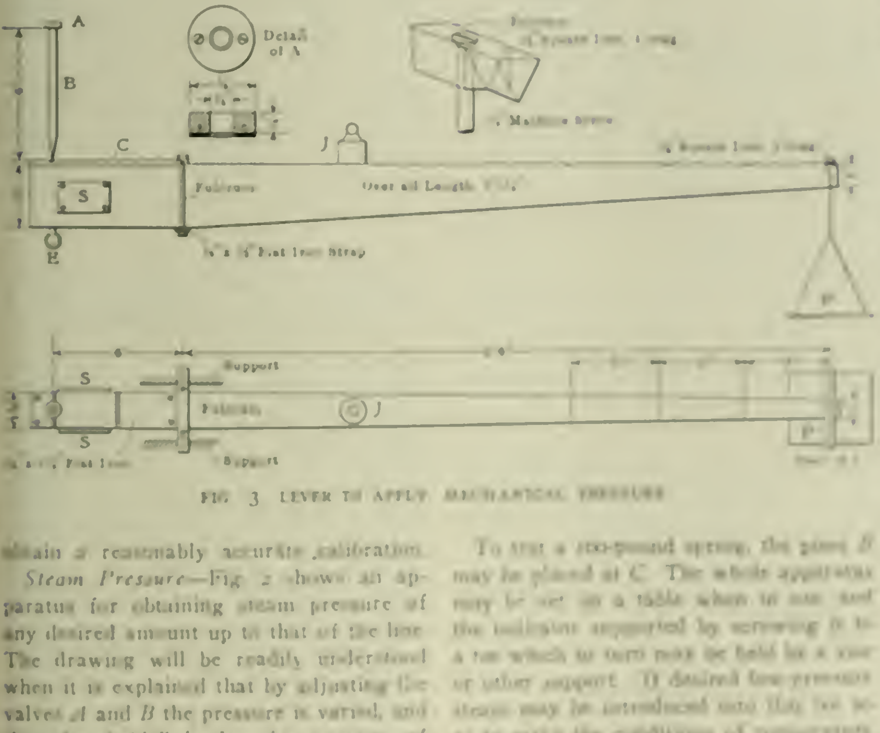

FIG. 3. LEVER TO APPLY MECHANICAL PRESSURE

To test a 100-pound spring, the piece *B* may be placed at *C*. The whole apparatus may be set on a table when in use and the indicator supported by screwing it to a tee which in turn may be held in a vise or other support. If desired low-pressure steam may be introduced into this tee so as to make the conditions of temperature, friction, etc., more nearly those obtained in practice.

In the series of tests performed under the direction of Professor Carpenter, it appeared that a calibration of indicator springs tested cold resulted in an average spring scale 1.8 per cent. less than that obtained when heated first. Professor Carpenter further states that by reducing the spring scale determined with the spring cold by this per cent. an error of not more than 1 per cent. may be expected.

Whichever apparatus for testing is used the results are to be applied correctly to calibrate the spring. For this purpose any of the following three methods may be selected, depending upon the degree of accuracy desired.

METHODS OF CALIBRATION

Referring first to Fig. 1, the figures placed on the horizontal lines give the distances of each line from the bottom one or zero. Obviously, the distance between two lines corresponding to the same pressure represents double the value of the friction of the moving parts in the position corresponding to that pressure. It will be seen that to apply these results correctly it would be necessary to alter the ordinate of each point on the diagram and to construct an entirely new one. This, however, is so cumbersome a process as to be out of the question, especially as a single calibrated value of the spring scale combining those of the ascending and descending scales usually gives very acceptable results.

Extreme Values—To obtain a rough approximation of this combined scale, the highest ordinate of each set of lines, Fig. 1, may be divided into its corresponding pressure and the two averaged. Thus in the example cited,

$$\left(\frac{50}{1.71} + \frac{50}{1.81}\right) \div 2 = 28.4.$$

This is a crude result and has the disadvantage that it is impossible to tell its limiting degree of accuracy or whether the error is positive or negative. The method has this merit, however, that if one of the scale divisions of a gage is known to be correct, then by its aid the above determination may be quickly and conveniently made. For example, suppose a gage has been compared with a known boiler pressure of 90 pounds and its error determined at this pressure. If now a simple slide-valve engine with indicator connections is accessible, it may be used instead of the apparatus in Fig. 2. To do this the indicator cock should have [illegible] so it is [illegible] of which [illegible] to the indicator fitted with the spring to be tested and the other on the gage. If now the throttle of the engine is put on dead center so that it will not start, the steam valve and one of the cylinder drain valves may take the place of valves *A* and *B* in Fig. 2. The steam is first allowed to flow through the drain from the main and then the lower valve slowly closed until the gage registers 90 pounds. A line may then be drawn to give the ascending scale. The drain should now be closed to raise the pressure above 90 pounds and then [illegible] opened until it has dropped to that amount to obtain the descending scale.

Graphic—A close approximation of the actual spring scale may be obtained by plotting the results in the form of two curves, as shown in Fig. 4, pressures as abscissas and heights of lines as ordinates.

A straight line is passed through each curve, so inclined as to deviate from it as little as possible. If, now, the tangents of the angles made by these straight lines with the vertical axis are separately multiplied by the ratio of the scales of abscissas to ordinates of the curves, the values resulting will be the new ascending and descending spring scales. From Fig. 4 these values are,

$$\frac{10}{0.2} \times 0.589 = 29.45$$

and

$$\frac{10}{0.2} \times 0.577 = 28.85,$$

the mean of which is 29.15.

Inspection of these straight lines shows that neither of them passes through the origin of coördinates, and it may be said generally that this is a characteristic of such calibration curves. The cause of it is lost motion in the pencil linkage, and friction. If these did not exist, a straight line passing through the origin and parallel to the one found would result.

Least Squares—The graphic method depends upon estimating the "most probable" straight line represented by the points plotted and is necessarily a guess. But it may be expressed algebraically, and from the equation a value of the spring scale may be found by the method of least squares. By this process the best obtainable result will ensue. No attempt will be made here to explain the theory of the method; only its particular application to the subject under consideration is given. The equation of the calibration line is,

$$p = h\,s + c,$$

from which

$$ph = h^2\,s + ch,$$

where

p = Pressure corresponding to the hight of the ordinate h,
s = Spring scale and
c = Unknown constant.

The observations shown in Fig. 1 are substituted in these equations thus, to obtain the descending scale:

$$\begin{aligned} p &= hs + c \\ 10 &= 0.41s + c \\ 20 &= 0.76s + c \\ 30 &= 1.09s + c \\ 40 &= 1.44s + c \\ 50 &= 1.80s + c \\ \hline 150 &= 5.50s + 5c \end{aligned}$$

$$\begin{aligned} ph &= h^2s + hc \\ 4.1 &= 0.1681s + 0.41c \\ 15.2 &= 0.5776s + 0.76c \\ 32.7 &= 1.1881s + 1.09c \\ 57.6 &= 2.0736s + 1.44c \\ 90.0 &= 3.2400s + 1.80c \\ \hline 199.6 &= 7.2474s + 5.50c \end{aligned}$$

The last equation of each series is the sum of the equations preceding it, and dividing these resulting equations respectively by the coefficients of c contained in them, the following results are obtained:

$$30 = 1.1s + c$$

$$36.29 = 1.3177s + c.$$

From the solution of the two equations:

$$s = \frac{6.29}{0\ 2177} = 28.89$$

pounds for the descending scale, and similarly for the ascending scale, $s = 29.33$ pounds per inch. The mean of these values is 29.11.

To compare the results obtained by the three different methods, the following is instructive:

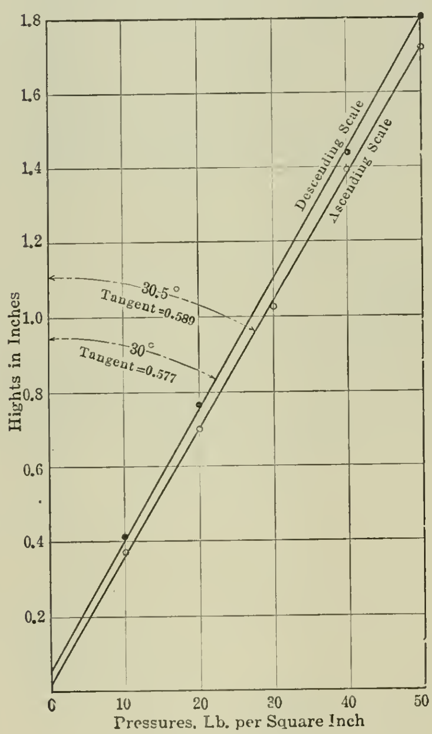

FIG. 4. CALIBRATION CURVES FOR A 30-POUND SPRING

Method.	Ascending Scale.	Descend'g Scale.	Mean.
Extreme values..	29.25	27.8	28.5
Graphic..........	29.45	28.85	29.15
Least squares....	29.33	28.89	29.11

An examination of these results shows that there is 0.13 per cent. of error involved in the graphic method, assuming the value obtained by least squares as correct. The accuracy of this method is dependent upon that of the estimation of the straight lines and the limitations common to graphic measurements. Referring to the first set of values tabulated, that for the ascending scale is fairly close; but, because that for the descending scale is low, the mean is 2 per cent. in error. The explanation for these disparities is found on the calibration curves. If the points whose coördinates have been used in the calculation lay on the lines, and if the ordinates of these points were corrected by subtracting from them the intercepts of the lines with the vertical axis, respectively, the results would be correct. It is impracticable to determine these intercepts, however, without actually drawing the lines. The error caused by neglecting them obviously is less appreciable when the values of the ordinates are high, and this is the reason why the hights at the greatest pressures are used in the calculation.

In conclusion, it may be well to lay stress upon the fact that the accuracy of calibration is primarily dependent upon the truth of the pressure-measuring device. If weights are used, as suggested, their values must be definitely known, as any error will be magnified. The conditions of practice, as to lubrication, etc., must be as far as possible duplicated. If the method of least squares is used the calculations must be performed with precision to the last decimal, as will be apparent from the sample calculations in this article. In any case, the more determinations made the closer will be the result. With reasonable care in making observations, distortion of the pressure line may be compensated for within 1 per cent. of error.

Motive Power Equipment for Textile Establishments

In an informal talk before the Southwick Textile Club at Lowell, Mass., recently, Charles G. Burleigh referred to some of the blunders made in the motive equipment of textile mills and pointed out the advantages of alternating-current motors and steam turbines for that class of work. To begin with, he strongly urged leaving the engineering details of the power equipment to the manufacturer of the apparatus, selecting a manufacturer who has had creditable experience in this particular class of work. This advice was based on the hypothesis that no reputable manufacturer can afford to recommend anything else than the most satisfactory types and sizes of machine.

Direct-current generators and motors are less desirable than alternating-current machines, he said, because of the limited voltage, which militates against a central power plant for a large group of factory buildings, and the commutators and brushes of the motors, which are undesirable from the insurance point of view and are much more expensive and troublesome to maintain than the simpler induction motor. The gradual increase in the speed of a direct-current motor, due to the heating of the field-magnet winding and consequent decrease in field excitation during each day's run, was also cited as a serious disadvantage. In order to avoid overspeeding a textile machine after the field winding of the motor becomes warm, he explained, it must be operated at less than its rate of maximum production while the motor is warming up.

Mr. Burleigh then reviewed briefly the advantages of electric drive over distributed shafting and belting, flexibility of control being the chief benefit.

He advocated the use of the steam turbine for the prime mover in the power house on the score of reliability, economy in first cost, operating expense and floor space, absence of oil in the exhaust steam and the feasibility of taking steam out from the intermediate stages for dyeing, bleaching, etc. He favored the Curtis type of turbine because it is obtainable in either the vertical or the horizontal form, the speed rate, in revolutions, is lower than that of other types, the distance between bearings is shorter, there is no appreciable end thrust in the horizontal form and the clearances are relatively large for a given economy.

The Conservation of Our Water Powers *

By John F. Vaughan

There are two subjects we have heard a great deal about lately: (1) The combining of corporate interests, and (2) The conservation of our natural resources.

Probably the most important example of corporate combination has been in the merging of steam railroads into a few comprehensive systems. This has been followed by a more or less successful movement to consolidate lighter electric railroads, with a tendency further to combine these with the older steam roads. And now in the development of high-tension electrical transmission we have the physical means of combining widely scattered water powers, and in the adoption of electricity as a distributing medium a strong incentive for the combination of interests of all three of these classes: Heavy and light railroads and water powers.

As a matter of fact the combining of steam and electric railroads has already begun, and now there is scarcely a steam road in the country which is not seriously considering electrification of at least a part of its system, and there are many which are either acquiring or are actually developing water power privileges to furnish them with motive power. Here, then, among the railroads we find a common interest in the economic development of our water powers.

The second subject—that of the conservation of our natural resources—in its bearing on the welfare of the country is of general interest to railroad men, and so far as it affects the regulation of stream flow is of especial importance to them, wherever water power is available. As traffic grows, as train weights and speeds increase, and fuel becomes more scarce and more costly, water must be more and more depended upon for power.

The present rate of deforestation, increased as it is by fires set by passing locomotives, in its effect on the reliability of water powers, and on the increase of damage by flood, demands serious consideration.

Water-power Resources and Development

Now what are our water-power resources and to what extent have they been developed? The fullest source of information on the extent of the country's water-power resources is in the admirable hydrographic work of the United States Government, but unfortunately this is still insufficient for making more than approximate figures, and while the records of stream flow are fairly comprehensive, comparatively little is known of the possibilities of storage.

The following conservative estimate of the water-power resources of the country has been published recently by Mr. Van Schon. He gives the amount of water power already developed as 2,250,000 horsepower, and the available undeveloped power, without the help of storage, as [illegible] horsepower.

H. St. Clair Putnam, in his address before the recent conference called by the President at the White House, estimated the total unconserved power available in the streams of the United States considerably higher, i.e., 30,000,000 horsepower, which is equivalent to the total power of all kinds now installed in our land industries. He assumed that with storage and supplemental plants this may be increased to 150,000,000 horsepower, or five times the present total power of all kinds in use. Now, when we find the demand for power increasing at the same rate as our manufactures, mining output, product and railroad earnings—that is, doubling every ten years since 1870—we have evidence enough of the increasing value of water powers. Right in New England, yes, even in Massachusetts, where Dr. Stillman has made the surprising statement that there is more water power going to waste than is consumed in the whole of Niagara, we have plenty of opportunity for improvement.

Requirements for Successful Development

Now what are the requirements for this successful development, and why has it not been more rapid? The reasons have been partly lack of available market for the energy, partly the excessive cost of development and partly the difficulty of stream regulation. With the old type of water wheel and costly mechanical transmission, it was necessary to use the power at the wheel, and then with perhaps only a part of the fall available without elaborate and costly canal systems. The more recent turbine and pelton impulse wheel, although utilizing the full head of the fall, have been still hampered by the necessity for using the power near the fall. But now, with the growth of electrical transmission not only can remote markets be reached, but powers formerly inaccessible may be developed and operated singly or in groups, for better economy and efficiency. Thus the differing characteristics of power markets may be largely equalized and better service and larger returns obtained from the investment.

The best examples of the consolidation of water powers are in the California system, where plants scattered through the mountain valleys feed into common networks of transmission lines, serving large territories with power for railway and industrial plants, pumping, etc., and in some cases delivering the discharged water for irrigation; and the best example of combination of markets is in the great systems of Niagara, delivering power over hundreds of miles of lines for an infinite variety of uses.

We have good examples of the use of water power by railroads in the plans of the Chicago, Milwaukee & St. Paul, which is already making the initial development of some [illegible] horsepower available in 35 miles of the St. Joe river, for operating its trains electrically over the Great Divide, in the electrification of the Cascade tunnel of the Great Northern railroad, in the conversion of the Harriman lines around San Francisco, in the equipping of the New York Central for operation by Niagara power, and in many light electric railroads all over the country.

Requirements for Economical Use

Let us see what the principal requirements for the economical use of our water powers are:

Stream flow should be considered so as to get the maximum energy out of the stream as a whole, and not merely for the benefit of certain isolated plants. For instance, no one plant with storage should be allowed to hold back the natural flow when required by down-stream users who have no storage to draw on, or to flood them with excess water when detrimental to their interests.

The storage facilities of the drainage basin should be developed as far as practicable for equalizing the natural flow of the river, increasing the capacities of the various developments and reducing possible damage from floods. For instance, where any development uses more than the capacity of the ordinary natural flow of the stream, [illegible]

*A paper read before the New England Street Railway Club.

by other power, or the excess sold as cheaper secondary power subject to interruption, even an average stream will waste more power than it can use, and a torrential stream, which may flow in flood over one hundred times its low flow, will give up only a few per cent. of its total energy. It is evident that expensive storage cannot be accomplished without the coöperation of the power users and an equitable sharing of the expense.

A Good Example of Stream Control

Perhaps the best example we have of stream control is in the Merrimac river, where through the coöperation of milling interests at Lowell, later joined by Lawrence mills which shared the expense, the storage facilities at Winnepesaukee, Squam and other lakes were developed and a comprehensive plan of stream measurement and control established, and today the use of water at Lowell, Lawrence and Manchester is so closely watched and regulated that during dry months practically no water is wasted, and during last summer's drought, although the various small tributary streams furnished practically no supply, the flow of the river held up remarkably well.

As far as possible various plants should be tied together to feed into a common network of distributing lines so as to utilize the stream flow to its best advantage, to equalize local peaks and irregularities of load, to reduce surplus investment in spare and breakdown capacity, to cut down distribution costs, and to improve the regulation of the system. By such combination the number of units in each plant may be reduced, hydraulic and electric designs simplified, complication of switching and control cut down, and a corresponding saving made in fixed charges and operating costs. In this way many communities may be served which otherwise could not support the burden of individual development.

Arrangement with other power producers should be considered for the interchange of surplus power, especially where the peak demands are not simultaneous. For instance, an agreement between a lighting company and a coal mine in Pennsylvania for the interchange of power up to 2500 kilowatts, where the mine shuts down before the peak of the lighting load, now enables each to reduce its fixed charges on spare equipment and to improve its load factor.

Utilizing Surplus Power

Surplus power during light demand, or surplus water, should be utilized for industrial purposes, such as pumping, electrochemical or metallurgical processes. For example, the electrical recovery of peat from wet bogs and the manufacturing of fertilizers and certain other products of modern chemistry from nitrogen recovered from the atmosphere are not wholly visionary, nor is it necessarily crazy to use surplus flow to pump water into reservoirs above the natural water levels for use during dry periods or excessive loads. In certain localities surplus or discharged water should be utilized for water supplies or irrigation. Groups of plants now on the old series canal systems, or plants otherwise inefficient in the use of water, should be redeveloped.

Robert E. Horton recently pointed out, in an address before the Schenectady branch of the American Institute of Electrical Engineers, a number of opportunities of this kind among our eastern streams; as, for instance, at Holyoke, where there are about fifty mills taking water from a series of canals at three different elevations; at Cohoes, at the junction of the Mohawk and the Hudson, where about thirty mills draw on five canal levels. There are also many cases where for the same reasons the available fall is divided up by series of low dams, each with its own wheels dependent on the dams above for water and liable to backwater during flood.

Obstacles to be Overcome

There are, of course, many obstacles to overcome before our streams can be properly controlled and their power utilized to best advantage; legal tangles to straighten out, franchise restrictions to modify, dams to build and to rebuild, and innumerable physical and operating details to work out. But water is a permanent asset which is neither burned up like fuel nor carted off like our mineral resources, but returns with every fog and rain storm to be used again.

In the interdependence of the territories embraced by the various watersheds our interests in this asset become national, warranting federal control, or at least State action under federal supervision, and already we have in the hydraulic work of the New York State Water Supply Commission, established under the Fuller bill, a substantial advance made in the study of the storage possibilities and in its effect on present and future water powers of the State, and in the National Conservation Commission, appointed by the President, a definite establishment of Government policy. Both of these commissions recognize that the conservation of our water supply is of sufficient importance to call for comprehensive plans of water storage and stream control, and that the Government should eventually distribute the cost of such improvements among all interests in proportion to the benefits received.

On this basis, then, the water-power interests will be required to carry only a burden in proportion to the benefits they receive; and such a policy will not only enable individual enterprises to develop their resources to best advantage, but will give their properties a more definite and permanent value.

In this general movement toward stream betterment there is a definite beginning of a more economic use of our water-power resources, and in the growth of electrical transmission a means of reducing both first cost and operating expense. And from whatever point we view the matter we have plenty of reasons for encouraging the conservation work already begun by the Government and, in addition, plenty of opportunity for studying the improvement of our existing powers and the development of new.

Comparative Tests of Coal

By Peter H. Bullock

At present there is a good deal of uncertainty about the quality of coal delivered to customers in the East, and this applies to all coals regardless of the names they may be sold under. Coal has been sold and delivered under a hyphenated name that carried only a suggestion as to quality, and that suggestion would only be founded on the fact that either before or after the hyphen there would be a familiar name. John Smith-Pocahontas, or Georges-Paul Creek might be very good or very poor coal. Some buyers have adopted the B.t.u. system, the price to be a sliding scale determined by the analyses of samples of the coal. This seems to be fair, but it is one thing to know how many B.t.u. there are in any coal, and quite another to catch all the B.t.u. in the furnace.

It would appear that the only information needed by the purchaser is, how much water can be evaporated under regular conditions with a dollar's worth of coal? The exactness of chemical analysis is not to be doubted, but it is also certain that a fireman will sometimes do better with coal that does not show up the best when so tested.

It will undoubtedly be admitted that better tests can be made in small plants where all the coal and water used can be weighed and the steam generated applied to the usual and regular service. In large plants where there are many boilers and frequent changes of men, it is practically out of the question to deal with the whole plant and get satisfactory results. Of course it is possible to cut out the feed pipe of one boiler and weigh the coal and water fed to it in any given time, but the expense and the uncertainties that attend such a test make it advisable to provide a simple apparatus for this especial purpose Accordingly, the writer has designed and put into operation a small plant for comparative tests of all coal purchased. It will be noted that the word comparative is used, for the simple apparatus installed leaves out many things that are taken in standard tests. Not but what these data are valuable, but because they are not necessary in a case where the efficiency of apparatus is not a question, and it is only necessary to determine how much water one dollar's worth of A, B or C's coal will evaporate in a furnace and under precisely the same conditions.

Testing Apparatus

The testing apparatus is simply a plain return-tubular boiler 16 inches in diameter and 4 feet long, with thirty $1\frac{1}{4}$-inch tubes 3 feet long. It is set in firebrick and has a dumping grate of $1\frac{1}{2}$ square feet area. It has no fittings except a gage glass, and is fed through a funnel from a tank setting high enough for the purpose. The outlet pipe is short, open to the air and large enough to carry off all the steam the boiler can make. The stack is 8 inches in diameter and is used only to carry away the smoke, the necessary draft being furnished by a fan and engine run by steam from another source, so that the intensity of the draft can be maintained at any desirable point, and is measured by a U-tube at the ashpit.

When a test of fuel is to be made, light wood is burned until steam is flowing freely from the pipe. The hight of water in the gage glass is then noted and 4 pounds of fine wood is put into the furnace to start the coal fire. Then 100 pounds of coal is burned, and all the water that possibly can be is evaporated. When the coal is all burned the hight of water in the gage is left exactly the same as at the beginning of the test. It is then known how much coal has been burned and how much water evaporated.

The tubes, furnace and ashpit are now cleaned and all the refuse weighed, giving the percentage of combustible. To get the moisture in the coal $6\frac{1}{4}$ pounds, or 100 ounces, is put into a shallow baking pan which is placed in a flue where there is a current of air at 120 degrees and is left there for five hours, when it is again weighed and the loss noted. There may be some objection to this method, for it may be claimed that in order to get all the moisture out of the coal, the temperature should be 212 degrees. This treatment, however, leaves the coal practically dry, is as fair for one man's coal as another's, and the higher temperatures would in some cases carry off volatile gases that might better be left, as they have a fuel value which the seller is entitled to have the benefit of. The temperature of the water used is taken. The price of the coal is known, the equivalent between any temperature and 212 degrees is known, and it is then a simple matter to obtain the comparative amounts of water that the coal from A, B or C has evaporated in the same apparatus and under exactly the same conditions. The data can be reduced to either of two units: cost of evaporating 1000 pounds of water, or how much water will one dollar's worth of coal evaporate? The comparative economy is the same whichever unit is used.

A Question of Moisture

There is a question in regard to the moisture in the coal at the time of the test and the moisture in the coal at the time it was weighed for shipment. The bills are made out at the time of shipment, and if the coal is wet when weighed the water in the coal is paid for. The sample tested may have become partly dry so that the actual amount of coal burned would be that much more than would be represented in the bill. On the other hand if the coal was dry when weighed and it had been exposed to wet weather, the amount of fuel in the test would be less by an amount equal to the weight of water added. Recently a car was received that had been three weeks in transit and showed 9 per cent. of moisture in the 120-degree five-hour test. If the facts as to moisture could be settled when the coal was weighed and billed, it would be easy enough to make the proper allowance for any wetting or drying it got between the weighing and the testing points. This seems to be practically out of the question, and, of course, every dealer would claim that the coal was dry when weighed and that he ought to have the benefit of the doubt in the test.

In a trial test under standard conditions the quality of the steam as to dryness has to be taken into consideration, but in this apparatus the coal is burned to the best of our ability, clean water is fed into the boiler and to all appearances nothing but good, honest steam goes out of the pipe. At any rate it is the same as to conditions at all times, as an even draft is maintained and about as much coal burned per square foot of grate per hour as in regular work in the fire room.

The writer has uniformly found a greater per cent. of ash than the sellers want to admit. This may be due to the fact that the tubes, setting and furnace are brushed clean after each test and everything is weighed as ash, for it all comes from the coal and certainly is not combustible. In tests under commercial conditions, no doubt considerable ash and dust escape that properly belong in the ash column.

Tests of Sample Lots

In samples Nos. 1 and 2 in the tests following the coal was the same, only in No. 2 sample it had been exposed out of doors to the sun and rain for six months in an open box. For samples Nos. 3 and 4 coal was taken from the same car, only No. 4 had been kept in a closed box indoors for six months. The last two samples tested substantially the same, while sample No. 2 showed a loss from exposure. It is improbable, however, that coal in large, deep piles will lose its heat value to any great extent, although the exposed surface of a large pile for a few inches in depth might readily do so.

Recently the writer made a test of some coal and put another similar quantity under water for a future test, the first sample being left under water until [illegible] it would be perfectly saturated, or, of course, the other would be when taken out for trial. For an exact comparison this method would appear to be better than to make figured corrections for moisture contained; besides, it keeps the local conditions of firing the same in both cases.

In the test records the unit of comparison is the cost of evaporating 1000 pounds of water into steam at zero pressure, and the formula is:

$$\frac{1000 \times \text{Pounds of coal burned} \times \text{Price per ton}}{\text{Pounds of water used} \times \text{Factor of evaporation} \times \text{Pounds per ton}}$$

Samples Nos. 1 and 2 were taken from the same car and each weighed 100 pounds with 7 per cent. moisture. Sample No. 1 was tested at once and No. 2 six months later after being exposed to the weather in an open box, so that at the time of the test it carried 12 per cent. of moisture. As the lots of coal when bought and weighed were the same, and the moisture at the time of testing different, the computations were made on dry coal in each case, so that instead of using 100 pounds as weighed, 93 pounds of dry coal was substituted, and the amount of water considered to be in the coal was added to the amount evaporated. No. 1 sample contained 11.5 per cent. of ash, and the cost to evaporate 1000 pounds of water was found to be:

$$\frac{1000 \times 93 \times \$4.40}{(796 + 7) \times 1.157 \times 2240} = \$[illegible]$$

Sample No. 2 contained 12 per cent. of ash and the cost was:

$$\frac{1000 \times 93 \times \$4.40}{(587 + 12) \times 1.17 \times 2240} = \$[illegible]$$

Samples Nos. 3 and 4 each weighed 100 pounds and were taken from the same car. No. 3 was tested at once and No. 4 was put into a closed box and kept six months. Moisture was not found in either case, and ash in both lots was 14½ per cent. To evaporate 1000 pounds of No. 3 cost:

$$\frac{1000 \times 100 \times \$4.05}{811 \times 1.142 \times 2240} = \$0.195$$

and of No. 4:

$$\frac{1000 \times 100 \times \$4.05}{807 \times 1.179 \times 2240} = \$0.197$$

At the time the tests of samples Nos. 1 and 2 were made, the 12 per cent. of moisture seemed excessive, as 8 or 9 per cent. is usually considered about the limit. The writer has since made several tests for moisture and found that dry coal soon absorbs and carries up to 12½ per cent., but samples from lumps often left under the cover for several months seldom show over 4 or 5 per cent., [illegible] when unloaded. Can the [illegible] know the coal makes its [illegible] to the company without including [illegible] qualities with it? is a question that [illegible] would like answered.

The Plunger Hydraulic Elevator

Practical Instructions in the Care and Management of the "Standard" Plunger Elevator, Illustrating the Essential Features to Look Out For

BY WILLIAM BAXTER, JR.

Whenever it is desired to take out the main valve of the Standard plunger elevator, it can be removed through the back end of the valve cylinder. Before it can be drawn out, however, the rack at the end that rotates the pinion of the pilot valve must be thrown out of gear. To do this all that is necessary is to remove the hood in front of the pilot valve, into which the rack runs, and then the shoe that holds the rack and pinion in mesh can also be removed and the rack can be pushed to one side so as to clear the teeth of the pinion. When this is done the valve can be drawn out of the back end of the valve cylinder without difficulty.

To remove the automatic stop valves the cylinder head must be removed, and also the bonnet under the center. The cranks that operate the automatic stop valves are fastened to the shafts on which the operating levers are mounted by means of caps, and the screws that hold these caps can be reached when the bonnet is removed. If the cap is taken off the crank can be pushed upward and can be drawn out, together with the valve, through the end of the valve cylinder; all of which can be readily understood upon examining the valve drawing, Fig. 283, shown in a previous article. The cranks are keyed to the shafts, to prevent them from turning, and in putting the valve back care must be taken that the key is returned to position and the screws tightened up as much as they were before, so that there may be no danger of working the parts loose thereafter.

Pilot Valve Removal and Adjustment

The pilot valve, body and all, can be removed by taking off the end hood the same as for throwing the rack out of gear, as explained above. When this hood is removed, the bolts that hold the pilot-valve body can be reached and taken out and then the valve can be removed, together with the shaft that carries the pinion and the cams that prevent too rapid reversal of the elevator motion. A side view of all these parts is given in Fig. 307, which is a vertical section. This drawing does not show the means by which the valve body is fastened to the end casting of the main valve body; these consist of lugs that spread out on each side of the shaft L'' at the top and bottom, opposite the bearings through which the shaft slides. A view of the valve body at right angles to Fig. 307 would show these lugs, on opposite sides of the parts *E* and *F*. To remove the valve alone, all that is necessary is to take off the connecting arm *D* and the lower cap *C*; then the valve can be drawn out through the lower end.

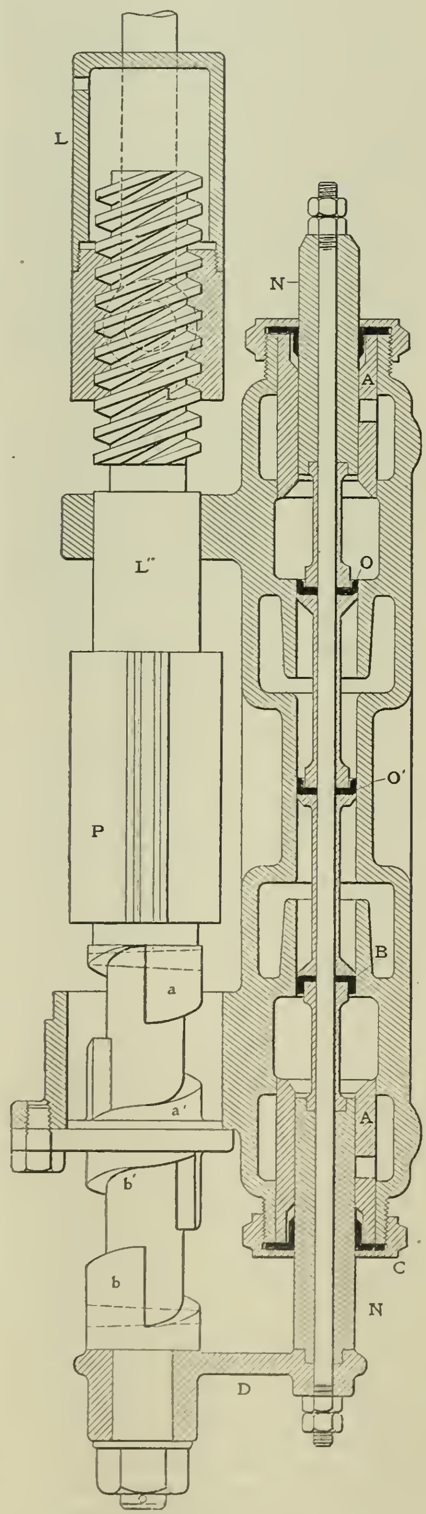

FIG. 307

Referring to Fig. 307 it can be seen that no provision is made for adjusting the position of the pilot-valve cup packings, nor for adjusting the cams *a*, *b*, *a'* and *b'*. Adjustment of the position of the cup packings would only serve to vary the lap of the valve, and such adjustment is not only not necessary but not advisable, because the manufacturers know better than anyone else what the adjustment should be and they make the valve of proper proportions. Increasing the depth of the cups will not have any effect on the lap of the valve, because they enter their seats back end first and make a joint after entering a certain distance, independent of the depth of the cup. Under certain conditions, if the edge of the cup projects beyond the end of the cylinder, water may force its way between it and the cylinder and thus leak through. This is not likely to occur, but as it may, it is wise to use cups of the proper depth, and no deeper. The cams require no adjustment, because all they are intended for is to prevent moving the lever any farther, in stopping, than it was moved in starting; and if once made of the proper dimensions to accomplish this result, they will always do so.

The only adjustment provided in the pilot valve is in the ports through the sleeves *A*, *A'* at the ends of the valve, and the similar adjustment on the side ports, which was fully explained in the article describing this apparatus. If in the course of time the water flowing through these port holes enlarges them so as to cause the main valve to close too rapidly in stopping, the proper adjustment can be obtained by running in the adjusting plugs a trifle. It may be found in making such changes that the car speeds up too fast in starting when the valve is partly opened in order to run at a slow speed. If this should be the case, the acceleration can be reduced by screwing in farther the plug opposite the port hole in the inner end of the sleeve *A*, and if after doing this the car does not get under headway fast enough when the valve is fully opened, the acceleration can be increased by drawing out one of the other adjusting plugs. In making these adjustments it should be remembered that a very small difference in the opening of the ports will make a decided difference in the rapidity with which the elevator will get under way; hence, the position of the plugs should be changed only a little at a time. In the type of valve shown in Fig. 283 the main valve is moved to the right to cause the elevator to start upward; it is also moved to the right to stop the elevator on downward trips. Therefore, if the flow of water through the ports of the top sleeve *A* is decreased, the effect will be to reduce the acceleration in starting on up trips, and to prolong the stopping on down trips. To stop going up and to start going down the main valve must be moved to the left, hence, if the adjusting plugs opposite the ports in the lower sleeve *A* are run in, the up stops and the downward starts will be made slower, and *vice versa*.

If the elevator is arranged so that the cylinder discharges into an open tank located on a level with the main valve, there will be no back pressure to force the water into the cylinder through the bypass connection, and the adjustment of the velocity of motion of the main valve must therefore be made so as to reduce the velocity enough to prevent jumping the plunger off the water in the cylinder when the car is brought from its maximum speed to a stop. If, however, the water in the cylinder is discharged into an elevated tank, or into a pressure tank, the valve is adjusted with reference to starting on the downward trips, so that the car may not move so rapidly as to produce an unpleasant sensation. Therefore, it will be seen that the adjustment of the plugs at the lower end of the pilot valve, opposite sleeve *A*, must be made with reference to the rapidity of stopping on the upward trips, with one method of piping, and with reference to starting on the downward trips with the other method.

The adjustment of the plugs opposite the sleeve *A* at the top of the pilot valve is made with reference to the rapidity of starting on the upward trips, and stopping on downward trips. There is little danger of starting too rapidly, because the water flowing into the cylinder has to lift the load, and it cannot very well get it under headway so rapidly as to produce an unpleasant sensation, unless the lifting capacity of the plunger is excessive, and the load in the car is light. In stopping on the downward trips, however, the reduction of speed can be so rapid as to greatly increase the tendency to buckle the plunger, hence the adjustment of the plugs at the top of the pilot valve should be made with reference to the rate of retardation of speed in stopping on the down trips, and this adjustment will be found satisfactory for the starting on upward trips.

In the valve shown in Fig. [illegible] the movement of the main valve is the reverse of that above explained, that is, the valve moves to the left to start on the upward trip, instead of to the right; hence the top adjusting plugs are used to do just what the bottom ones do in Fig. 283.

The Packings

All the packings used in the valves of the Standard plunger elevators are leather cups, as can be seen by looking at the various drawings we have presented. These packings are replaced in the same manner as in the elevators of other makes previously explained, and require no further explanation here. The stuffing box at the top of the plunger cylinder is packed either with hemp or any good soft packing, or with a specially constructed double cup leather packing. The cross-section of this packing is shown in Fig. 308. The packing is made in two parts, *A* and *B*, both of leather. These two parts are cut on one side so that they may be slipped over the plunger from the side, and they are placed in the stuffing box so

FIG. 308

that the joints are on opposite sides of the diameter.

To keep any hydraulic elevator in perfect running order it is necessary that all the packings be kept tight; if they are not, the car will not remain stationary when stopped at a floor, but will move gradually either up or down, according to where the leak is located. In plunger elevators, if the stuffing box at the top of the cylinder leaks the car will settle when standing at a floor. It is an easy matter to determine whether the cylinder stuffing box leaks or not, for if it does the water can be seen trickling over the top of the stuffing-box gland. If there is no leak at this point, then the trouble will be found in the main valve, which will permit water to flow through to the discharge pipe; hence, the packing in the piston that closes off the discharge must be renewed. If the car creeps upward after being brought to a stop it indicates that the cup packings in the valve pistons that close the supply ports are leaky. Sometimes the plunger after being brought to a standstill, creeps up a short distance and then creeps back, and continues this alternating motion indefinitely. This indicates that the pilot valve is defective, but as it is an occurrence that can take place with any type of hydraulic elevator it will not be explained here. In a future article this subject will be discussed in detail, by the aid of diagrams that will make the action perfectly clear.

In addition to keeping all the packings in good condition it is necessary that the running gear of the valves be not allowed to get out of adjustment. The rope that moves the pilot valve and those that operate the automatic stop valves must be examined frequently to see that they are in good condition and their fastenings tight, particularly so in the stop-valve ropes, because these valves are safety devices.

With the Standard plunger elevator system in which the discharge tank is closed and a pressure is maintained therein, it is necessary that the pressure be kept up to the proper point to obtain the best results. The pressure is required to cause the water to follow up the plunger when the valve is closed suddenly in making a stop on the up trips. If the pressure is permitted to drop the plunger may be drawn away from the water in the cylinder, with the results already explained. There is no danger of getting the pressure too high, as this is limited by the height of the reversed goose neck provided for that purpose. It is not desirable, however, to permit the pressure to rise above the proper point because too much water will be forced out through the goose neck, and this will have to be replaced by water drawn from an outside source, which generally will be at a lower pressure; hence it will represent just so much power thrown away. It is also necessary that the supply of air in the discharge tank be well maintained; otherwise, the pressure will vary too much when water is drawn from the tank or discharged into it. Whenever the construction of the building permits, the pressure in the discharge tank is obtained by locating it at the proper elevation, as this is decidedly the best arrangement, as the pressure then cannot vary. With an elevated tank all that is necessary is to keep the water at the proper level, so that the pipe running down to the cylinder may always be far enough below the surface not to draw in air.

Municipal Producer Gas Plant at Peru, Ind.

A Lighting and Power Installation Which Supplanted a Steam-Engine Plant and Has Shown an Appreciably Reduced Consumption

BY OSBORN MONNETT

Producer-gas power is being successfully used in the municipal plant at Peru, Ind., generating electricity for city pumping, street lighting, commercial lighting and power service. It is supplanting a steam plant which has been variously estimated as producing a brake horsepower-hour on from 5 to 15 pounds of coal and, to date, with light loads and uneconomical conditions, has succeeded in reducing the of one pound of coal per horsepower-hour. At present the one unit installed, a view of which is given in Fig. 3, carries all of the street lighting, consisting of 160 series arcs, all of the pumping load and day power load, and half of the incandescent lighting. This necessitates running twenty-four hours per day.

The city pumping is done with two 2-stage Worthington centrifugal pumps, series, maintaining the maximum volume capacity of one pump and doubling the pressure.

The layout of the plant is shown in Fig. 2, and it can be seen that provision has been made for doubling its capacity. At present there are two 150-horsepower Smith suction producers installed, using semi-anthracite pea coal costing $4.50 per ton. The coal is delivered from the rail-

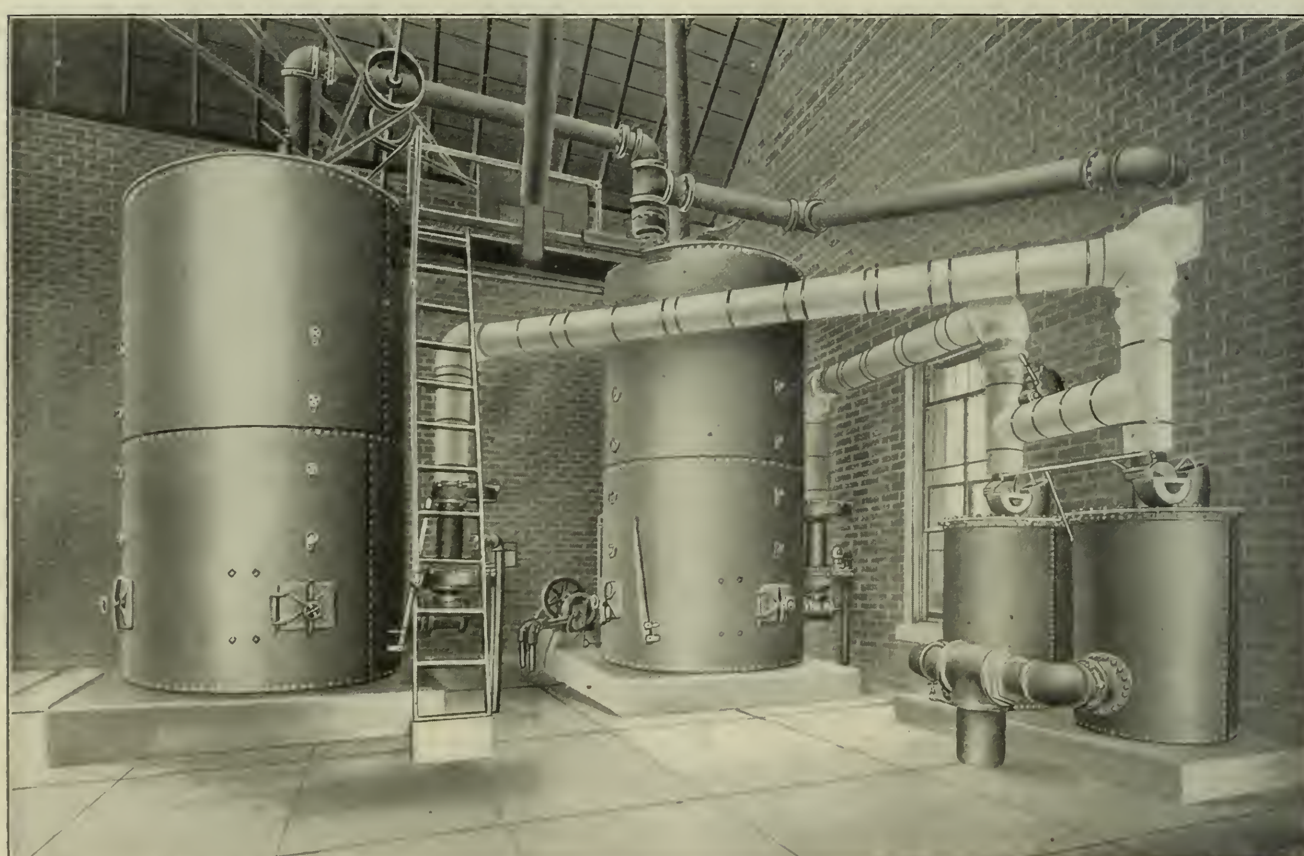

FIG. 1. PRODUCERS IN MUNICIPAL GAS-POWER PLANT AT PERU, IND.

consumption to 1.6 pounds. The steam plant consists of high-speed engines driving 133-cycle belted alternators through a jack shaft. During the period of transition from steam to gas power it has been thought advisable to change to the more modern 60-cycle system; consequently, both plants must be kept in operation temporarily and for this reason it has not been possible to load the gas-power plant sufficiently to come within its guarantee each driven by a 60-horsepower Western Electric induction motor. The pumps are located in a cement-lined water-tight pit, adjacent to the power plant, and are below the level of water in the wells from which the supply is obtained. Each pump has a capacity of 1,500,000 gallons in twenty-four hours, against the city pressure of 55 pounds. Valve connections are provided so that in the event of an alarm of fire the pumps may be connected in road cars into a storage bin and brought by an underground screw conveyer to a bucket elevator which discharges into a hopper. From here the coal is spouted to the charging platform of the producers. Centrifugal scrubbers are used, belt-driven by an 8-horsepower induction motor. A 6-horsepower "Model" gasolene engine is installed to operate a blower for starting the fires and a small air compressor for use in starting the engine; it also serves to furnish power for the centrifugal scrubbers before current is available for the motor.

The heat of the exhaust is utilized to generate the steam necessary for the producer generator and also to preheat the air used. In Fig. 1, at the right, can be seen the economizers in which this exchange of heat takes place; the exhaust gases from the engine pass in at the side and out at the bottom. The economizers also muffle the exhaust effectively, so that no other arrangement is necessary for this purpose, the exhaust pipe merely passing under the floor to a trench outside of the producer house.

Main Generating Unit

The main generating unit consists of a 300-horsepower vertical four-cylinder "Model" gas engine, direct-connected to a 200-kilowatt Western Electric revolving-field three-phase 60-cycle generator, with exciter belted from the main shaft. The engine, which was built by the Model Gas Engine Works, Peru, Ind., operates on the four-stroke cycle, with power strokes in the cylinders in the order of 1-3-4-2. An unusual feature is the construction of the cylinders, which are cast integral with the cylinder heads. This is well shown in Fig. 3, where the cylinder is seen to consist of one unbroken casting from the crank case up to the top of the head. This construction has been followed with satisfaction for years in all the smaller engines built by the company and is therefore continued in the larger sizes. It eliminates the gas joint and the water joint, and correspondingly reduces the liability to trouble. A partly sectional view of the cylinder is shown in Fig. 4. One important advantage of this construction is that by the elimination of the cylinder-head studs, an exceptionally large space is obtained for cooling water around the exhaust valve cage, which is obviously advantageous in cooling this important member. The cage and valve complete may be easily removed from the cylinder for inspection and repairs. On the valve stem is located a dashpot to cushion the valve when closing; this is shown in Fig. 5, which illustrates the valve and cage complete with the rocker arm, spring and dashpot. From Fig. 6 the method of cooling the valve itself will be apparent. The stem is hollow and the incoming water passes through an inner tube down to the valve head and up through the annular channel between the wall of the valve stem and the outside of the tube, passing out through a hose connection.

At the side of the cylinder is the inlet-valve chamber, over which a removable cover is bolted, making it easy to remove the valve for regrinding and repairs. Both valves receive their motion from cams on a shaft located outside of the crank case, the movement being transmitted through rollers to the push rods.

On the push rod leading to each exhaust is a small hand lever which when turned has the effect of lengthening the rod and holding the exhaust valve [illegible] open throughout all strokes. This isolates the cylinder so that examination can be made and minor troubles corrected without shutting down the engine.

Ignition and Starting

Ignition is effected by a make-and-break system. The igniter shaft runs along the side of the cylinders, driven by bevel gears from the cam shaft. A belt-driven magneto is provided for regular operation and a battery is held in reserve.

For starting there is a [illegible] carrying two auxiliary cams on the end of the cam shaft. When this is shifted over by a

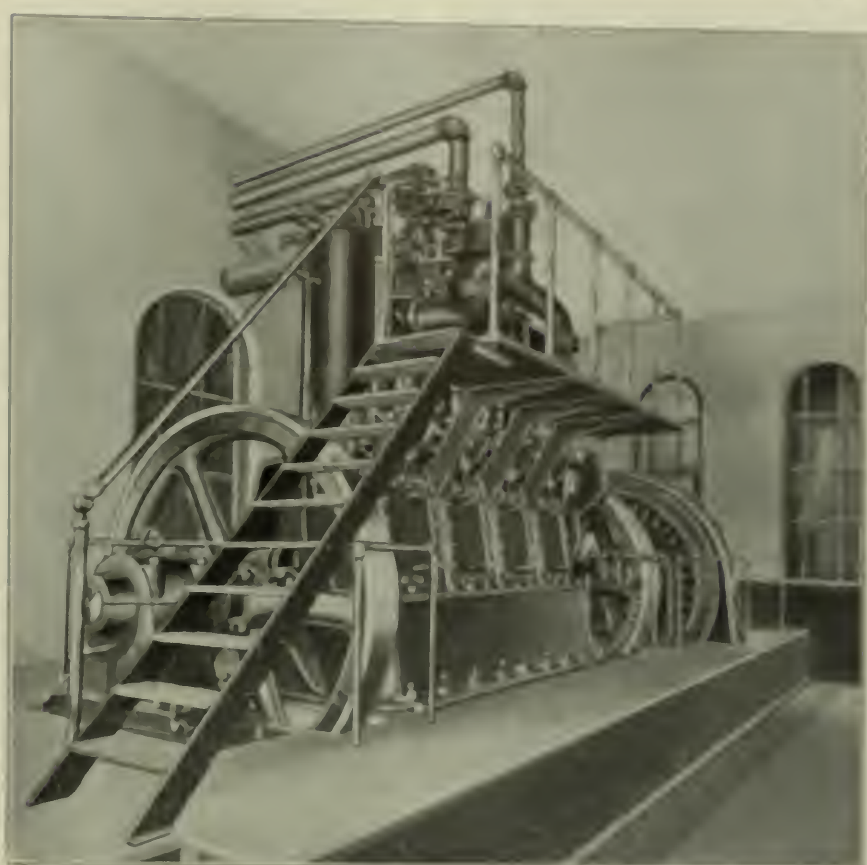

FIG. 3. ENGINE ROOM OF MUNICIPAL PRODUCER GAS-POWER PLANT AT PERU, IND.

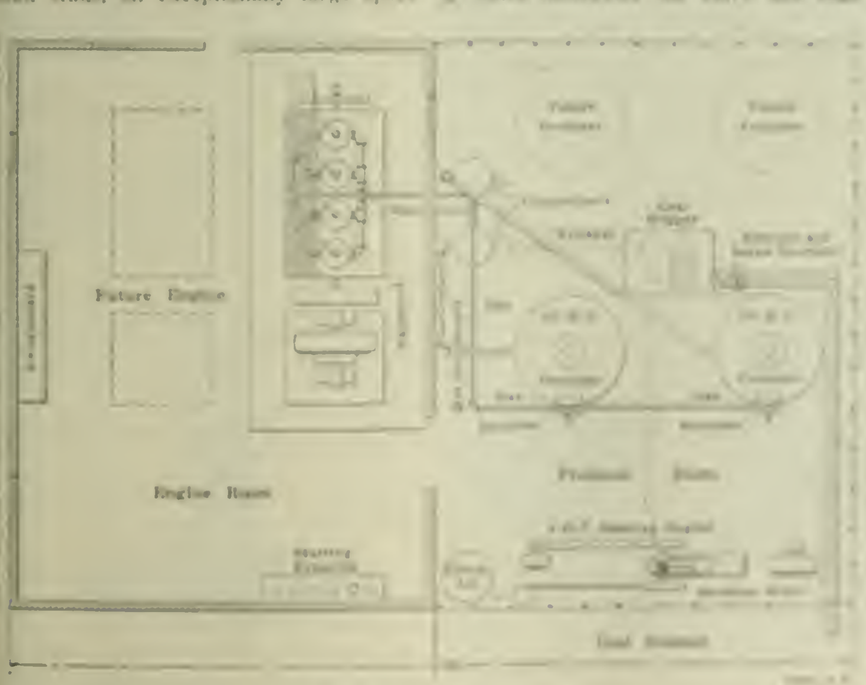

FIG. 2. LAYOUT OF PLANT

lever it throws out of commission the inlet cam on the first cylinder and one of the auxiliary cams opens the exhaust valve at each revolution; the other auxiliary cam engages a poppet valve in an air-supply line and is properly timed to run the first cylinder on compressed air until the others pick up the charges of mixture.

With the solid construction of the cylinders adopted on this engine, one of the first questions occurring to an operating engineer would be as to the method of removing a piston. This is accomplished by taking out the exhaust-valve cage, screwing an eye-bolt into the piston and, after disconnecting the crank-pin brasses, lowering the piston and connecting rod down into the crank case; they are then taken out through the crank-case doors. The piston, as shown in Fig. 7, has three packing rings above the wristpin and one below; it is also provided with three oil rings.

The lower end of the connecting rod is of the marine type and a plain cast-steel box, working on a wristpin sleeved with bronze is used at the upper end. One of the special features of the engine is the provision for varying the compression pressure by shortening or lengthening the connecting rods. The rods are hammered-steel forgings, finished all over, and screw into the top casting where they are locked in position with ⅞-inch studs and nuts, as indicated in Fig. 7. With this arrangement the compression can easily be changed to suit any kind of fuel or any altitude. Fig. 8 shows the complete details of construction.

The Main Bearings

Five main bearings are provided, with an outboard bearing outside of each flywheel. The bearings are set solidly into the frame, each one being braced with a heavy reinforcing rib which extends downward to the bottom of the frame and is firmly grouted to the foundation. As the thrust on the bearings is all downward, no adjustment is provided other than that necessary to follow up on the bearing caps. In order to prevent unequal wear of the bearings by reason of differences in lubrication, splash lubrication is not relied upon entirely; oil is forced to each bearing by a pump driven from the cam shaft. Oil from this pump is also forced to each piston in two places,

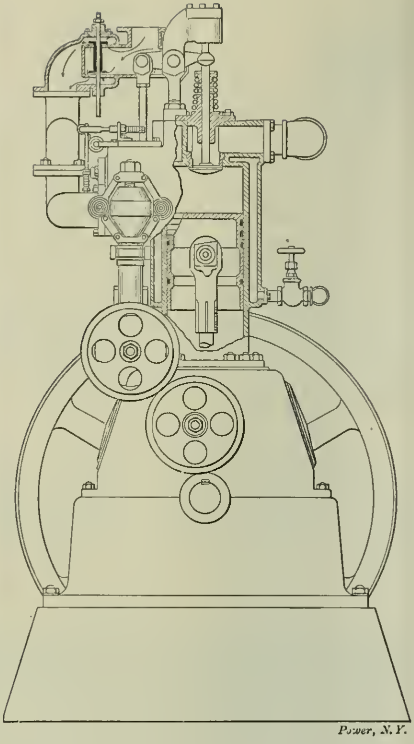

FIG. 4. PART SECTIONAL ELEVATION OF ENGINE

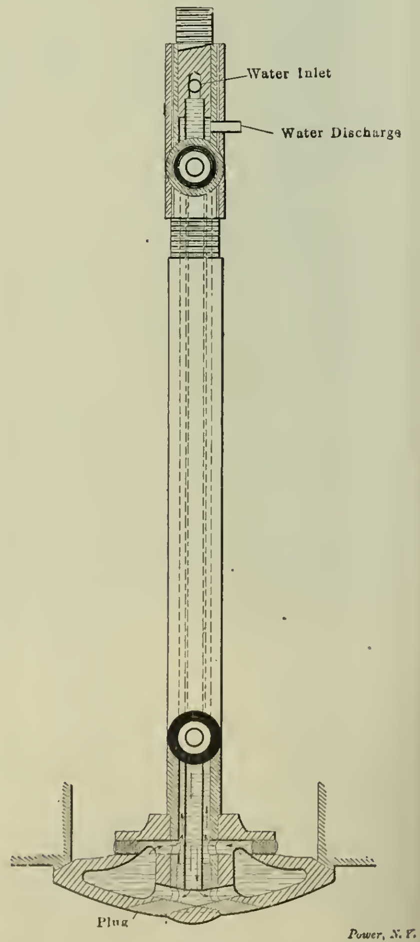

FIG. 6. SECTION OF WATER-COOLED EXHAUST VALVE

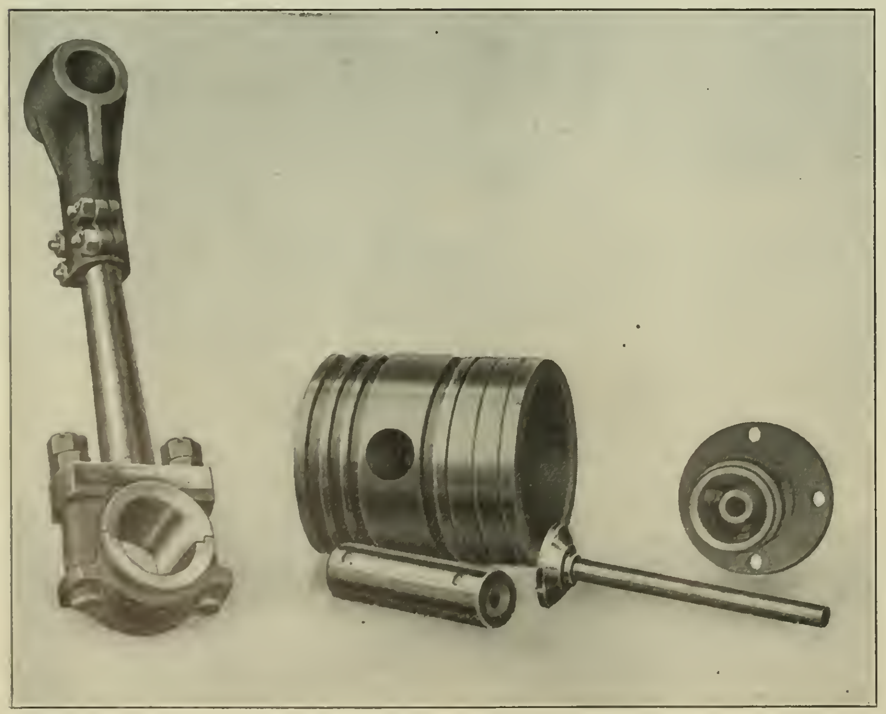

FIG. 7. PISTON, AND CONNECTING ROD

one on the thrust side and one on the opposite side.

Gas and air come to the engine through 5-inch supply pipes, each of which is provided with a lever-actuated gate valve by the manipulation of which the proper mixture may be obtained. The mixture then passes through a balanced throttling valve, shown in section in Fig. 4, which is controlled by the governor. The cylinders are connected in pairs by two inlet manifolds, and they are in turn united directly under the throttle valve.

The flyball governor is gear-driven and

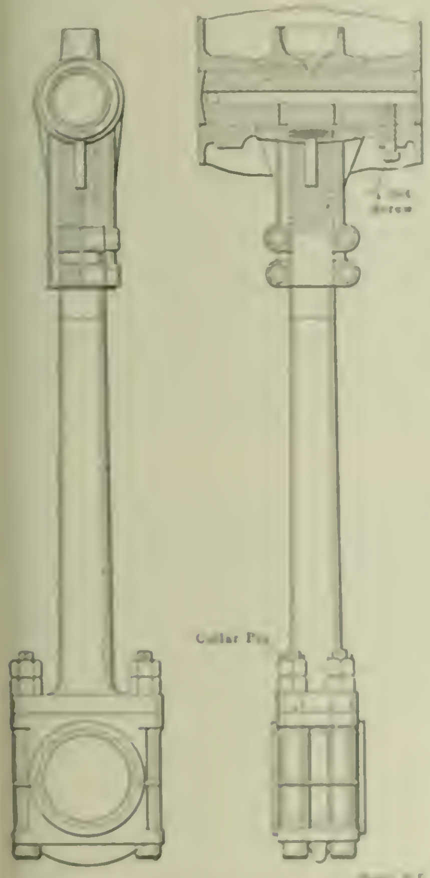

FIG. 8. DETAILS OF CONNECTING ROD

equipped with a dashpot to facilitate steadiness of operation. Ball-and-roller bearings are used in the governor mechanism and linkage.

According to a press despatch a company has been formed at Vineland, N. J., with a capital of $100,000, to develop the water power of the Maurice river. It will be known as the Maurice River Light, Heat and Power Company. A dam one-half mile long will be constructed, affording a head of 16 feet. Marcus Fry, of Vineland, is secretary.

The Combined Associations of Engineers of Brooklyn, N. Y., are up to the minute, especially in matters social, and they have already secured the date of July 18 at Bellwood park, N. J., for their annual outing.

Energy Charts for Steam

By R. M. Neilson

In steam-engine investigations involving the question of work obtainable from a given weight of steam, or the steam consumption to produce a given amount of work, it is, of course, necessary or desirable to know the maximum amount of energy obtainable from the steam. Mechanical-engineering pocket books and treatises on the steam engine commonly give tables of the properties of saturated steam, which include a column setting forth what is termed the *total heat* of steam. These "total-heat" values are often of great use; they represent the heat required to be put into 1 pound of water to raise it from 32 degrees Fahrenheit to the boiling point and convert it into steam at the boiling-point temperature. This temperature varies with the pressure, as is well known, and consequently the "total heat" depends on the pressure; at atmospheric pressure it is 1147 B.t.u., at a pressure of, say, 200 above atmosphere, it is about 1200 B.t.u. A "total-heat" table is, as aforesaid, of much use. For example, with steam-generator problems it gives—after deducting the difference between the feed temperature and 32 degrees Fahrenheit—the heat required to be supplied to the water in the boiler per pound of feed.

These total-heat values do not, however, represent in any way the work which can be got out of the steam. If we are told that a steam engine consumes 12 pounds of steam per hour per indicated horsepower, with a steam pressure of 150 pounds and a vacuum of 26 inches (with the barometer at 30 inches), we may want to know what would be the steam consumption of an ideal engine working under the same conditions, or—what comes to the same thing—how many foot-pounds of work is obtainable from a pound of steam expanding from 150 pounds to a pressure of 4 inches of mercury. No tables, as far as the author is aware, have been published which give this information. The information can certainly be obtained with a little trouble from entropy-temperature or other heat-energy charts which are in fairly common use, but not, the writer considers, in a sufficiently convenient manner. The average engineer wants a direct reading.

The charts shown on the accompanying supplement were prepared by the writer to give this direct reading. It is unnecessary to say here how the charts were prepared,* but it is desirable to explain how they should be used and, in order to do this, it is necessary to say something about the conversion of the energy of steam into mechanical work.

Steam does mechanical work when it expands against a resistance. Such expansion may take place in a steam-engine cylinder, the resistance being the load on the piston; or it may take place in a nozzle—say of a turbine—the resistance being the weight of the steam, the velocity of which is increased. Work in the one case is done in moving the load on the piston and in the other case in giving kinetic energy to the steam.

The steam may receive heat during the expansion, as in the case of a steam-jacketed engine cylinder, or it may have heat abstracted from it (beyond that converted into work) and transferred as heat to other bodies, as in the case of an unjacketed steam-engine cylinder. When the steam neither receives nor loses heat, as heat, the expansion is commonly termed adiabatic; but, as there is some difference of opinion as to the meaning of this term,** the word isentropic, about which there is no difference in opinion, will be used. The word isentropic signifies that no heat is added to or withdrawn from the fluid during expansion and, therefore, from the law of the conservation of energy, it follows that if the expansion is isentropic the work done, whether in driving the piston or in giving kinetic energy to the steam, must be an exact equivalent of the heat energy given up by the steam. In the case of saturated steam, the heat energy given up corresponds to a definite drop in pressure, so that a fall from one pressure to any other pressure by isentropic expansion corresponds to the performance of a definite amount of mechanical work. This work, whether performed in moving a piston or otherwise, is expressed on the charts in foot-pounds per pound of steam; in the case of steam expanding in the nozzle of a steam turbine it represents the kinetic energy acquired by the steam.

The smaller chart gives the work of expansion from initial pressures of from 25 to 250 pounds to final pressures of from 15 to 200 pounds, the initial pressures being written [illegible], while the abscissas or horizontal distances represent the final pressures and the ordinates or vertical distances the mechanical work done.

The large chart is a continuation of the other but deals with final pressures below atmosphere, the scale for final pressures being made much greater [illegible] than in the other chart.

How to Use the Charts

As an example of the use of the charts take the case of a noncondensing steam engine which consumes 25 pounds of steam per indicated horsepower per hour. This steam is supposed to be saturated [illegible] and at 175 pounds [illegible] gage pressure—that is [illegible] pounds absolute. It is required to compare the

*This is explained in the author's book "The Steam Turbine," [illegible]

**[illegible]

steam consumption of this engine with that of an ideal one; with an engine in which all the available energy in the steam would be shown on an indicator diagram.

Referring to the smaller chart, it will be seen that the energy obtainable from the expansion of 1 pound of steam from 170 pounds to 15 pounds (approximately atmospheric pressure) is 136,000 foot-pounds. Therefore to work at the rate of 1 horsepower for one hour, which means doing

$$60 \times 33{,}000 = 1{,}980{,}000$$

foot-pounds of work, would require

$$\frac{1{,}980{,}000}{136{,}000} = 14.6$$

pounds of steam, as against the 24 pounds actually used.

To show another and more important use of the charts, suppose that an exhaust steam turbine takes 33 pounds of steam per kilowatt-hour when the steam is supplied at atmospheric pressure (say 15 pounds per square inch absolute) and the vacuum is 27 inches, with the barometer at 30 inches (say 1½ pounds absolute pressure). It is required to find what less vacuum we can afford to have to obtain the same steam consumption, if we supply the steam to the turbine at 5 pounds above atmosphere, say at 20 pounds absolute. The kinetic energy obtained from 1 pound of steam expanding from 15 pounds absolute to 1½ pounds absolute is seen, on the large chart, to be 113,600 foot-pounds. Drawing a horizontal line through this point to cut the curve denoting 20 pounds absolute pressure, we find the final pressure to be about 2.1 pounds absolute; say 25.7 inches of vacuum with the barometer at 30 inches, the 5 pounds additional steam pressure therefore only allowing of a reduction of 1.3 inches of vacuum.

This assumes that the effective efficiency* of the turbine was equal in the two cases, which is generally approximately true under the conditions considered, but is not true with high steam pressures or very high vacua.

As a third example, suppose that it is desired to expand steam from, say, 200 pounds per square inch pressure, absolute, to 1 pound absolute, in four steps or stages so that the steam gives up the same amount of energy in each.

The energy obtainable from the complete expansion is, it will be seen from the large chart, 260,000 foot-pounds. Therefore, the total energy given up at the end of the first, second and third stages is 65,000 foot-pounds, 130,000 foot-pounds and 195,000 foot-pounds, respectively; and, by noting where the 200-pound curve cuts the horizontal lines representing these amounts of energy, we find the final pressure at each of these stages. These final pressures will be seen to be 70 pounds, 21 pounds and 5.05 pounds per square inch, respectively.

It may be well to point out that it must not be thought that there is an error because the chart gives the energy of 1 pound of steam in expanding from 70 pounds to 21 pounds, or from 21 pounds to 5.05 pounds, or from 5.05 pounds to 1 pound, as other than 65,000 foot-pounds. This is because, in the four-stage expansion considered, for every pound of steam at the start, we have not a pound of steam at the beginning of the second, third and fourth stages, but a pound of fluid which is partly steam and partly water, some of the steam condensing (according to well known laws) during the expansion.

Other uses of the charts will suggest themselves. In fact the writer has found that many problems that would have been ignored, or the results simply guessed, on account of the trouble of obtaining the available energy in the steam will, by the use of the charts, be scientifically solved.

*The effective efficiency is the ratio of brake work to available heat energy.

Value of High Pressure

The advantages of high-pressure steam, even when used in the single-expansion cylinder of a locomotive, are brought out in the "Report on High-Pressure Steam in Locomotive Service," issued by the Carnegie Institution, of Washington, of which a resumé has been issued by the University of Illinois.

Tests were made under the direction of W. F. M. Goss, dean of the College of Engineering at Illinois, in the laboratory of Purdue University, while he was connected with that college, to determine the performance of a typical locomotive when operating under a variety of conditions with reference to speed, power and steam pressure. The results of one hundred such tests have been recorded and show that the steam and coal consumption vary with the pressure as follows:

Pressure Lb. Per Sq.In.	Steam Per Ind. H.P.-H., Lb.	Coal Per I.H.P.-H., Lb.
120	29.1	4.00
140	27.7	3.77
160	26.6	3.59
180	26.0	3.50
200	25.5	3.43
220	25.1	3.37
240	24.7	3.31

The same results are shown graphically on the accompanying diagram. They show that the higher the pressure the smaller the possible gain resulting from a given increment of pressure. An increase of pressure from 160 to 200 pounds results in a saving of 1.1 pounds of steam per horsepower-hour, while a similar change from 200 to 240 pounds improves the performance only to the extent of 0.8 of a pound per horsepower-hour.

An increase of pressure from 160 to 200 pounds results in a saving of 0.16 of a pound of coal per horsepower-hour, while a similar change from 200 to 240 pounds results in a saving of but 0.12 of a pound.

How to Make a Tool Board

In order to make a tool board large enough to hold all the wrenches, hammers, screwdrivers, etc., one may have use for, and wishes to keep in a handy place, first gather all the tools together and arrange them on a table in the position desired, so as to take up the least space and yet not be crowded when placing the heavy part of all tools upward. Then by measuring the length and width the amount of lumber required is determined. Note the thickness of the thickest tool and make that the thickness of the boards.

Call it, for example, 2 inches. Then get enough clear pine stock 1 inch thick and the same amount of second quality, also 1 inch thick, to make the size of board desired. Butt joint the best lumber and glue the joint and clamp well. When dry, place all the tools on this board, arranged as when on the table, and make an outline drawing around each with a pencil. Then nail on the second quality of 1 inch stock to the back, with the strips running at right angles. Then bore and jigsaw through both boards spaces to conform to the shapes and sizes of the tools, making the fit snug. Mark each piece 1, 2, 3, etc., as you saw them out; also number the places from which they were taken.

Next find the center of gravity of each tool by placing each across a knife edge until it just balances; mark the spot on the tool with chalk and place the tool back in the [illegible] space. Then in order to allow a good grip to be taken [illegible] tool, gouge out an opening [illegible] in proportion to the size and weight of the tool. Next nail [illegible] on the back, and [illegible] all the openings at the back [illegible] "[illegible]" [illegible] difference of thickness between the tools will thus be compensated for by [illegible] the backing [illegible] openings. Glue or nail them [illegible] when the tools [illegible] be flush with the outside of the board.

Next nail ogee molding round the edges and finish with sandpaper. Paint first with drop black, then a good coat of wood filler on front, back and sides, then two coats of shellac and two of furniture varnish. Rub down with [illegible] before applying the last coat of varnish. Next paint the bottom only of each tool receptacle white. The board when finished will have an appearance something as shown in the illustration.

A HOMEMADE TOOL BOARD

With this tool board all the tools are in sight, and if one is missing the white back will act as a telltale. They are so arranged that no amount of knocking [illegible] will knock them out.

If the back and front of such a board be varnished alike it will prevent warping. In hanging such a board I would advise the placing of two or more screws at the back close to the bottom, allowing them to stick out ½ inch, so as to make the board stand slightly back at [illegible] and so obviate the possibility of any tool falling out by jar or vibration.

Henry [illegible]

[illegible], N. Y.

Sparkless Commutators

Here are a few hints which, if followed by Mr. Baker, will help him to run his [illegible] without sparking. Keep the machines clean and dry and the commutator smooth, true and free from [illegible] [illegible] the copper coating of the brushes to come into contact with the commutator [illegible] [illegible] inch above the [illegible] and [illegible] sandpaper the heel and toe of the brushes round, after sandpapering each to a fit with no sandpaper [illegible] and use no lubricant of any kind on the commutator [illegible] [illegible] the brushes [illegible] when making contact on the commutator [illegible] When the load is light [illegible] brushes back and forth [illegible] until the proper [illegible] is found and then leave it [illegible].

If Mr. Baker follows these simple rules and still has sparks at the brushes he had better [illegible].

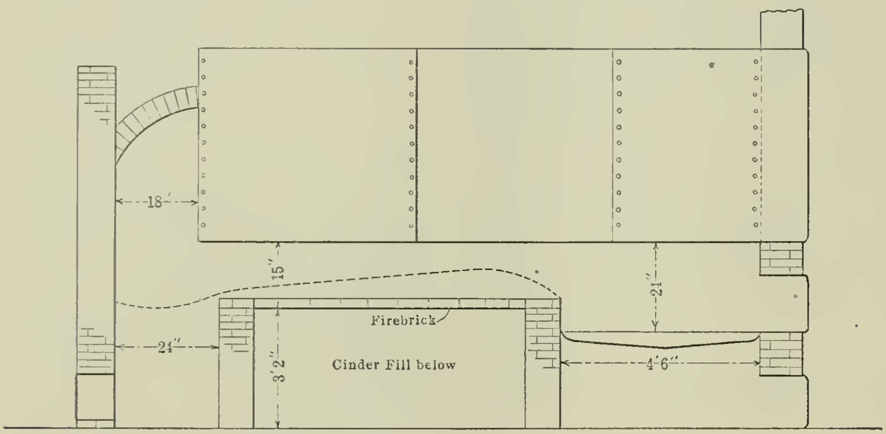
Frank [illegible]

[illegible], Mass.

Burns Too Much Coal

In our electric-light plant we have two 66-inch by 16-foot return-tubular boilers, set as shown in the accompanying sketch. We burn slack soft coal and occasionally run-of-mine, our regular working steam pressure being 100 pounds.

One boiler only is operated at a time, and usually at a comparatively light load, our runs being from sunset to midnight, with a short morning run during the winter. Our peak load amounts to about 75 horsepower for two hours, gradually running down to about 15 horsepower at midnight.



ONE OF THE BOILERS IN MR. SPRAGUE'S PLANT

I have never operated a boiler set in this manner for burning the fuel we do. I refer more especially to the combustion chamber, its construction making a contracted passage for the gases. The dotted line shows how I found the combustion-chamber ashes heaped up on my first cleanout, the rear end being entirely full. I have formerly been accustomed to combustion chambers that were much larger, either being entirely open behind the bridgewall, or sloped off to the rear from the top.

Our furnace is 6 feet wide by 4½ feet long. I am of the opinion that we would have better results from our fuel if the grates were set farther from the boiler shell, and in view of the light load it may be advisable to brick off part of the grate bars in the rear. The boilers have flush fronts and the lower part is separate, which would facilitate the construction of a dutch oven, should such construction seem advisable. The stacks are 32 inches in diameter and 60 feet high, and we have an excellent draft, but no damper regulator.

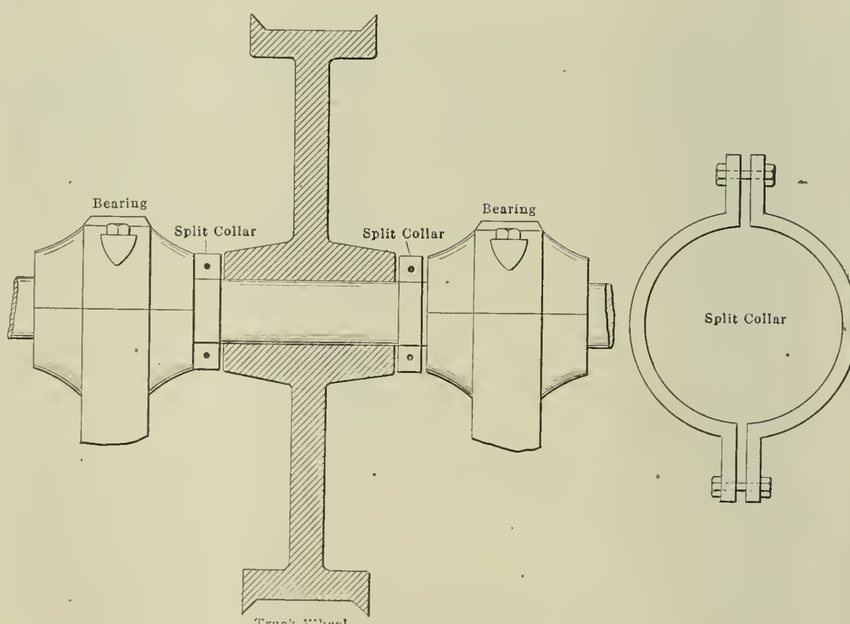
In checking over our output I find we are using about 18 pounds of coal per kilowatt, which I consider nearly double the amount we should require. Our engines are all in good condition and first-class adjustment. We run noncondensing.

G. S. Sprague.

Geneva, Neb.

Remedying a Traveling Crane Trouble

A traveling crane was driven by a double vertical steam engine and boiler located on the crane. The engine and boiler were replaced by a motor last summer, and after a few days it was noticed that the trucks on each end of the crane were not running in line.



HOW A TRAVELING-CRANE TROUBLE WAS REMEDIED

Upon examining the wheels on both trucks I found considerable play between the two bearings and the hub of the wheels, as shown in the illustration.

I filled this space with split collars, but in order to give the wheels a little play, a ¼-inch space was left between the hub and the two bearings. After the collars were put in place and the crane started, no further trouble developed.

H. Jahnke.

Milwaukee, Wis.

A Lighting Problem

In reply to Mr. Rolph's letter, as the transformer voltages or the lamp voltage were not given, I assume that the voltages are 110 volts between the middle lead and the outside ones and 220 volts between the outside leads of the transformer, and that the lamps are for 110 volts. If the lamps are of the assumed voltage, then series connections would not do; but if the lamps he has in mind are designed for series grouping, and if desired to run that way, it would be advisable to have a choke coil across the lamp terminals, so that in case the lamp failed, the coil would take its place and keep the remaining lamps burning.

As the town is small, it would be better to run the lamps in multiple and use 110-volt lamps. This would only require another length of wire in addition to that required on the series circuit, and the extra insulators and pins. This would do away with the necessity of the choke coil, and each lamp would be independent.

To balance the transformer it would require seven of the lamps per circuit, one circuit taking the middle and outside lead and feeding in one direction and the other circuit taking the middle and opposite outside lead and feeding in the other direction.

Another scheme would be to feed the circuits with 220 volts and connect the lamps in multiple series. This can be best determined by local conditions. The arc circuits are connected all right, but it is best to run the three wires both ways from the transformer for the commercial circuits, and care should be taken to keep the load evenly divided between them.

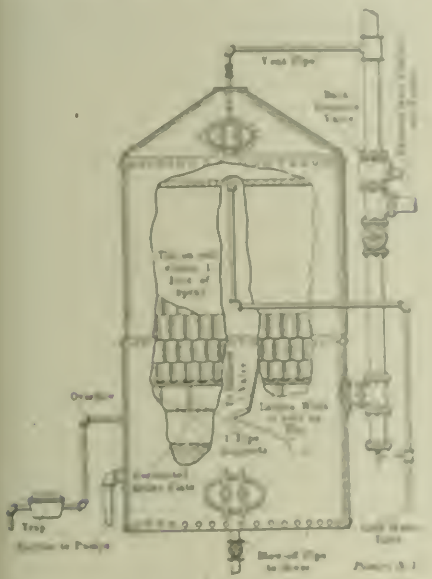
Lincoln Place, Penn.

A Homemade Heater

The accompanying sketch is of a homemade heater made out of an old tank. It is 6 feet in diameter and 10 feet high, and takes care of 1000 horsepower of



A HOMEMADE HEATER

boilers. The draintile must be renewed about once a year, according to the condition of the feed water. It has been in use about one and one-half years and at the present time there is no sign of any oil in the boilers.

JOHN S. JUNG.

Milwaukee, Wis.

Difficulty in Starting a Motor

One of our customers using a 5-horsepower 220-volt two-phase motor experienced considerable difficulty in starting, due to the belt slipping off. The motor was not furnished with a starting compensator and the owner did not care to go to the expense of procuring one, so we rigged up a four-pole double-throw switch, as shown by dotted lines in Fig. 1, and at the same time connected the neutrals of the two-pole transformers together.

The switch was thrown to the right, the motor starting off without a jerk, and when up to speed the switch was thrown to the left. On starting the situation was as shown in Fig. 2, the motor leads 2 and 3 being connected to line 2, motor lead 4 to line 3, and motor lead 1 to line 1, making one half of each phase acting together on a full coil of the motor; this gave 155 volts instead of 220, as the voltages of the two phases are 90 degrees apart in

FIG. 1

FIG. 2

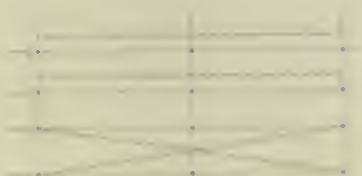


FIG. 3

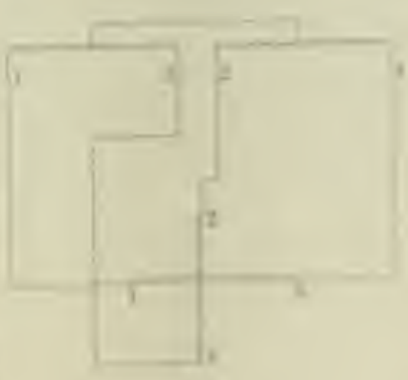

FIG. 4

phase and the resultant voltage is the square root of the sum of the squares, or

$$\sqrt{110^2 + 110^2} = 155.$$

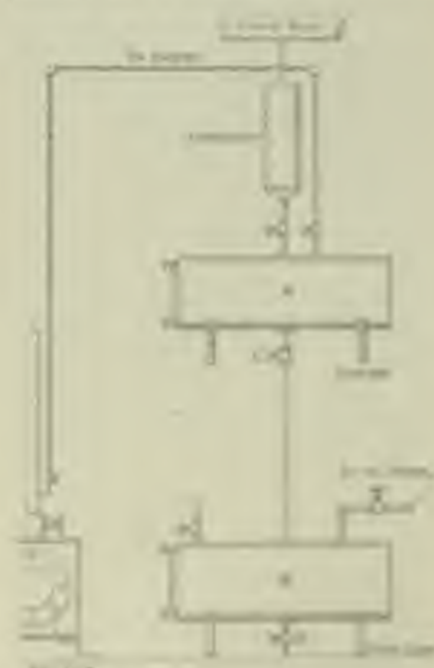
The same effect would be obtained by connecting the switch as shown in Fig. 3, giving result as shown in Fig. 4, and would give the same current in all coils of the transformers, but the starting current is [illegible] a short time that this is [illegible] necessary.

LORENZ B. CLARK.

Brookfield, N. Y.

Cylinder Oil Distributer

The oiling system herewith described is in operation in a large steel mill. In the engine room are twelve engines in a row, all the same size and speed. There is but a lubricator in the plant. The cylinder-oil tank, which is located in a convenient place, has one pipe connection to the steam main and another to the sight-feed glasses. The supply for each engine is regulated by a feed valve at the bottom of the glass. The line from the steam main to the supply tank is provided with a condenser.



CYLINDER-OIL DISTRIBUTER

The novelty of this system is the [illegible] tank arrangement. The supply tank A [illegible] is placed on the wall and supported by brackets. Tank B is placed on the floor and is connected with tank A which is provided with a gage glass. When tank A is nearly empty, B is shut off from it by closing the valve C, and it is drained from the bottom drain pipe. The valve D is then closed and the tank filled with oil. Then opening the valve [illegible] the oil [illegible]

The advantage of this arrangement is that there is no need for an expensive outlay for lubricators and the oil supply is not cut off from any engine or pump while filling.

EDWARD T. BINNS.

Philadelphia, Penn.

The Actual Cost of Power

In one of the recent issues, in the editorial on "The Actual Cost of Power," I read the following statement: "It is important for the engineer to be able to figure power cost, including the fixed charges, however, when occasion arises, and to appreciate the influence of the annual interest, depreciation, insurance and taxes on the unit cost of power produced." True, this is important, but to what end? To find out if the production is economical, or if the plant is efficient?

The most accurate computation of the cost of power can only show that its unit cost has increased or decreased; and in the editorial mentioned we find the statement that the unit cost decreases when the output increases, and *vice versa.* Therefore, it follows that by knowing his actual cost of power the engineer will only learn that the good or poor work of the sales department has made him produce cheaper or more expensive power. What will he gain through such knowledge?

He will have sufficient data to "kick" against the management of the concern; he will learn—perhaps—what the profits of his employers are; he will learn how difficult it is to do another man's work, and he will be kept in training in the high art of arithmetic. All this is a considerable gain to him personally, but is it all so very useful and necessary?

He will not have learned what his task really is. All these computations will not show him what his part is in the process of decreasing the cost of production; they will not teach him how to increase the immediate efficiency of his power plant. He will have to ask his employers to engage standard-practice specialists, who will determine standard-unit costs and work out a system of record keeping which will enable the engineer to find out at each given moment what the total efficiency of power generation is, where the leaks in the numerous steps of the transformation of energy, from the coal pile to the switchboard are located, how large the losses are in each step of this process, and which of these losses depend upon inefficient operation and which upon outside causes.

By the actual unit cost of power generated it is impossible to know whether the plant is doing well and the engineer is up to his task. The data of previous months are of little use, as it is valueless to compare casual and inaccurate figures with others which are also indefinite. That would only be an attempt to bluff oneself and others by irrelevant and absolutely misleading data. To make any comparisons one must have scientifically determined standards, just as one must have a zero point and a boiling point on a thermometer scale.

It often happens that with a high actual unit cost the efficiency is much higher than with a lower one, and then the activity of the engineer must be in quite another direction than the one which might be prompted by the casual figures of actual cost. The type of calculations recommended in the article quoted will be also useless for a comparison with unit costs of neighboring power plants. These plants have other prices and specifications of fuel, other fixed charges, etc., and, therefore, there is very little sense in trying to compare unit costs before they can be measured by a common scale and from a common zero point; in other words, before the plants are standardized and before special efficient engineers have given into the hands of the permanent staff the scientific methods of determining the plant's efficiency.

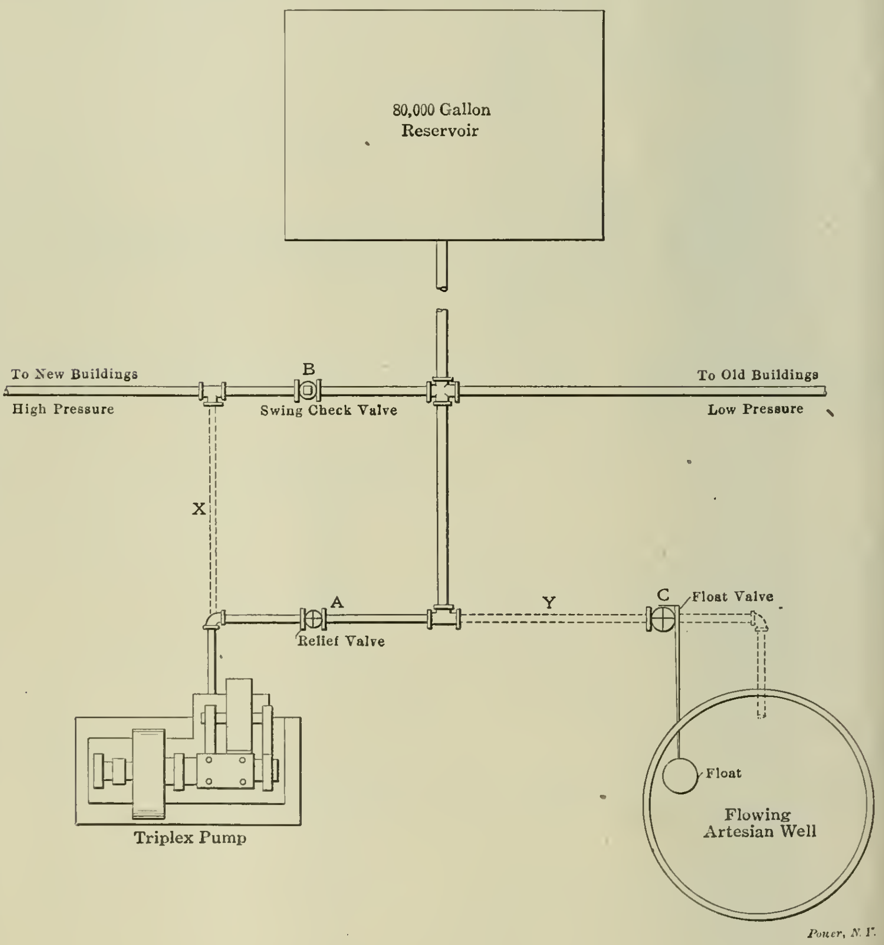
New York City.

Increasing Water Pressure

Several years ago about half of a large factory was rebuilt, the old buildings being replaced by new and modern structures two stories higher. Difficulty was at once experienced in getting water to the top floors of the new buildings.

A water pressure of 27 pounds was maintained by an 80,000-gallon reservoir and a triplex power pump. The new buildings required between 35 and 40 pounds pressure, so it was necessary to raise this pressure about 13 pounds, while keeping the pressure on the rest of the system at its normal value.



GENERAL LAYOUT OF WATER SYSTEM

The sketch shows the general layout of the system. The full lines, with the exception of the valves, indicate the system as it was before alteration. The dotted lines and valves show the additions that were made.

On the top of a hill, half a mile away, is the 80,000-gallon reservoir. At the factory is a flowing artesian well. The reservoir is connected through the pump to the cistern of the well, and the factory mains are tapped from a point between the pump and reservoir, so that the factory may draw its water from either source. The reservoir is kept full by the extra water pumped when the pump is running.

The required extra pressure was obtained by putting a relief valve set at 45 pounds between the pump and the reservoir at *A*, a swing check valve on the high-pressure supply pipe at *B*, and connecting the high-pressure main beyond the check valve to the pump through the pipe *X*. This arrangement permitted the pump to feed the new buildings at 35 pounds pressure, or more, while the old buildings remained on the lower-pressure system. In case the pump was shut down, the reservoir would supply both old and new buildings, the former as formerly, and the latter through the swing check valve, but at a low pressure.

During certain seasons of the year the flow of the well declines and becomes insufficient to supply all the water needed. In order to keep enough water in the well cistern to supply the pump for the higher buildings, at such times, a supply pipe *Y* was tapped from the main to the cistern through the float valve *C*, which was set so as to keep the water at the required level.

The desired results were thus accomplished at the expense of three valves, about 10 feet of piping at *Y*, and some 3 feet of piping at *X*. The plan has proved entirely satisfactory, and has been working for several years.

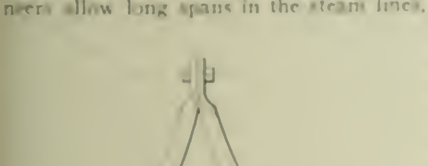
Chicago, Ill.

Support for Flanged Piping

In putting up large steam pipes I have noticed that some steamfitters and engineers allow long spans in the steam lines,



FLANGED PIPE SUPPORT

and although hangers are used, a great strain still remains on the flanges.

The way I have done is to use two clamps on steam pipes, one on each side of the flange, and bolted tight to the pipe (see illustration). I then take two pieces of iron and make a V-shaped piece to act as a keystone and prevent the pipe from sagging, thus removing the strain from the flanges.

E. H. Marsh.

Wheeling, W. Va.

The Centrifugal Pump

The discussion on centrifugal pumps has been very interesting to me and I think some good practical points have been brought out. George H. Gibson very clearly explains his idea of the action of the water in his article in the January 12 issue, page 122, but I think his argument applies more to pumps with the circular casing than those of the volute form and as it was a common volute pump that started the discussion, I confined myself, in a previous letter, to that type of pump, so I was not as surprised as Mr. Gibson imagined when I heard of "other types." I will give my reason for wishing to know if the statements relative to closing the discharge valves of centrifugal pumps while running at full speed applied with equal accuracy to the common low-lift volute pump.

Some time ago I was visiting a large manufacturing establishment and the engineer was showing me a centrifugal pump there used for filling a large reservoir, when all at once the pump started to run hard, the belt slipped and snapped and finally came off the pulley. The engineer excused himself with the remark that some fool had shut down the discharge valve by mistake and that he was going to have a lock put on it. With that he left me and I went over the rest of the plant and eventually went home without seeing the engineer again.

This pump was a common volute pump and I should guess that the discharge pipe was about 10 inches in diameter. I never thought any more about it until I saw the statement about the decrease in power needed when the discharge was closed, and as this was so directly contrary to this incident I naturally was doubtful if this applied to this type of pump and so asked for more data. I note that G. H. [illegible], in his article on page 247, states that in his experience with about 20 centrifugal pumps he found that the power required to work against a column of water without discharge is about equal to the power needed when discharging fully under seven-eighths of the head. I mention this in comparison with Mr. Gibson's article merely to show that different results appear to be obtained under various conditions. I also note that Mr. [illegible]'s experience is that centrifugal pumps when operating with discharge closed require less power, but I am of the opinion that his pumps were not of the common volute type, as he speaks of an 80-foot lift.

I am sorry I cannot make any definite statement myself, but I have since tested one of these pumps to see what effect closing the discharge valve has, and I am not positive that the pump I saw threw off the belt because the discharge valve was closed, but the engineer certainly seemed to know what the trouble was just from the way he spoke of it as though this had happened before.

Has anyone had a similar experience with a common low-lift volute form of centrifugal pump?

[illegible]

Exeter, N. H.

A Homemade Filter

The sketch shows a filter I have just completed. It is made out of two 50-

A HOMEMADE FILTER

gallon cans. I cut the top out of one can and the bottom out of the other and used them for the strainers at the top [illegible]. It is painted so I have no occasion to feel ashamed of it.

Although it works well, I had much rather have a proper filter made by any good firm.

[illegible]

Scaled Boiler Surfaces

Referring to the discussion of Hilton Williams' article by H. E. Gansworth in the January 5 number, and by Eriths' Engineering Company, Ltd., in the February 9 issue, the tests quoted by Mr. Gansworth included an item of considerable interest, but not mentioned in his quotation. Two boiler tests were made on a locomotive-type boiler working at a high rate of evaporation. One test was with the tubes and fire sheets covered with an average of ⅛ inch of carbonate scale. The other test was made under exactly similar conditions, but after the boiler had been cleaned of all scale. The result was an average of 10.5 per cent. loss due to this thickness of carbonate scale.

At another time, performance sheets expressed in terms of power generated, all under similar conditions, were kept for three months previous to and for three months after scale removal. The scale was mainly carbonate, and the result at the coal pile was 10 per cent. in favor of clean surfaces. On the other hand, many tests which are on record, and whose reliability is beyond dispute, tend to indicate that the effect of scale is much less than as herewith indicated, and others show that it is higher. I believe that these disagreements may sometimes, though not always, be reconciled when the real governing conditions are taken into account.

Rankine, I think, found that the heat resistance of dry carbonate-of-lime scale is about seventeen times that of iron, and that of sulphate of lime forty-eight times. Carbonate scales are soft and porous and sulphates hard and dense. The carbonate coating may be considered as a pipe covering, only the particles are somewhat cemented together instead of being loose. No engineer would expect much of a pipe covering that was saturated with water. The heat resistance of a porous scale in a boiler should be looked at in the same light.

If the rate of evaporation is low, and especially if the scale in question is in a part of the boiler, or its auxiliaries, where the flue gases have lost some of their heat, and the feed water has not reached its maximum temperature, the scale will be damp to some extent. If, however, the rate of evaporation is high, the body of the scale will be dry, or contain nothing but highly superheated steam, and in this condition it approaches the condition of a dry pipe covering, and we have an excellent heat insulator which, considering its thickness, compares favorably with what we know of the value of magnesia pipe coverings in general. This may account for the fact that tests made at high rates of evaporation generally show decided loss on account of scale. In any case, especially at low rates of evaporation, the composition of the scale should be taken into account and this may account for the vastly different results that have been obtained.

Even if in some cases porous scale causes only slight loss at low rates of evaporation, the fact that at high rates the loss is great makes the subject of considerable importance in view of the results of certain tests at the St. Louis Exposition, and the resulting tendency greatly to increase the volume and, therefore, the velocity of gases passing over any given heating surface, all with a view to greatly increasing capacity at very slight cost in economy.

E. W. Fiske.

Urbana, Ill.

Repairing Commutators

In the plant where I am employed there are three 250-kilowatt 600-volt three-phase rotary converters, all of which are subject to flashing, one being extremely so. This trouble probably occurs more frequently in rotary converters than in direct-current generators, due to the "bucking" or flashing-over characteristic of some of these machines. If this burning occurs out on the brush-bearing portion, or outer end of the commutator, it is not so difficult to handle, but when it is on the inner end, where the armature leads connect to the commutator, it is much more serious, as it is hard to get at it.

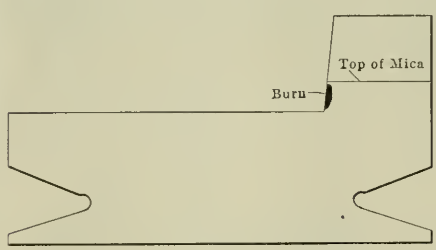

FIG. 1

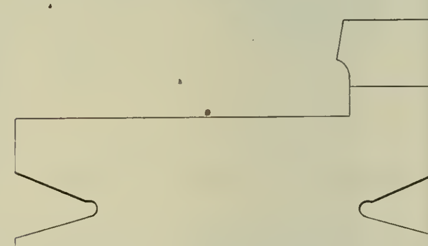

FIG. 2

In the three converters mentioned, burning at this point became so serious that it was necessary to cut off the copper with the lathe, increasing the length of the brush-bearing portion of the commutator until the tool went in behind the burned places, leaving the hard, firm mica between the bars. Figs. 1 and 2 will illustrate the idea, Fig. 1 showing the original shape of the commutator bar and Fig. 2 how it was cut away.

While the remedy suggested by Mr. Work, a solution of silicate soda and a filler, in the January 5 number, is probably the best we have, it is by no means a panacea. An experience extending over three years convinces me that one should not be too hasty in congratulating himself on the permanency of the repair, especially if the commutator is run where oil is likely to get on the surface, or if it is on a high-voltage machine. In some instances this filler seems to deteriorate under the action of oil.

As Mr. Work says, every particle of charred mica must be removed, and if the job is undertaken by anyone who does not fully realize the importance of having the cavity thoroughly cleaned, failure is most sure to result. The writer has used both powdered glass and plaster of paris as a filler for the silicate soda (water glass) solution, and prefers the former where any length of time may be had for the repair to dry before starting up the machine. With powdered glass, the mixture forms a doughy mass which is easy to handle and force into the cavity. If plaster of paris is used the mixture hardens almost before it can be applied, making it necessary to work very rapidly in applying, or else break it up again after it has set, which is bad practice.

With either filler, if the cavity is small, as between two commutator bars, the mixture will harden in a few minutes sufficiently to allow the machine to be started, but if the cavity is large some time will be required for it to dry, the longer the better. Where the mixture before drying forms a ground, the drying has been in some instances hastened by allowing a light current to flow through the filling to the ground, but care must be exercised that it does not become too warm.

One of the converters previously mentioned has been running for several months with a two- or three-ounce plug of the mixture (with plaster of paris as a filler) packed into a hole between the commutator bars and the clamping ring, the hole having been burned out from a ground against the clamping ring. In another is a plug of powdered glass as a filler between the bars of the commutator and the clamping ring of the thickness of the original insulation. When this repair was made the machine tested partially grounded, but the slight leak through the mixture soon dried it out until the machine tested clear. If a good fit can be secured it is probably better to use mica than the mixture spoken of, but the fit must be good or the trouble will surely appear again. If the trouble is on the outer corner of the commutator a crevice may be sawed out between the bars across the corner, care being taken to see that the bottom of the crevice is perfectly straight. A tight-fitting piece of mica with a perfectly straight edge should then be forced to the bottom of the crevice, after which the bars should be lightly calked on each side of the mica to hold it in place. The mica can then be trimmed off and smoothed up to conform with the surface of the commutator.

In a job of this kind it is important that more than an approximate fit be obtained and the angle at the surface of the commutator formed by the new piece of mica should not be less than 45 degrees. If so, the point of the new piece at the surface of the commutator will be so thin it will not stay in place, furnishing an inviting place for a new beginning of the trouble. In one or two instances the writer has sawed out the mica across the end of the commutator down to the clamping ring, securing a square corner for the new piece at the surface.

Whether mica or the filling mixture is used the work must be most carefully done or permanency will be lacking, and even with the utmost care permanency will be in doubt.

Where circumstances justify, if the trouble has become very serious, it is probably better to strip off the clamping ring, loosen up the bars and put in new insulation and also commutator bars, if the old ones are badly damaged.

Handley, Texas.

The Modern Surface Condenser

In Mr. Orrok's letter in the December 22, 1908, number, he says that where good surface efficiency is possible and there are no serious air leaks, the air pump of ordinary size is usually more than sufficient. This is a rather vague statement, and not at all on the scientific lines he is anxious to pursue. When are air leaks beginning to become serious, and what does he consider the ordinary size of an air pump?

Mr. Orrok will, I believe, have noticed the great difference in opinions, and in actually operating plants, as to the size of air pumps. If he invites five tenders for certain conditions he will find the air pumps varying in sizes by at least 100 per cent. What the capacity of the air pump means and how it affects the surface efficiency of a condenser I will show by an example.

We will assume a condenser of a certain cooling surface, condensing a certain weight of dry-saturated steam per hour, accompanied by a certain weight of air from leaks and other sources, the cooling water of a fixed quantity per hour entering at 25 and being discharged at 40 degrees Centigrade. We further assume that this condenser maintains an absolute pressure of 0.12 atmosphere, and consequently the steam temperature at the condenser inlet will be 50 degrees Centigrade. The condenser is further assumed to be built strictly on the countercurrent lines, so that the mixture of air and vapors removed by the air pump may have a temperature of 30 degrees Centigrade. The mean difference of temperatures between the steam and water spaces will then be

$$\frac{50-40}{2}+\frac{30-25}{2}=7\tfrac{1}{2}$$

degrees Centigrade. The tension of the vapors at the air-pump suction is then 0.04 atmosphere absolute, corresponding to the temperature of 30 degrees Centigrade, consequently, the tension of the air at the place of removal will be

$$0.12-0.04=0.08$$

atmosphere absolute (Dalton's law).

We now increase the effective displacement of the air pump by 100 per cent., but otherwise leave everything unchanged. The next consequence will be that the pressure of the air at the air-pump suction drops to one-half of the original pressure, or 0.04 atmosphere absolute. Some trial calculations will then show that in order to preserve the original mean difference of temperatures between the steam and water spaces, that is $7\frac{1}{2}$ degrees Centigrade, which is necessary to keep the condenser doing its work, the initial temperature of the exhaust steam must drop to 45 degrees Centigrade, and the temperature of the mixture of air and vapors at the other end of the condenser must rise to 35 degrees Centigrade, when the total pressure will be 0.095 atmosphere absolute, leaving 0.055 atmosphere absolute for the vapors withdrawn with the air, this corresponding to 35 degrees Centigrade, and the total pressure to 45 degrees Centigrade. By doubling the air-pump capacity we have thus improved the vacuum by 0.025 atmosphere, or nearly ¾ inch. But the velocity of the exhaust steam at the inlet end of the condenser will now be 31 per cent. higher, and that of the air and vapors leaving 100 per cent. higher, and besides the percentage of steam in the mixture will be higher, and this is where the surface efficiency comes in, which will be increased, resulting in a still better vacuum and further increase of velocity, until a limit is reached by the increased resistance of flow. These facts have been taught by experience to all builders who endeavored to reduce the cooling surface of otherwise efficient types of condenser.

I now turn to the rate of condensation per square foot. Mr. Orrok again refers to record rates obtained by experiments under certain conditions. I think I have dealt with these and had better speak to figures, asking Mr. Orrok to point out to me any condensing plant in practical operation, "for turbine and cooling-tower conditions," i.e., 80 degrees Fahrenheit cooling water and an average vacuum of 28 inches on a 30-inch barometer, between the cleaning times, showing a rate of condensation of more than 12 pounds of steam per square foot and per hour. I will even go farther and allow 75 degrees Fahrenheit cooling water, although this is not good practice and calls for quite enormous towers.

Referring to Hausbrand's book on "Evaporating, Condensing and Cooling Apparatus," I, of course, know this. The author has had great experience in apparatus for distilleries, sugar factories and others, but has probably never built a steam-condensing plant or a cooling tower. I should like Mr. Orrok to try to design such plants from this book, and I am sure he will have some fun doing it. I can also assure Mr. Orrok that I know the other great book, that of Weiss, which is nearly always quoted when condensing matters are discussed. This book has its great merits, but strangely enough hardly touches on the question of heat transference and, instead, dwells on the countercurrent principle to unbearable length, the result of this one-sidedness being some fallacious deductions relating to the capacity of air pumps. Professor Josse's paper has up to the meantime been published.

In conclusion, I would say that from a scientific standpoint there is now sufficient information at hand to enable manufacturers to build efficient condensing plants. The surface condenser itself will hardly be subjected to radical changes as long as we have to adhere to straight cylindrical tubes. This is not so with the air pump, which for high vacua is open to many improvements. The greatest trouble, however, is the uncertainty about the amount of air to be handled. It is the air which makes condensing so complex a problem, as it not only affects the air pump, but the condenser also. The builders of condensers have to guarantee their plants for high vacua under unfavorable temperatures of the circulating water, without in the slightest way being protected against excessive air in the system.

A correct and reasonable guarantee for a certain vacuum should be based on the quantity of steam to be handled, the temperature of the circulating water and the amount of air carried into the condenser by the steam (or in the case of a jet condenser, by the water also). But as matters are standing, the estimate of the amount of air to be handled is an exceedingly rough one, and we lack the methods to measure the air actually discharged from a condensing plant. A clause like "Provided that the system is reasonably (or perfectly) free from air leaks," means, of course, nothing. Here is the point where scientific experiments on actually operating plants have to set in. If Mr. Orrok can help in this and his efforts will be greatly welcomed by the profession.

How Improve the Diagrams?

Last fall I took a week off, and not knowing just what to do, I thought of taking indicator diagrams. Among others I obtained those shown in Figs. 1 and 2. These diagrams were taken from a Rey-

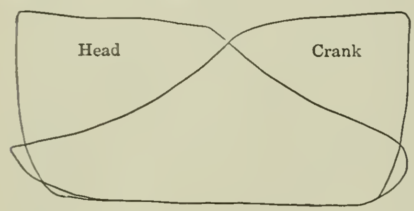

FIG. 1

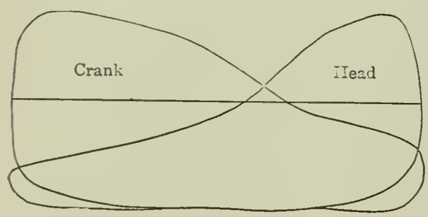

FIG. 2

nolds Corliss cross-compound engine. The high-pressure cylinder was 20 inches in diameter, the low-pressure 42 inches in diameter; stroke, 48 inches. The boiler pressure was 150 pounds per square inch; receiver pressure, 15 pounds; the revolutions per minute, 107; scale of spring for high-pressure, 80, and of the low-pressure cylinder, 15.

I should like to have the readers give their opinion of these diagrams, as to what changes would be necessary to make the engine give a better looking diagram.

Boiler Efficiency

In the issue of February 2, page 239, there appears an article giving certain results relative to tests of run-of-mine coal as compared to briquets made therefrom, which is an abstract from a recent bulletin of the United States Geological Survey, in which it is stated: "In all classes of service involved by the experiments, the use of briquets in the place of natural coal appears to have increased the evaporative efficiency of the boiler tested."

The publication concerns itself more particularly, of course, with the matter of briquets, but the statement in the paragraph quoted is so far in error that it seems desirable that attention be called to it. The question is, how can the change of fuel affect the efficiency of a boiler? A boiler is efficient due to its design, the material entering into its construction, etc., and the purpose of the boiler is to abstract the heat from the gases flowing over it. Its ability to do this is dependent upon certain features of shape and arrangement of parts, and the efficiency of a boiler as a heat abstractor cannot be altered without changing the shape of the apparatus. If we have a plain cylindrical boiler without tubes in it, and we alter it by placing tubes therein so that the gases also pass through them, we have increased the efficiency of the boiler materially, but if in one case it should have coal burned under it and in the other briquets, the efficiency of the boiler would in nowise be affected, because in each instance it would be the same plain cylindrical boiler.

In my opinion it is well to call attention to these features, as it tends to a better understanding of the matter of boiler performance.

Power Plant Records

In the February 2 number was an article on "Power Plant Records," by Mr. Bogart, which interested me greatly. I get all my meter readings at 7 a.m. The coal is conveyed to the boiler house on a small car, weighed on track scales and totaled once a day. All records are kept on a properly designed report sheet. By using a recording wattmeter and a water meter it is possible to come very close to what the boilers are doing. As to the live steam we are using we can only guess at that. We use recording pressure gages, a recording voltmeter and a recording meter on the heating main. Meters on the air compressors would help some. With the appliances I have, it is interesting to see the changes in the average evaporation, due to one cause or another.

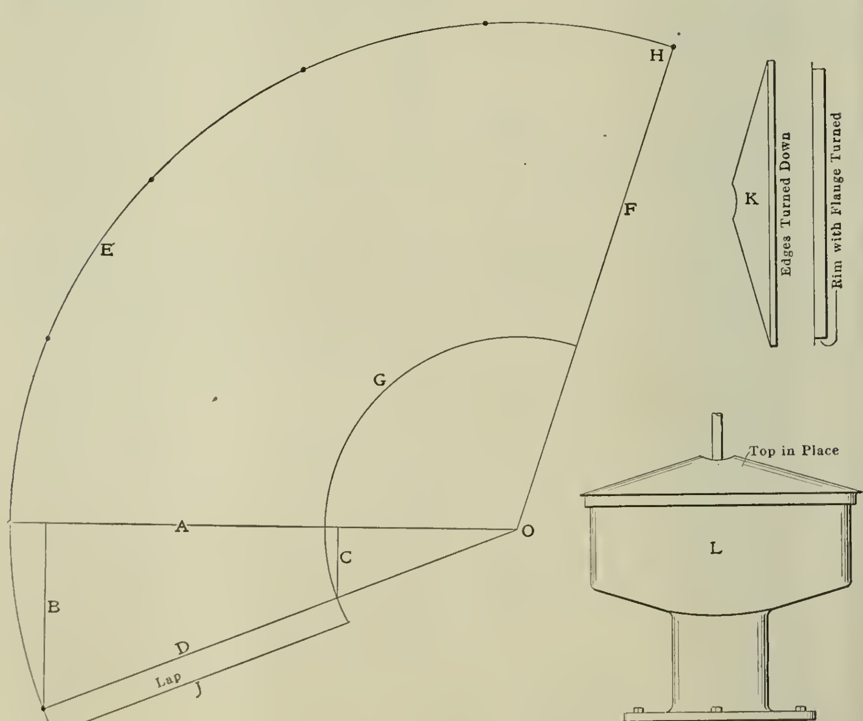
Making Dashpot Covers

The accompanying illustration shows how I made covers out of heavy tin for my dashpots, to keep out dust and dirt. The cover was made large enough to fit nicely over the top of the dashpot. The hole in the cover was made large enough to leave room around the rod so the air can pass out when the dashpot is on the upward stroke, without lifting the cover. An explanation of the method used in making the dashpot cover is as follows:

First draw the line *A*. Then draw the line *B*, equal to one-half of the diameter of the cover, and at right angles to *A*. Lay off the length or hight desired from *B* on *A*, and draw the line *C*, at right angles to *A*, equal to one-half the diameter of the top. Then draw the line *D*, from *B* to *C*, up to *A*, cutting it at *O*. Set the dividers equal to the line *D* from *O* to *B*, and placing the stationary leg at *O*, draw as much of the circle *E* as necessary. Then set the dividers equal to the distance between the lines *D* and *A* in the circle *E*, and space off six times this distance on the circle *E*, as shown. From the point *H* draw the line *F* to the point *O*.

Next set the dividers equal to the distance between the line *C* and the point *O* on *D*, and draw the circle *G* to the line *F*.



METHOD OF LAYING OUT AND CUTTING DASHPOT COVERS

If lap is desired to fasten the ends together, add this on by drawing the line *J*, parallel to line *D*, at a distance equal to the required lap. Then by cutting along the lines *F*, *E*, *H*, *D* and *G* the cover is ready to be put together. A rim is then soldered on as shown at *K*. At *L* is shown the cover as applied to the dashpot.

CHARLES H. SPARBER.

Fertile, Minn.

A Harmless Scare

That a good engineer may make mistakes is not to be disputed, and often these mistakes are amusing, rather than serious. A case in point occurred recently where a gas engine and producer had been installed in the basement of a department store in the heart of the business district of a Western city. One of the requisites of this installation was that there should be no noise from the exhaust of the engine, and to accomplish this end, a large tank, buried in the floor of the engine room, had been used for a muffler, and from this tank a 6-inch exhaust pipe extended up seven or eight stories to the roof of the building. The plan worked nicely, the exhaust was quiet, and for months the plant ran beautifully.

The engine was rated at 75 horsepower and was started with compressed air. One morning the engineer turned on the air as usual, the engine began turning over and drew a charge of mixture into the cylinder. The charge did not ignite, however, and the mixture was expelled nonignited into the exhaust muffler. This was repeated several times. The engineer was at a loss to understand why the engine did not start, and kept turning it by compressed air until it had made 20 or 30 revolutions, and the unexploded charges drawn through the engine and pumped into the exhaust system had become sufficient in volume to fill the exhaust tank and the entire pipe line to the roof. In the course of his hunt for the trouble, the engineer discovered that he had neglected to turn on the switch connecting the magneto with the igniter. This he promptly did, and the engine "picked up" all right on the next revolution.

The engineer, being in the engine room, felt no disturbance beyond a slight thud when the first charge of burnt gas was exhausted into the muffler. On the other hand, those on the outside of the building were treated to an explosion that sounded like the bombardment at Manila and which shook the entire section of the wholesale district, calling out both the police and fire departments. Patrol wagons rushed hither and thither, the police dreaming of anarchistic bombs and the fire department hunting for a bursted boiler with its attendant horrors. The location of the noise was traced to the block in which the engine was, and the police and firemen, searching the buildings, finally arrived in the engine room, where they found the engineer placidly going about his business. He insisted that there had been no explosion from his engine; he had heard nothing at all and there was nothing to credit up to him. Since then, however, he has been very careful to throw the switch before starting his engine, on the basis, to paraphrase the old saw, that an ounce of prevention is better than a visit from the police and fire departments.

Safety Valve Formulas

In the paper upon safety-valve capacity, contained in the March 9 number, I gave briefly the results of two extended series of tests, one upon safety valve lifts and the other upon the coefficient of steam discharge in safety valves. The omission of a complete table of the former results has led to a serious misconstruction of them in the editorial in the same issue, in which they are quoted. In an endeavor to correct this, the results are here given with a little more detail.

The lifts at popping point of the seven 4-inch stationary-type valves of different design set at 200 pounds were 0.064 inch, 0.031 inch, 0.056 inch, 0.04 inch, 0.024 inch, 0.082 inch and 0.137 inch. Of the six 3½-inch muffler locomotive valves, set also at 200 pounds, the lifts at the popping point were 0.072 inch, 0.040 inch, 0.076 inch, 0.065 inch, 0.051 inch and 0.140 inch.

Inspection of these figures indicates, as by far the most important conclusion, the fundamental necessity that an adequate formula for rating safety-valve capacities must include a specific term for the valve lift. A necessity which arises from the fact that the great variation of over 300 per cent. in the lifts of the same-sized valves for the same pressure makes the assuming of any single value for the lift, however carefully selected, an assumption liable to large error.

There are two hypotheses in the editorial. First, "that the lift * * * * is around 3/32 inch (0.094) for all valves in normal condition," and second, that "any maker will guarantee a valve of any size to lift 3/32 inch (0.094 inch) when the valve pops and to stand at that height as long as the pressure is maintained." Irrespective of what safety-valve makers may be able or care to guarantee, the error of these assumptions as applied to valves as they exist and are actually put upon boilers is very great, which is apparent not only from the tests cited, but from the figures given by manufacturers themselves.

The advocacy of "low" lifts and the generally admitted existence of so-called "high" lifts, brought out in the discussion at the A. S. M. E. meeting, indicate further that a uniformity of lift results for the same size of valve not only does not exist, but is not sought for nor desired by the different manufacturers of safety valves. In view of this lack of uniformity it would seem wise to leave the determination of valve-lift values to the manufacturers themselves as essentially their own proposition. On the other hand, the question of valve-capacity rating is of vital importance to and must be considered by users, insurers, designers and makers of steam boilers.

Obviously, in a formula as suggested in the editorial there can be no distinction corresponding to the great existing variation of valve lifts and under such a formula valves with 0.031-inch lift must receive the same rating and specifications as valves with 0.094- and 0.14-inch lifts. In assuming a given lift, as there done, not only are the valves whose lifts are less than the assumed value overrated, resulting in the liability of over-pressures, but using it with valves whose lifts are greater than that assumed a boiler would be over-safety-valved, which magnifies the strain on the boiler due to that cause, if such exists, as suggested at the A. S. M. E. meeting. And these errors, resulting from the use of a formula similar to that in the editorial, are not small enough to be negligible, for with the most carefully selected assumed average lift they amount to as much as 150 per cent. each way.

The only adequate method, therefore, is to require manufacturers to state definitely the lift of their valves, verify it upon them and then rate them accordingly, by the use of a capacity formula which includes a term for the lift. Adopting a rule as suggested in the editorial and having manufacturers to qualify under it with unknown lifts, which in cases are but one-third of that assumed, would mean a deliberate throwing away of the evidence of valve-lift research recently conducted by a number of independent parties, including the United States Government at Annapolis.

The inadequacy of such rules as that suggested in the editorial has already been recognized by the safety-valve committee of the American Railway Master Mechanics' Association, which in its report of May 18, 1908, cited a variation in the safety-valve lifts of nine different makes of valve of from [illegible] to [illegible] inch, and recommended a capacity rule (based upon heating surface) which includes a term for the effective area of valve opening, obtainable only by determining the valve lift.

And last, the added complexity of the rule as given in the editorial over that containing a term for the valve lift is very slight, especially if the constant recommended in the latter is changed [illegible] per cent. to the [illegible] formula given:

$$D = [illegible]$$

whereas that of the editorial is

$$D = [illegible]$$

New York City.

Gas Power Blowing Equipment at Gary, Ind.

Essential Mechanical and Operative Features of the Indiana Steel Company's New Gas Engine Installation for Blowing Furnaces

The almost exclusive adoption of gas engines at Gary for blowing the furnaces, as well as for electric service throughout the mills, represents the first decisive step in American steel manufacture toward full recognition of the development in gas-power equipment which has been going on for the last ten years. Outside of German practice, which has been so conspicuously successful, the only forerunners of this great undertaking in America are the gas-power plant of the Lackawanna Steel Company, at Buffalo, and the more or less experimental application by the United States Steel Corporation in the vicinities of Pittsburg and Chicago. It is not to be expected that so important a property as the Gary works would permit of the least uncertainty in the matter of gas-power application if such uncertainty existed, and it is, therefore, fair to assume that the experience of the United States Steel Corporation has been signally successful.

No. 3 Gas Blowing House

In a detailed study of so large a property, the subdivision of the work into the most important groups becomes imperative, and following the general order in which the Gary property has been completed, the No. 3 gas blowing house calls for first consideration. The first of the three gas-power houses to be placed in commission is typical of the general construction employed in the No. 1 and No. 2 blowing houses which are to follow. The systems of blast control, air starting, ignition, water supply, lubrication and organization of operatives are the same as contemplated for the other plants.

This No. 3 blowing house is located at the extreme northern end of the power property, next to the lake front, and is shown in the general photograph, Fig. 1, which embraces all those parts of the furnaces and contiguous buildings which have been put into operation. This view includes, at the extreme left, Nos. 11 and 12 furnaces, which are in operation, preliminary washers and the No. 3 blowing house in the foreground. At the extreme right is shown the storage-battery building and the north end of the electric-power house, which will next be put into commission and the general features of which have been described in previous articles. The third group of furnaces, Nos. 9 to 12, and the first to be put in operation, served by the No. 3 blowing house, will be duplicated in the first, second and fourth groups now under erection, Nos. 5 to 8 to be served by No. 2 blowing house and Nos. 1 to 4 by No. 1 blowing house, these being provided for at the southern end of the property. Thus there will be virtually three independent groups of furnaces, of which the northern is in every sense typical. These groups will only be connected by means of a 5-foot gas main extending between the various blower houses and operating somewhat as an emergency tie line. The air-blast lines for each group are, however, not interconnected, as in the case of the gas supply. Practically every operating function of these groups is, therefore, independently complete with the exception of the low-service water supply and the air-compressing plant by means of which the gas engines are started, this being located at a central point in the electric station, as later noted.

FIG. 1. GENERAL VIEW NORTH END OF GARY WORKS, NOS. 11 AND 12 FURNACES, WITH NO. 3 BLOWING HOUSE

The general assembly drawing, Fig. 6, shows in plan and elevation one of the eight gas blowing units, together with air blast, water, gas, air, exhaust and compressed-air mains. Each of these will be referred to in detail later. Figs. 3, 4 and 5 show general views from both gas and air ends of the end units. The building is laid out with 26 bays, 23 feet wide, aggregating about 600 feet in length and 104 feet in width. All the units are spaced 46 feet between centers, including two steam blowers.

It is to be expected that in so large an undertaking some steam reserve would be installed, which is the case, and, moreover, steam is a necessity for starting the furnaces. For each group of furnaces there is a plant of 16 water-tube boilers which supplies steam to a pair of steam blowing engines in No. 3 blowing house; a pair of 2000-kilowatt steam turbines in the electric house; a steam-turbine-driven pump in the pump house; fire pumps; hydraulic pumps and steam for miscellaneous purposes around the plant, such as steam coils for oil-settling tanks and for preventing the holder, preliminary washers and gas valves in the various distributing lines from freezing during cold weather. This boiler house is fitted for burning blast-furnace gas. This same steam reserve will be provided in each of the blowing houses to be built, as well as the electric houses, so that nothing short of a general disablement will cause the ever-dreaded stoppage of blast at the furnace tuyeres.

The blowing house contains eight gas blowing units aggregating in capacity 265,000 cubic feet of free air per minute, and in addition, two 45,000-cubic foot steam units. The layout contemplates that for each pair of furnaces three gas units will be required with a spare, the steam unit being held entirely in reserve. These 450-ton furnaces each require 44,000 cubic feet of blast per minute. As each blowing unit supplies 33,000 cubic feet of free air per minute the proportion of capacity will be evident. For the returning gas a cleaning plant capable of handling nearly 176,000 cubic feet per minute is required. The gas for the hot-blast and steam-boiler plant is only partially cleaned in the dust catchers and preliminary washers, which remove the greater part of the heavier foreign matter.

It is estimated that about 30 per cent of the blast-furnace gas produced is required in the stoves, leaving 70 per cent available for outside purposes, or deducting 10 per cent for boilers and loss in washing, somewhat over 60 per cent for gas power. Consequently the secondary cleaning plant of tower and Theisen washers needs to take care of only about 105,000 cubic feet per minute. This corresponds to the capacity of seven tower and Theisen washers, leaving one unit of each in reserve. This amount of purified gas, which now averages about 95 B.t.u. per cubic foot and will approximate 90 B.t.u. after the furnace burdens have assumed their normal condition, will develop 66,000

plant as a whole. The general disposition of parts is clearly shown in Figs. 4 and 5, Fig. 4 being taken from the power end of the near engine and Fig. 5 showing more clearly the Slick rib and driving gear. These large units are set down to the floor level with openings 17 feet wide between supporting piers to provide access to the exhaust valves. This works out quite favorably, giving a depressed floor between the two sides, 5 feet below the main floor, with galleries running along the cylinders at the floor level, as shown in Fig. 7. This avoids entirely the bad feature of an exhaust-valve pit, which was encountered in early attempts to locate the engine at the floor level. Underneath this depressed floor, which is of steel plate, run the exhaust-pipe lines.

the inlet and the exhaust valves at each end are driven from a single eccentric, as usual with the large Westinghouse double-acting engines. This gear permits setting the valves so that the exhaust and inlet periods overlap, which makes possible a more perfect cylinder filling than would otherwise be possible and also a certain amount of scavenging due to the inertia of the incoming and outgoing columns of gases.

The piston rods are interchangeable, end for end, so that in case of necessity they may be transferred from one cylinder to another. The pistons are secured in place by external nuts forced up and turned off flush with the piston face. The piston itself is cast in a single piece, symmetrical in section about both axes and without

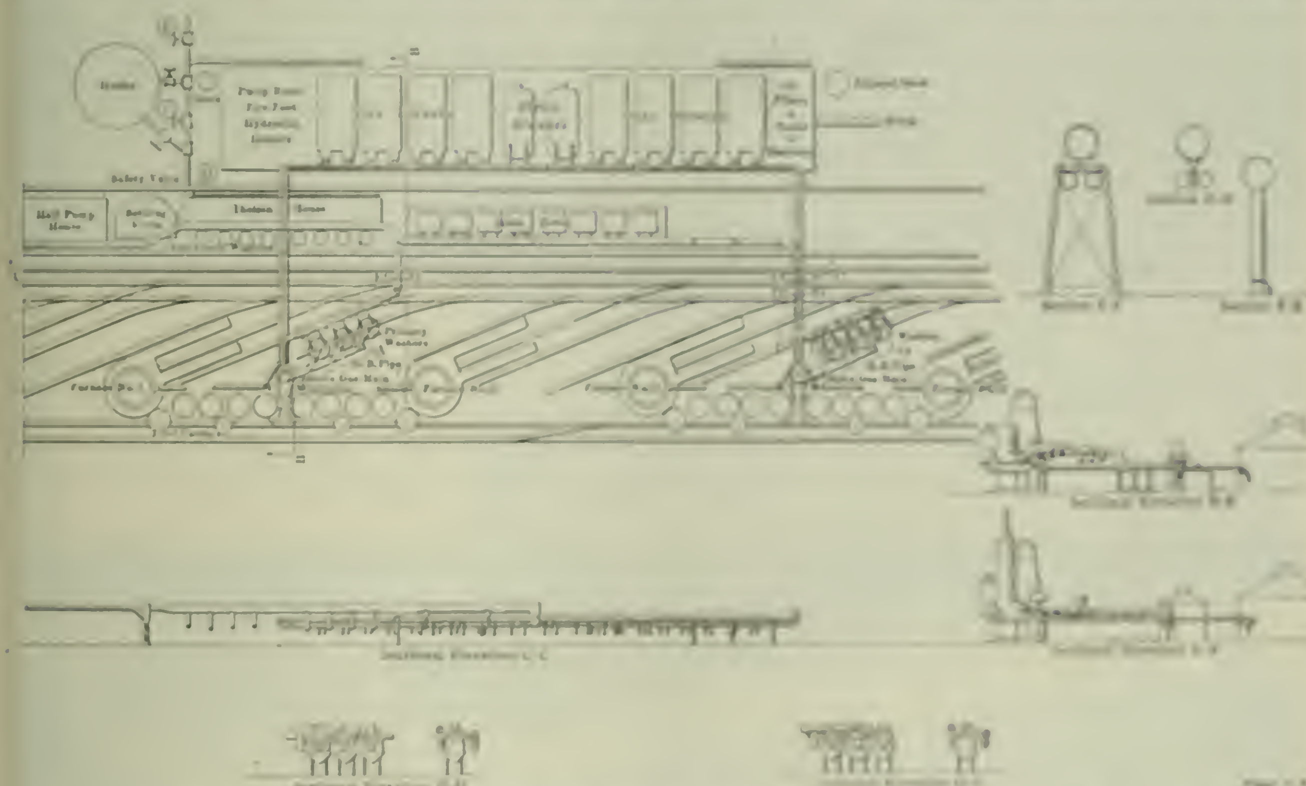

FIG. 2. GENERAL VIEW OF SOUTH GROUP OF FURNACES, SHOWING ARRANGEMENT OF WASHING PLANT, BLOWING HOUSE, PUMP HOUSE, ETC.

indicated horsepower in gas-engine cylinders well loaded, which is more than sufficient to operate the blowing house and half of the electric house. The tower washers are a modification of the Zschocke type.

The Blowing Unit

As the details of construction of the Westinghouse horizontal double-acting gas engine have been described in previous articles*, it is only necessary to review here certain of the essential features which have the most important bearing on the successful operation of the

The engine itself is in all respects identical with the builder's standard design for a 3000-kilowatt electric unit. It works on the four-stroke cycle and is double-acting, with a compression pressure of 200 pounds at full load. No attempt at special methods of scavenging or constant compression has been made, although the valve design permits of this to a certain degree, if desired. The lay shaft is located on the outside, supported on pedestal bearings independent of the engine. This arrangement avoids the use of spiral-gear drive for the lay shaft, which is driven by spur and bevel gears, each provided with a floating collar to equalize the wear and practically eliminate back lash. It will be noted that both

headers, plugs, or cored ribs. Fig. 9 shows this construction. The liner is supported from inside the opening, as shown. This construction places the inner wall or hub of the piston under direct compression, relieving the bolting strains in the rod considerably. These rods are not corrugated or otherwise compensated for deflection, which is hardly desirable, and just sufficient to keep the packing rings free. All rod packings are of the standard metallic-ring type, are water cooled, but lubricated by the force-feed system.

The air and gas pipes are entirely separate from the cylinder body (see Fig. 8), approaching the valve chambers at the top from opposite sides so that the mixing of gas and air is not perfect until the

*POWER AND THE ENGINEER for April 28 and December 8, 1908.

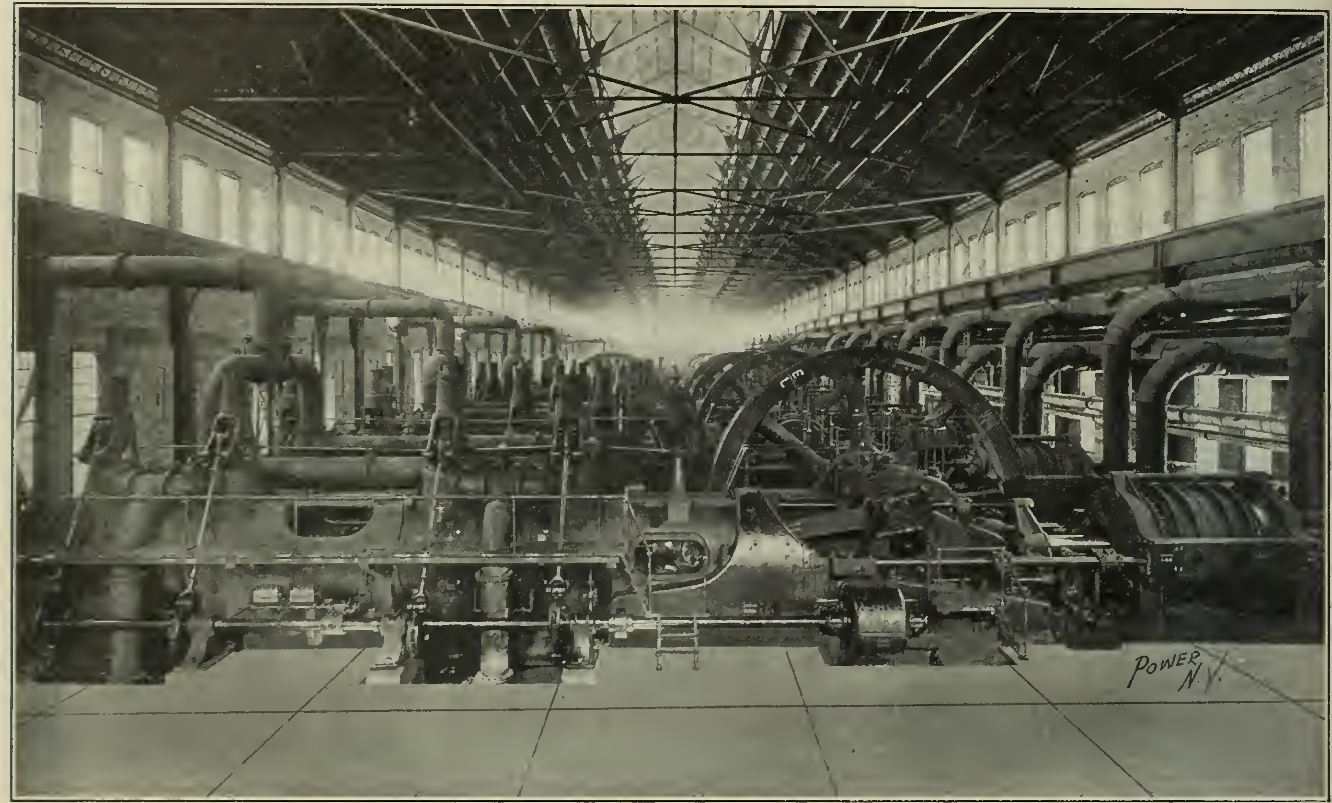

FIG. 3. GENERAL VIEW OF INTERIOR OF NO. 3 BLOWING HOUSE FROM SOUTH END

inlet valve is reached. Although Fig. 8 shows solid cylinder and jacket walls, they are cut apart at all openings and bushed.

Cooling System

Fully one-third of the cylinder jacket consists of a removable band around the center of the cylinder, so that easy access can be had to the remotest jacket spaces. The advantage of this feature has been demonstrated by previous experience of the builders with the clogging of cylinder jackets by deposits from muddy cooling water. A mud ring is provided at the bottom of each cylinder exhaust jacket which may be quickly slipped off without disturbing the exhaust-valve cage, thus opening the entire jacket space for clean-

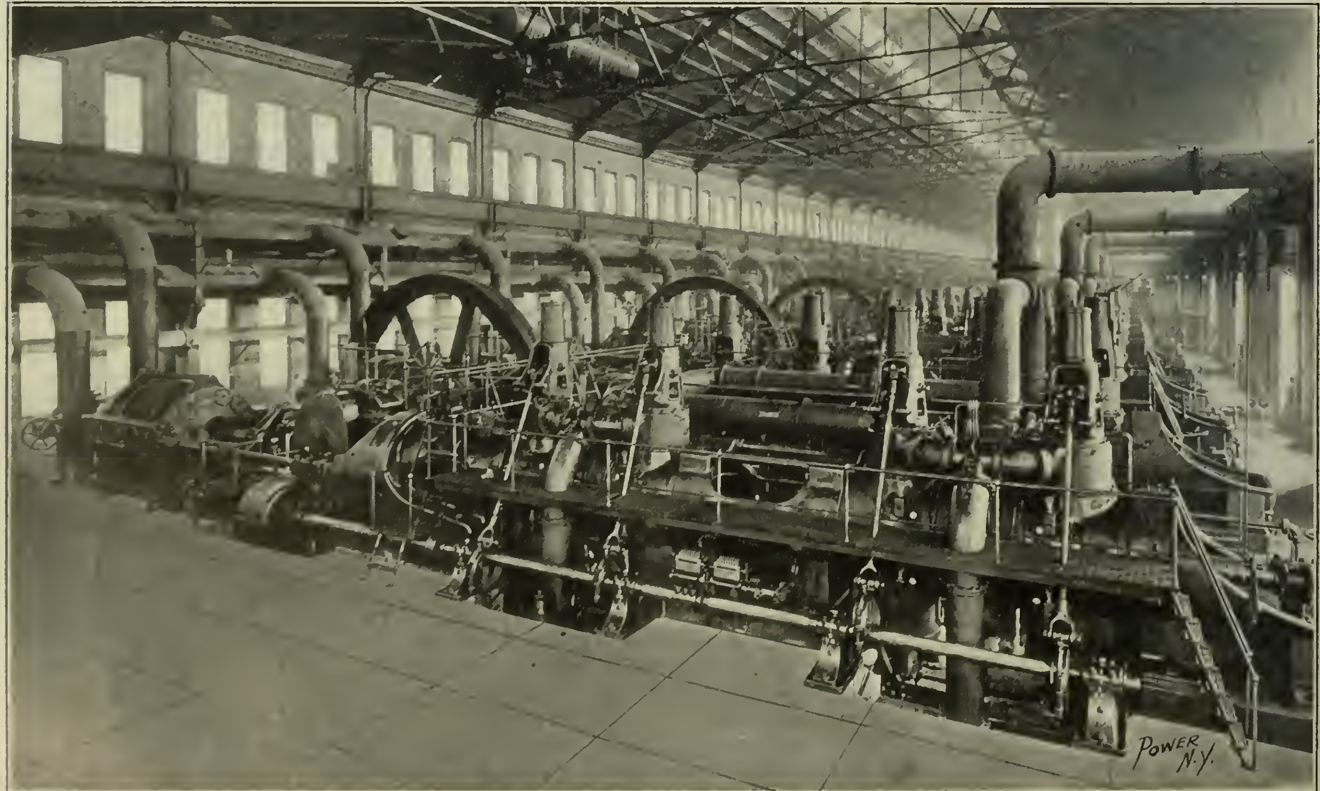

FIG. 4. GENERAL VIEW OF UNITS FROM POWER END

ing with a hose. Cooling water is provided at a pressure of about 35 pounds for all the parts from a 16-inch main running the length of the building. A single valve controls the supply to each side of the engine and plug valves in each water circuit are provided so that the rate of flow, once set, need not be changed. These separate circuits serve all the important parts, each having a visible overflow so that the quantity and temperature of the jacket water in any circuit can be determined at any time. Each exhaust-valve circuit has a separate overflow. Being insignificant in amount, the water is wasted, but other circuits are arranged in series as far as possible. Cylinder-jacket water enters first through the exhaust-cover chambers, escaping into the cylinder at the bottom, just under the exhaust port—the hottest part—ascending around the cylinder jacket to the top, where it overflows, always keeping the jacket full. To economize water farther, the pistons and heads are supplied in series on the countercurrent principle. After passing the front and rear heads of the forward cylinder in series, the warm water enters the piston rod at the middle crosshead, thence through the piston and out at the front end. In all cases, water enters at the bottom and overflows at the top of the chamber to be cooled so as to keep the parts full. This series system provides a fairly even temperature at all four packing glands, which would be impossible if both pistons were in series—one hot and the other cold. Telescopic supply pipes are used at the intake ends of the piston rods instead of knuckle joints.

Exhaust Pipes

The four individual exhaust connections for each cylinder enter a 30-inch exhaust manifold (one for each side) which communicates with an 8x10-foot brick tunnel running the full length of the building and discharging into a 100-foot stack at each end. This tunnel has an arched brick roof, but is not otherwise protected against the possibility of [illegible] explosions. All waste discharge water from the engine jackets drains into the exhaust tunnel (see Fig. 6) and serves to cool the exhaust gases and thereby to reduce their volume and consequently the back pressure on the engine. It will be noted from Fig. 6 that deflecting [illegible] are provided at each entrance to the manifold, which gives the exhaust gases a definite direction and thereby reduces the resistance of exit. Means for sealing each of these manifolds while men are working on the engines is provided in the form of a dip at *D* which may be filled with water and thus operate as a [illegible] seal. A drain valve controls this and also a seal for the jacket overflow. During cold weather the engine exhausts [illegible] run dry in order to utilize the heat for warming the building.

Gas Supply

Along the west wall of the building a 7½-foot steel gas main rests on structural wall brackets and communicates to each blowing unit through a 24-inch supply pipe equipped with a gate valve and a pressure-regulating butterfly valve, as shown in Figs. 4 and 6. The latter is required to reduce the pressure of the gas delivered to the engine exactly to atmospheric so that air and gas may be drawn into the engine at the same pressure and thus have the same proportion as determined by the respective inlet-valve settings. The butterfly valve is operated automatically by a small gasometer shown at the rear of the engine and in Fig. 10, which communicates with the supply pipe on the engine side of the butterfly valve. Similar butterfly valves located at the entrance of each inlet valve enable the operator to adjust the proportion of gas and air to any desired value to suit the quality of the gas.

Air Intake

An especially neat feature is the method [illegible]

[illegible]

Compressed-air System

[illegible]

FIG. 5. [illegible]

[illegible]

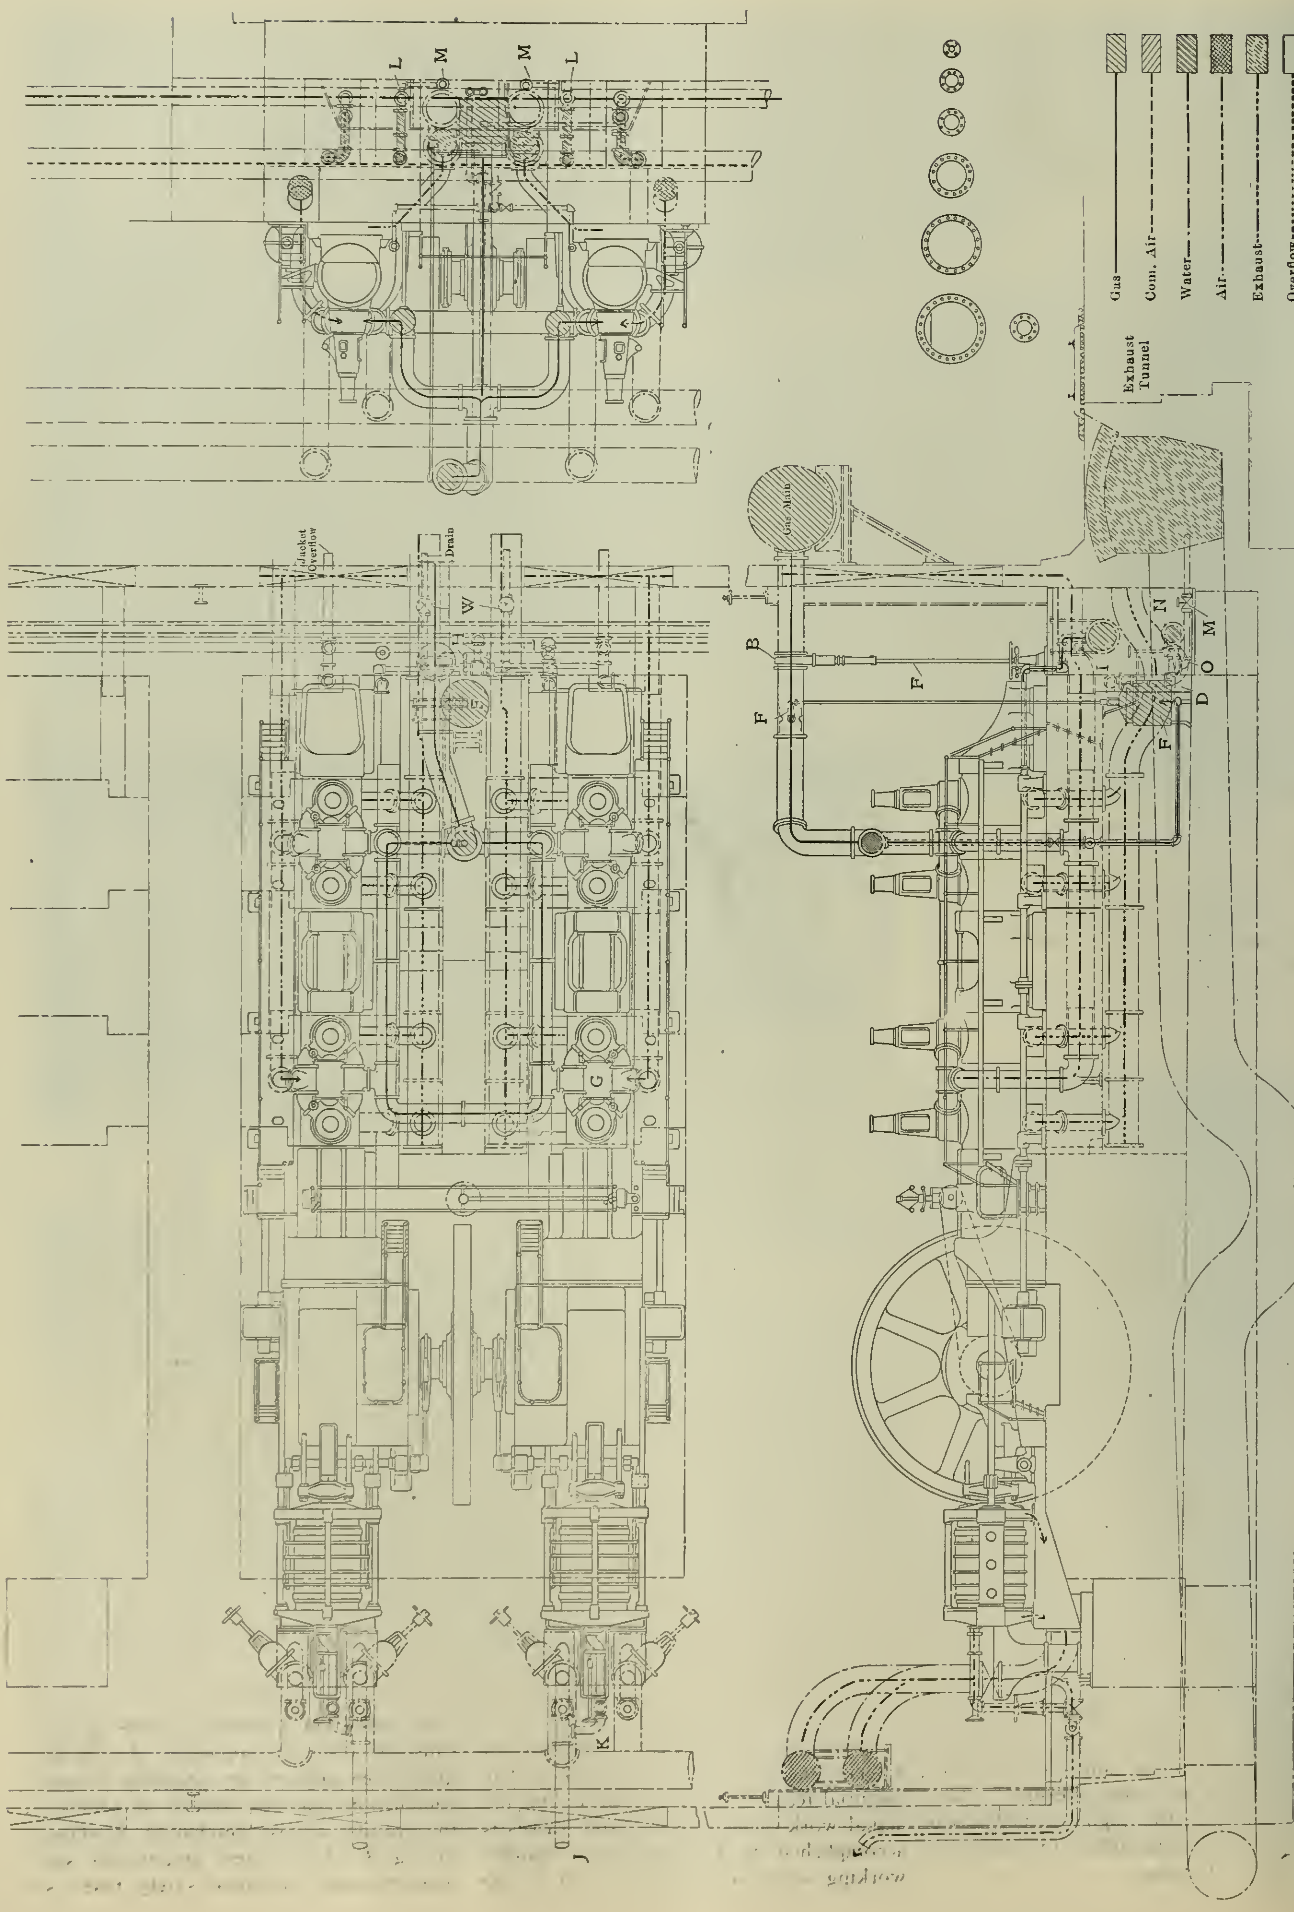

FIG. 6. GENERAL PLAN AND ELEVATION OF COMPLETE BLOWING UNIT

that a short-circuit of any one will not affect the others.

Both electrodes are insulated from the cylinder body so that a double ground is necessary to complete a short-circuit of an igniter. Grounding, however, usually occurs from sweating inside. Consequently, vents to the atmosphere are provided (see Fig. 12).

The make-and-break system is used exclusively on these engines. Although the igniter is standard with either mechanical or magnetic trip gear, the Gary engines are entirely equipped with the latter in for the field magnets of small bipolar dynamos and motors of rectangular outline. Being in series with the igniter, the magnet winding serves for the spark coil.

Ordinarily, the igniters receive current at about 110 volts from a small motor-generator set supplying each of the engine panel boards. The motor-generator is driven from the alternating-current bus-bars of the electric-power station. It is, of course, highly probable that this distant source of supply will sometimes be cut off by accident. In anticipation of such an accident connections have been equipment. Whereas in the early days it was one of the most uncertain.

LUBRICATION

Both the cylinder and the engine oils are handled by automatic systems, grease cups being used only on small, slow-moving parts, such as links, valve-gear cams, etc. In the design of the oiling system, provision has been made for the strictest economy in oil consumption and reliable feeding. For this purpose, the continuous-return system is used with set-

FIG. 7. VIEW BETWEEN ENGINE CYLINDERS

order to avoid the excessive complications arising in the provision of three sets of igniters mechanically driven. The usual rotary timer, driven from the engine lay shaft, is used. It is thoroughly protected by an iron casing and runs in oil. By rotating the casing through a few degrees, as indicated by a graduated scale, the ignition may be advanced or retarded while the engine is in operation. The magnetic trip, which has recently been perfected, is shown in Fig. 12 in contact with the igniter stem. The electromagnet inside is of the so-called iron-clad type used provided with the storage-battery house nearby, and automatic apparatus is being constructed which will instantly throw the engine ignition circuits over to the storage batteries in case of trouble with the regular supply. And as the north and the south sections of the blowing house will be separate in this respect, the possibility of a complete shutdown is [illegible] remote. With all igniter wiring run in a protected conduit and thoroughly insulated with suitable [illegible] and [illegible], the ignition system becomes one of the most reliable parts of the engine tling [illegible] filters and pumps in series. The system [illegible] is equipped with a [illegible]-gallon storage tank, resting upon the lower chords of the roof trusses, as shown in Fig. 4. From this point oil is distributed by gravity to the different parts on each blowing engine at a positive static head of about 15 feet. A simple valve controls the supply to each side of each unit and the various bearings are served by four groups of sight-feed lubricators. When these are once adjusted for the proper rate of flow, they need not be changed, so that the work required of maintain proper lubrication on these large engines is very small.

All the engine oil is returned to a common header leading to the basement filter plant, first reaching a group of three settling tanks 15x3¼x4 feet deep, where it is heated by steam coils and the sludge allowed to separate out (this sludge is caught and used in other machinery around the works). Next, a pair of vertical separating tanks removes the last traces of water. Finally the oil passes to a pair of special filters, from which it is pumped through a meter back to the roof tank. The fresh make-up oil is drawn from a 25,000-gallon tank which is large enough to take the entire contents of a railroad tank car (run in on the siding). As a precaution, a second 25,000-gallon tank is provided for overflow or storage.

Cylinder lubrication is taken care of by automatic force-feed pumps driven from the engine lay shaft and embodying the special feature that the eight individual circuits leading to various parts of each engine cylinder (including rod packings and exhaust-valve stems) are accurately timed so that oil is delivered into the cylinder only just before the end of the exhaust stroke. This allows two complete strokes of the piston before combustion takes place, during which the oil is effectively spread over the surface of the cylinder. The result of this system is that oil is injected only in small quantities and at the most effective moment. The cylinder-oil circuits run about 12½ drops per minute on the large engines, at full speed; the packings take somewhat more and the exhaust-valve stems about half that rate. It is contemplated in the completed plant to serve all of these cylinder-oil lubricators (32 in number) from a central point, putting a small meter in each feeder line to determine the rate of oil consumption. The oils used at present are "Red Engine" oil and "Diamond A" cylinder oil, both mineral oils.

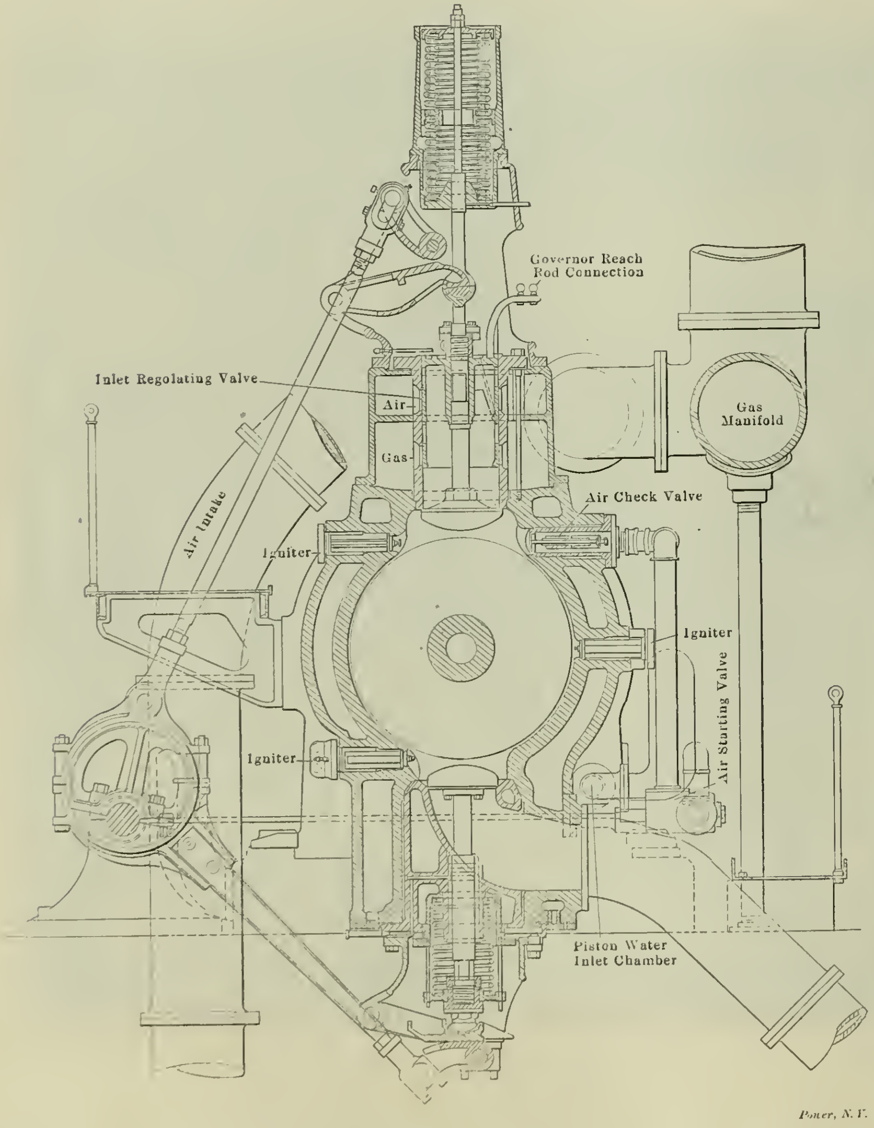

FIG. 8. DETAIL CROSS-SECTION OF GAS ENGINE THROUGH VALVE CENTERS

Gas Cleaning

This plant differs from those in the Pittsburg district in that the closed-top type of furnace is employed, that is, with no explosion door. All of the large piping is designed to withstand the maximum pressure which has been found to be produced by the explosion of a perfect mixture of blast gas and air uncompressed. Relief vents are, however, provided at several points in the open water seals of the primary, secondary and Theisen washers, so that an explosion in the furnace not damped out in passing through the tortuous passages of hot-blast stoves and piping would be relieved at one of the above-mentioned vents.

FIG. 9. 42-INCH ONE-PIECE GAS-ENGINE PISTON

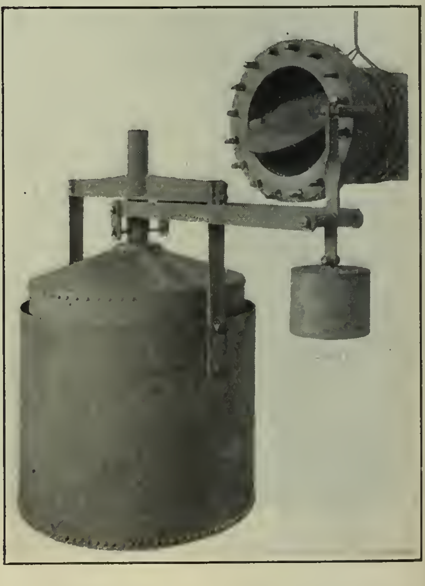

FIG. 10. GASOMETER PRESSURE REGULATOR SHOWING METHOD OF OPERATING BUTTERFLY IN GAS INLET

The dust catchers are of standard construction, but the primary washers are an improved type of Mullin washer, consisting of a central conical distributor suspended about 1 inch above the surface of the water, which is maintained at a constant level by an open overflow. The edges of this cone are deeply fluted, resembling in plan the shape of a starfish, so that a relatively great surface is presented to the gas, which is forced to spread out in a thin sheet over the surface of the water. Here the greater part of the suspended dust is deposited and drawn off below. In the tower static washers the gas is forced to ascend through a latticework continuously wetted with Korting sprays. It is also passed through several sheets of falling water obtained by conical baffles arranged in series at the base of the washer, replacing the individual baffle washers usually provided. In the Theisen washer house, final cleaning is accomplished, and the gas delivered to the mains with only 0.02 of a grain of foreign matter per cubic foot of gas. This is ample for gas-engine work, and actually exceeds the purity of the air at times at the engine intakes in the Pittsburg district. A similar cleaning plant at the Bessemer works has shown gas as clean as [illegible] grain at times, averaging [illegible] grain, while a slip in the furnace increases this considerably.

All of the overflows from the water seals of the primary tower and Theisen washers are returned to settling basins 20x40 and 12 feet deep, arranged so that the heavier material has an opportunity to settle out and may be reclaimed. A central division wall divides each basin into two compartments, one of which may be in use while the other is being cleaned.

As the Theisen washers normally deliver gas at 5 to 7 inches pressure, it is evident that if a break should occur in the supply main or its own water seal there would be danger of air being pumped into the holder, resulting in an explosive mixture. To prevent this, a large butterfly valve is installed between the Theisen washer house and the holder, which may be closed in such an event while the holder would then receive gas through the main from the blower house below.

In case the holder should leak or otherwise be out of order, large gate valves geared down for hand operation are installed in both the inlet and the outlet risers with a third valve in a bypass between so that the holder may be entirely cut out of service, the gas system then relying on the holder below, at No. 2 blowing house. Another butterfly valve in the holder intake line is arranged to close automatically when the holder has reached its upper limit.

Operating Force

Much of the ultimate success of the Gary installation depends directly upon the efficiency of the operating force. Although as many of the more perfunctory operations have been taken out of the hands of the operators by the use of automatic appliances, yet a high order of intelligence is required in the few men [illegible] contact with the care of the plant. These men must use their heads more than their hands. It may be supposed that so large a plant would require an army of men to operate it, but such is not the case. In normal operation, the No. 2 blowing house will be in charge of a chief engineer for

FIG. 11. DETAILS OF AIR-INTAKE [illegible]

each operating watch. Each engine crew will consist of an engineman and two oilers, the oilers will handle the blast valves during furnace operation, and the water, gas, oil and air valves when starting up, with the engine driver in direct charge at the throttle. This makes a

FIG. 12. [illegible] AND MAGNETO [illegible] OF ENGINE

[illegible] crew of [illegible] to tend the [illegible] 25,000 horsepower of gas engines. Considering that much of the [illegible] work occurs in operating the valves of the blowers, the amount of labor required for these engines is small, and in the case of the [illegible] power house even this would be reduced.

New York Civil Service Examinations

The New York State Civil Service Commission announces the following examinations to be held on March [illegible]

Assistant [illegible] engineer, State and county hospitals and institutions; [illegible] and maintenance when employed in institutions. Candidates must have had two years' practical experience as [illegible], boilermaker, [illegible], fireman, engineer or electrician, including at least one year in the operation of stationary engines or electrical machinery. Subjects of examination and relative weights: Practical questions on the operation and repair of steam engines, boilers, steam-heating apparatus and electrical machinery, [illegible]; experience and personal qualifications, [illegible].

Chief engineer, [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]. Subjects of examination and relative weights: [illegible] [illegible] [illegible] [illegible] [illegible].

The commission recently [illegible] a new form of application for competitive examinations, and candidates are advised not to use blanks of issues printed before [illegible]. The new blanks may be obtained by addressing the Commission at Albany, N. Y.

Safety Valves

Continuation of the Discussion of the Subject before the American Society of Mechanical Engineers at Its February Meeting

Albert C. Ashton,

of the Ashton Valve Company, said that in his opinion what is most needed today is not necessarily a safety valve of greater capacity, but rather a better understanding of the proper proportioning of safety valves to boilers, for which there is no rule universally recognized and adopted. Mr. Whyte's paper touches upon this point and cites some recent tests made to determine the comparative capacities of pop safety valves on the market. While these tests show what the so-called new style high-lift valves will accomplish under certain favorable conditions, they do not prove that high-lift valves so made are a success in all applications. High lift is conducive to pounding upon the seat and to the lifting of water, and Mr. Ashton cited instances which had come to his knowledge where the use of valves having abnormally high lifts had been disastrous.

If high-lift valves were for a certainty an improvement, safety-valve manufacturers generally would change their designs, as can be easily done, and make nothing but high-lift valves. There may be some virtue in making valves with a lift a little higher than, say, 1/16 of an inch. but to make them with a lift of ⅛ of an inch, as appeared to be the trend of Mr. Darling's paper and of Mr. Lovekin's remarks, the speaker considered to be excessive and not advisable for general application.

Such being the situation, it was of little value, in his mind, to discuss the question of the capacities of safety valves, for whatever valve is desired the manufacturers can produce; but the speaker did hope that the society would interest itself in the question, which is of interest to the engineering profession, as to what is the best and most practicable schedule or formula that can be safely adopted for general use in determining the capacity of relief that safety valves should give on various-sized boilers at various pressures.

A. B. Carhart,

superintendent of the Crosby Steam Gage and Valve Company, devoted his remarks largely to springs. A safety valve should be designed by calculating the total spring load required to be exerted upon the disk when the valve is closed, then the suitable amount of further compression needed for vertical lift of the disk when the valve opens, with a reasonable allowance for a reserve of further possible free movement of the spring in compression, and thereupon determining the dimensions of the spring that will carry this load at its point of greatest efficiency, with due regard for flexibility, sensitiveness with accurate adjustment, and durability in service.

Within the limits of elasticity the deformation or deflection or compression is proportional to the force or pressure which produces it, and in a spring of given dimensions equal increments of force or pressure applied will produce equal amounts of compression. For example, if it requires a total load of 2000 pounds to compress a given spring having a total possible compression of one inch so that its coils are solid, with no farther deflection possible, a load of 1000 pounds would cause this spring to shorten one-half of that amount, or one-half inch, and each 100 pounds of load more or less would cause a shortening or lengthening of one-twentieth or 0.05 of an inch.

The compression of a spring at a given load is proportional to the number of coils, and the simplest way to increase the total compression or movement is to lengthen the spring. This increase of compression in proportion to the increasing number of its coils is independent of the total load which the spring will carry, and does not affect that question. If a load of 1000 pounds will compress a spring of certain diameter dimensions one-half of its total possible compression, or one-half inch, then a spring of the same diameter but twice as long and having double the number of coils would be compressed by the same load one-half of its total movement, or one inch. A load of 1500 pounds would compress either spring three-fourths of its total possible movement and likewise either spring would be compressed solid under a load of 2000 pounds. But the action of the two springs in safety-valve service would be very different, for the longer spring would have its power exerted through a greater distance.

The total amount of compression of a spring for a given load may be increased by increasing the number of coils of the same diameters and pitch and thus increasing the total free length; by reducing the cross-sectional area of the rod; or by enlarging the overall diameter; or all or any of these dimensions at the same time. If the spring be excessively long in proportion to its diameter and pitch it may bend or buckle instead of compressing in a straight thrust, and if the number of coils be too great the reaction of the spring sets up an oscillation, which not only permits but aggravates the undesirable and destructive chattering of the valve. If the spring be too short, not only is the reaction too sudden but the active free coils form a smaller proportion of the total length. It is not possible to distribute pressure at the ends of the spring exactly even upon the coils, and the spring compression is greater on one side than on the other, transmitting an undesirable side thrust to the disk guides. If the pitch is too steep the fiber stress upon the steel is enormously increased, and the rod is fractured or a permanent set takes place. If too many coils are put into a fixed length of spring there will not be sufficient free space between the coils to permit the necessary movement, and when the pitch is thus too flat the spring will have insufficient reactive power or force because of the inadequate strain or fiber stress put upon the steel. The spring must have sufficient force to make the valve open and close promptly and positively and keep the seat tight, not only to give prompt relief but to prevent the constant simmering and leaking which cuts and destroys the seats and permits the deposits of lime solids upon any exposed threads. The requirements of positive control and extreme lift are thus to a large degree contradictory.

Under no conceivable conditions of actual service can sufficient steam pressure be brought upon the disk of a pop safety valve to compress the spring so that the coils would be solid, if it has been in any way reasonably designed for its original fixed load; and the additional spring compression due to the lift of the disk to produce the valve opening to relieve the boiler is comparatively little, possibly 0.08 of an inch, or commonly and preferably less, and never under any conditions to amount to 0.18 of an inch or, say, 3/16 of an inch in the extreme.

If after the fixed-load pressure is reached the spring has still 15/32 of an inch of unused possible compression, of which less than 3/32 of an inch will be required to accommodate the desired lift of the valve, there will still be 12/32 or ⅜ of an inch before the spring will go solid; therefore, the valve spring can be properly designed to carry its set load at much more than half of its total free compression and more nearly to its solid condition than would be wise with a car spring. I believe it to be proper to proportion the spring so that the set load is carried somewhere near two-thirds or three-fourths of its total free compression, proportioning the length and dimensions of the spring so that the total free movement will be sufficient to make the remaining unused compression of the spring ample for the lift of the disk, and a safe margin beyond.

As in making boiler tests the head bolt may be set down until the spring is solid, and if the valve is fitted with a lever the spring may at times be compressed solid by that means, I would not consider it proper to use in a valve with a lever, any spring that would not safely take a solid test without showing any permanent set or strain.

As to the fiber stress, experience shows that springs may best be stressed from 60,000 to 75,000 pounds per square inch at the fixed load which should compress the spring to about 70 per cent. of its total possible free movement. The remaining movement should be three or four times the lift of the valve in opening. Springs wound of bronze are notoriously inefficient and unenduring, and their depreciation and permanent set at comparatively low fiber stress more than counterbalances any possible advantage of slow corrosion. The torsional elasticity and power depend not upon the tensile strength as much as upon the temper and resiliency. Therefore, some of the new alloy steels have proved disappointing for this service.

The spring must have sufficient compression to afford the amount of valve opening fixed upon as reasonable and practicable, yet be kept within the least amount of movement that will satisfy these demands, for every spring has considerable eccentricity, depending upon the pitch and proportion of the coils; and, under the increasing compression or extension as the valve opens or closes, the ends have a movement which may be likened in some degree to the actions of the free end of a fire hose under pressure. The side thrust due to this twisting and untwisting eccentricity is transmitted to the valve disk and increases rapidly with each fraction of increased lift or opening of the valve.

Large movement of the spring in compression is undesirable. It is but a necessary means to an end; an evil to be kept within minimum limits. It would be an advantage if a satisfactory discharge area of the valve could be attained with even less spring compression than at present. The large lift of the disk is not a measure of capacity, but of inefficiency, for that valve which releases the steam with the least proportional lift or spring compression is to that degree the more efficient for its purpose, and at the same time more safe and reliable. The greatest cause of the sticking of the valve, when it does occur, is not corrosion of the seat face, but the binding friction of the disk guide against the sides of the well or throat of the valve. This cocking or binding effect can be decreased by any modification of design which will reduce the diameter of the cylindrical guide, or which will bring the guiding surface close to the plane of the seat, both of which would reduce the moment of the friction or cocking stress. Any device which reduces the lift of the disk and the spring movement to the least possible amount will also reduce the eccentric spring action and its effect, and, of course, any valve design which requires or contemplates an unnecessarily large lift or compression disadvantageously magnifies this effect.

In the well known annular type of valve the area of the disk open to the constant pressure of the steam is approximately only four-fifths of the total initial area of the disk under load in the bevel-seated form of valve having the same diameter and seat circumference. Therefore, the use of the familiar annular flat-seated valve is the logical way to reduce to a minimum all the difficulties of spring seating, especially where the space available for the spring is absolutely limited by the overall dimensions permitted by locomotive builders and boilermakers; for the spring need thus be of diameter and strength to carry only four-fifths of the load necessary in the lip type of valve, the vertical lift and spring compression require to be only 0.7 as much, or for the same lift will give one and a half times as much discharge area.

No preliminary lift is required to relieve the overlap of an adjusting ring, for the work of giving to the disk its sudden pop lift is performed by an auxiliary steam discharge bypassed through the central passages. This bypassed or auxiliary discharge adds its volume to the main discharge capacity and leaves an absolutely unrestricted and unthrottled free escape for the main flow of the released steam directly to the open air without any tortuous expansion chamber or deflecting ring. The outlet is across a flat seat which not only utilizes the full vertical lift, but gives a discharge opening of cylindrical form with efficient rounded edges, and has the further advantage of being impossible to jam or stick, and is easily refaced by rubbing on a face plate instead of grinding to a bevel; and as the disk can be made entirely without the ever cocking and sticking guides, the efficiency of the spring can be thus aided and utilized to the greatest possible degree.

Nearly every engineer of education and experience would be qualified and ready to suggest at least one apparently simple and more or less obvious improvement in the design of safety valves or springs, but nearly every such possible detail will be found to be already old. Almost every conceivable design or modification has been the subject of a patent, and most of these have been thoroughly tried with much expense and enthusiasm before being condemned and discarded. The various subterfuges of double or separate springs, one more flexible than the other, spiral springs of increasing diameter whose first movement in compression is rapid until the smaller and stiffer coils are brought into action; springs suspended in all sorts of universal bearings, and every method of end bearing and fitting have all been tried and abandoned by almost every maker and user of safety valves but are periodically redesigned or discovered by some new designer or inventor and brought forward for consideration again and again. Before any such expenditure are advocated a study of the file of long-expired patents would be enlightening and interesting.

E. A. May

of the American Radiator Company, of Chicago, discussed the safety valve as related to low pressure, house-heating boilers.

Whether a safety valve should be raised open to exhaust all the steam generated by the boiler at its maximum capacity or whether it should vary only for the pressure and above a predetermined point would appear to offer opportunity for profitable discussion, and until this point be established there can be no standard for general practice which can safely be used by all manufacturers of low-pressure boilers.

Rarely, if ever, has a safety valve on a low-pressure boiler been called upon to exhaust all the steam generated when running under its full steam-generating capacity. In the majority of heating plants the full amount of radiation is almost always in service condensing a large percentage of the steam generated, and even when the radiation is all cut out there is still circulation through the piping.

Practically every heating boiler has its damper regulator which when properly set checks combustion when a pressure of about two pounds is reached, so that maximum capacity is impossible.

Chimney conditions in the majority of heating plants are such that it would be almost impossible to drive the boiler to its maximum steam-generating capacity.

In practically all house installations at least two of these conditions exist, and in a majority all three are present, so that to select a valve large enough to exhaust all the steam which might be generated by the boiler under ideal conditions would mean a valve out of all proportion to actual requirements.

As far as the experience of the writer goes, it would seem apparent that with the average house-heating plant of cast-iron boilers the safety factors would be practically as follows:

First: Rate of combustion, eight pounds hourly on a maximum of [illegible] pounds.

Second: Chimney, [illegible] per cent.

Third: Operating pressure of safety, fifteen pounds.

It was the speaker's opinion that if valve manufacturers would indicate in addition to the size of the valve the capacity at its different adjustments for exhaust steam it would help conditions materially, not only from the standpoint of the boiler manufacturer, but for those whose duty it is to inspect the safety valve and it would farther materially aid in the matter of legislation.

It is undoubtedly true that valves can be designed and sold on their exhaust capacity without regard to their specific size; that is owing to the variation in design one valve might have a larger diameter with lesser lift than the other, while their capacity for exhaust would be identical.

If, however, the law specifies that for a certain evaporative power, at rating, of boiler a certain exhaust capacity should be maintained in the valve, each manufacturer could then determine for himself the proper valve to use.

The speaker wished to correct a possible wrong impression left by a remark of Mr. Darling. The committee appointed by the Franklin Institute to formulate a rule adopted its own unit and prepared a formula for safety valves, the results of which were exactly similar to the French rule, so that while they may not have known the factors on which the French rules were formulated, their own rules, formulated from their own data, brought it back exactly to the same result.

H. O. Pond,

engineer and superintendent of piping for Westinghouse, Church, Kerr & Co., said, in part, that the engineer about to design a boiler installation finds himself confronted by an array of rules, covering the application of safety valves, no two of which will give the same result, and the correctness of any of which may be questioned. In the past this has not been as serious a menace to life and property as it has become recently. For a number of years past the tendency has been to force boilers farther and farther beyond the standard ratings, and to get the maximum possible capacity out of a boiler installation; so that valves which may have been of the right size for boilers operating at low ratings undoubtedly would not be correctly proportioned for boilers forced to capacities as high as 200 per cent. of their rating.

The use of the superheater has also introduced an additional factor which must be considered when deciding upon a safety-valve installation.

The absolute absence of reliable data relative to safety-valve operation and the proportioning of valves for a given service was brought very forcibly to his attention something more than a year ago in connection with the design of some special boilers of large capacity equipped with superheaters. When asked for data relative to capacities of their valves none of the manufacturers was able to furnish any definite information.

No two manufacturers use just the same lift for valves of the same "catalog" size, nor are the sizes of seat, muffle ring and ports the same. These points must necessarily affect the discharge through the valve and they are not properly considered in the present rules governing safety-valve practice.

He agreed with Mr. Ashton that the lift of the valve is not the essential thing; the thing to be determined is how much steam any given valve will discharge under particular conditions. "That particular piece of information is one that none of the manufacturers up to tonight has been willing to give us, because they have not made the tests. There are some other tests being conducted and some being prepared at the present time which will give us more definite data on which we can base the proportioning of the safety valve."

F. L. Pryor,

professor of experimental engineering at Stevens Institute, has submitted the following since the meeting:

The information that the writer secured in some tests which he made some time ago in conjunction with Professor Jacobus to obtain the blowing-off pressures of safety valves, when tested with water and when tested with steam, may be of interest.

A standard 4-inch pop safety valve set for 125 pounds was mounted on a 4-inch pipe and so connected that either steam or water under pressure could be admitted to the valve.

In all the tests the pressure required to open the valves was determined by subjecting it alternately to steam and water pressure, the set of the valve being the same for the steam and for the water in each pair of tests. The water was at a temperature of 100 degrees Fahrenheit.

One set of tests was made over a period of fifteen days, the test of one day being with steam and the following day with water, and so on until the series was completed. The lapse of time between tests was allowed to insure that the valve had obtained its normal condition of temperature, etc. In a second series of tests the valve was tested at three different settings on the same day, viz., 104, 131 and 159 pounds, the spring and valve being in each case cooled in cold water before taking the measurement for the water-pressure test.

The third series of tests was made with the valve at a number of different settings from 105 to 165 pounds, one measurement being made directly after the other, no precaution being taken to insure that the valve had returned to its normal temperature before the next test, except that before operating with water pressure a considerable amount of water was flushed through the valve.

The results obtained in all the tests were in practical agreement and indicated that the blowing-off pressure with steam and with water did not differ to any great extent, although the pressure to blow off with water was higher than with steam.

In the case when the valve was allowed to cool for twenty-four hours the water pressure required to open it was about 3½ pounds higher than the steam pressure.

In the tests where the valve was cooled thoroughly with water the pressure with water was about 3 pounds higher than the steam.

In the rapid-change test the water pressure amounted to about 2.6 pounds more than the steam pressure.

In all tests the steam and water pressure recorded was that at which the valve was in full operation. In the case of the steam-pressure test there were two testing points below full-open pressure, which also have been noted: When the valve began to leak, which occurred about 2 pounds below the final blowing-off pressure, and with the rate of flow suddenly increased, which was about 1 pound below maximum.

Prof. Edward F. Miller,

of the Massachusetts Institute of Technology, said that while the weight of steam to be discharged through a locomotive safety valve need be only a small proportion of the steam generated by the boiler, as Mr. Whyte says, in the case of stationary boilers the safety valves must be able to take care of the entire capacity of the boiler.

The sudden closing of the emergency stop valve on an engine or a turbine, by instantly stopping the demand for steam, compels the safety valves to discharge, for a time at least, as much steam as the boilers were generating at the instant that the valve closed. He had seen plants where, on account of insufficient safety-valve discharge, the pressure went up 15 pounds above the blowing pressure of the safety valves. He believed that the correct way to figure a safety valve was to make the discharge area of the valve or valves sufficient to handle all of the steam that the boiler can make at its maximum rate of coal consumption. This amounts to making the size of the safety valve depend upon the grate area, the weight of coal burned per square foot of grate per hour and the evaporation per pound of coal burned.

The weight of steam flowing through an orifice with a slightly rounded entrance may be figured quite accurately by Napier's formula (sometimes called Rankine's formula), the accuracy of which for commercially dry steam has been shown by tests made under pressure varying from 30 to 150 pounds.

The discharge per second through an orifice with a sharp edge at the entrance, such as would be the case in a safety valve, has been found from actual tests on valves to be 0.95 of the amount figured by the Napier formula.

The opening needed in a safety valve may be figured as follows:

G = Grate area,
R = Rate of coal consumption per square foot of grate per hour,
9 = Probable evaporation per pound of coal under actual conditions,

$$\frac{G \times R \times 9}{3600} = \text{Weight of steam made per second.}$$

Equate this to Napier's formula and solve for A:

$$\frac{G \times R \times 9}{3600} = 0.95\,\frac{A \times P}{70};$$

$$A = \frac{G \times R \times 9 \times 70}{3600 \times P \times 0.95}.$$

The area of the opening through a safety valve is equal to the inner circumference of the seat times the effective lift. For a valve with a seat at an angle the effective lift is equal to the lift multiplied by the cosine of the angle which the seat makes with a horizontal.

For a 45-degree angle the effective lift is 0.707 × lift. Calling D the inner diameter of the valve, the opening is

$$\pi \times D \times lift \times 0.707$$

Substituting this for A:

$$\pi D \times lift \times 0.707 = \frac{G \times R \times 9 \times 70}{3600 \times P \times 0.95}$$

If the lift of the valve is $\frac{1}{10}$ of an inch,

$$D = \frac{G \times R \times 9 \times 70}{3600 \times P \times 0.95 \times \pi \times 0.707 \times 0.1} = \frac{G\,R}{P \times 1.206}.$$

If the lift is 0.05 instead of 0.10, the valve diameter D is doubled. Doubling the pressure will make the same valve with the same lift taking care of double the weight of steam. Illustration:

Grate area = 25,
Coal consumption = 18 pounds per square foot-hour,
Pressure = 120 pounds absolute.

$$D = \frac{25 \times 18}{120 \times 1.206} = 3.1$$

Pressure = 150 pounds absolute,
Grate area = 50 square feet,
Coal consumption = 25 pounds per square foot-hour,

$$\frac{50 \times 25}{150 \times 1.206} = D = 6.9 \text{ inches}$$

A valve as large as this would be replaced by two of equivalent capacity, and two valves of 4.88 inches diameter would give the same discharge with the same lift.

F. J. Cole,

consulting engineer for the American Locomotive Company, submitted a paper read by Mr. Pomeroy, quoting from a letter written by a prominent locomotive builder abroad to the effect that when the Ramsbottom duplex safety valves were introduced into the London & North Western railway, in 1868, they were made 3 inches in diameter at the seat each, and that size has been perpetuated notwithstanding the fact that boilers have nearly doubled in capacity and the pressures have increased 50 per cent. On the other hand, they have constructed boilers of a capacity of no more than that with which the two 3-inch valves were used, with two seats of duplex valves of 4½ inches diameter.

While it is desirable that definite rules should govern this matter, it is quite evident that peculiar conditions governing the draft on locomotives, the same necessity does not exist for safety-valve regulation as in the case of marine or stationary boilers, the action of the exhaust automatically taking care in a large measure of the generation of steam.

Locomotive boilers are carefully constructed with a factor of safety ranging from 4 to 5; they have an ample margin of strength and there is no cause for alarm even if the pressure does go temporarily 25 pounds above the normal blowing-off point.

With steam at 200 pounds pressure the temperature is about 387 degrees Fahrenheit; at 225 pounds the temperature is about 397½ degrees, or 10½ degrees higher. If the pressure temporarily goes 25 pounds above the normal it means that the entire mass of water has been heated 10½ degrees higher than before, and it is altogether probable that with this increase in pressure and temperature most all of the radiant heat in the firebox has been absorbed.

The writer was in favor of a thorough investigation of the subject, looking toward the formulation of definite and authoritative rules for the application of safety valves to locomotives, and invited attention to the following suggestions to be considered in their preparation:

First, diameter, number and kind of safety valves to be based on their capacity for discharging pounds of steam per second at different pressures.

Second, the maximum amount of steam which a safety valve may be required to discharge when the throttle has been suddenly closed after the fires had been urged to be based on the square feet of adjusted heating surface, so that the relieving valves [illegible] the [illegible] kinds of heating surface, which [illegible] water tubes, [illegible] long and short boiler tubes [illegible] [illegible] to their lengths and [illegible] for different spacing of tubes [illegible] be taken into consideration, or what would be simpler, some approximation of average value of heating surface, corrected to account for difference in length and spacing of tubes, the firebox heating surface in this case to be considered as a certain percentage of the whole for all sizes of locomotives.

Dr. Charles E. Lucke,

of Columbia University, had one idea to offer which he thought was not of very great value. It had occurred to him, in connection with some work, one of the boiler and not directly on the safety valve, that there is another element in this safety-valve question which, while it may be of minor importance, ought to be considered, and that is the time element. He had studied to a considerable degree rapidly rising and rapidly falling pressures, and believed as a result of these experiments, which have extended over many years, that it is possible in a closed boiler under pressure for a sudden increase in pressure to occur and go far beyond what any safety valve may be set for, even momentarily, and it may seem that because this excess is only momentary and measured in fractions of seconds it is of no consequence, but it seemed to him that, by reason of its suddenness, it is of far more consequence.

A suddenly applied load cannot be resisted by the same metal under strain as well as a steady load, and if by any reasonable series of circumstances the pressure in the boiler should suddenly rise, then the time element will enter. He did not say that it is possible for it to do so, but it may; and consideration of the subject may reveal more chances for this to occur than have been apparent in the past. If the pressure does suddenly rise it will go higher than the safety valve is set for before the valve opens, and will cause the boiler to [illegible]. Whether this is of any consequence in practical safety-valve work he did not know, but if it is the subject may be studied experimentally.

Professor John H. Barr

suggested that there is another point along the same line as Dr. Lucke's thought: [illegible] in the design of [illegible] the safety valves [illegible] of the [illegible]. If a boiler is [illegible] with a [illegible] according to 150 pounds pressure, and the pressure is suddenly [illegible], what [illegible] to the boiler? That is what [illegible] [illegible].

[illegible] of boiler explosions and [illegible] [illegible], will realize the necessity of [illegible] safety valves that are [illegible] [illegible] [illegible] [illegible] [illegible].

Garland P. Robinson,

State inspector of locomotives for the Public Service Commission of New York, said the problem in locomotive work appears to be what proportion of the maximum evaporative capacity of the boiler must be provided for. Present practice seems to show that it is necessary to provide for about 50 per cent. of the maximum evaporation.

The commission with which he is connected has collected reliable data on about 7500 locomotive boilers. During the past week he had calculated the valve capacity of 1000 of these boilers for the purpose of finding the average practice of safety-valve equipment. The greatest variations have been noted; for instance, boilers using 180 pounds pressure with valves of 1/16-inch lift have two 3-inch valves to take care of an evaporation from 1750 to 3350 square feet of heating surface. Again he found two 2½-inch valves used to take care of from 900 to 1900 square feet of heating surface. These cases represent whole classes and not individual boilers. Therefore, it would appear that no rule has been followed to determine the size of valve required.

In his opinion a formula based on the heating surface and providing for 50 per cent. of the maximum evaporation of the boiler will give satisfactory results for locomotives in freight and passenger service.

If the angle of the valve seat is 45 degrees we have

$$A = \pi D \times l \times 0.707,$$

where

A = Effective area opening of the valve,

D = Diameter of valve,

l = Lift of the valve,

0.707 = Cosine of 45 degrees.

Combining this with Napier's formula,

$$A = \frac{P \times 3600}{W \times 70},$$

the flow of steam per hour =

$$116 \times l \times D \times P.$$

Also,

Heat surface × evaporation per square foot of heating surface per hour = evaporation of boiler.

Combining we have:

$$\text{Heating surface} \times E = 116 \times l \times D \times P,$$

or

$$D = 0.05 \frac{H\ S}{l \times P},$$

where E = 7 pounds, or 50 per cent. of the maximum evaporation per square foot of heating surface per hour.

He had checked 1000 boilers and found the constant to be 0.0441 for present practice. Included in the 1000 boilers, however, are a number which are evidently under safety-valved, as the constant in their case is only 0.024. Eliminating this class of boiler, the constant for average practice is about 0.05, as given in the formula. He believes valves calculated by this formula will be of satisfactory capacity for road engines; also, if valves for freight engines are calculated by the formula with the constant 0.035 instead of 0.05, they will be of sufficient capacity.

William Boehm,

of the Fidelity and Casualty Company, was particularly interested in the statement of Dr. Lucke regarding the element of time. He did not know of any case of boiler explosion due to insufficient safety-valve area. The trouble about a boiler explosion is that after it occurs it is almost impossible to determine the cause; there is not enough of the boiler left. If a safety valve is too large it may, of course, relieve suddenly too great an amount of steam and in so doing cause a water hammer, and that water hammer may cause a violent explosion of the boiler. He believed that the correct method of proportioning safety valves was to determine the quantity of steam to be handled, rather than to take the heating surface as a basis.

President Smith

said that the possibility of the valve being too large has entered into the question in France. He did not know what the law is now, but several years ago the maximum size of the valve was limited as well as the minimum size.

H. C. McCarty

Reference has been made to the difficulties developing out of too large a safety valve, and too large a safety valve must be construed, he believed from experience, as one with too great a lift. Several of the speakers had referred to hammer blows. Hammer blows are the result of extraordinary lift, resulting not only in the destruction of the valve, but in damage to the boiler.

No suggestion has come to the notice of his company (the Coale Muffler and Safety Valve Company) in the years of their experience in producing the valves which they do, that any advantage would be gained in locomotive service by increasing the lift above that usually followed by the majority of the manufacturers; in fact, they had found the contrary to be the case. It is true that the lifting of water and the destruction of the valve have been clearly demonstrated in practice. Beyond this he believed that there is a more vital and more serious element of difficulty. Any disturbance of the water level, especially in the modern locomotive boiler, is a serious problem confronting every man who is responsible for locomotive maintenance. We aim to work the driest steam possible through the chests and cylinders and through the throttle, which is located at the highest point possible. His observation had been that any agitation of the water will lift water through the valve or cause it to pass through the throttle, if the throttle is open at the time.

The location of valves seems to be overlooked in many instances by designers. One speaker has referred to the placing of the safety valve on the dry pipe. Their experience indicates that the connection between the valve and the boiler should be at a point as high as the clearance will permit, and with the shortest possible intermediate connection.

M. W. Sewall,

of the Babcock & Wilcox Company, suggested as the two items that need to be considered: How much steam can the boiler make? How much steam will your safety valve deliver? If these two items are considered, the diameter and the lift, the approach to the safety valve and the discharge from the safety valve can all be readily taken care of, and when they are settled one maker can make a big-diameter barrel and small lift and another a small-diameter barrel and big lift, just to suit their own conditions or their own tastes, and when they come to place them on the market the one that comes out ahead will be the best for its own manufacturer.

George I. Rockwood

thought that it was obligatory upon Dr. Lucke, now that he had "thrown that scare into us," to state what his experiments were that lead him to believe the sudden generation of pressure in boilers possible. Mr. Darling's demonstration that the lifts of valves vary up to 300 per cent., making an enormous difference in the steam discharged, ought to interest the boiler-insurance companies, and he did not see why these companies had not conspired together in some such way as do the ordinary fire underwriters—have a laboratory of their own and find out the conditions which affect the design of safety valves and devices in general that are used about the boiler plant, and then lay the law down to the several manufacturers and deliberately "Approve" their devices (and spell the approve with a capital A), and not write insurance where those devices are not used. That is the club that is most successful in producing splendid apparatus for fire protection, and he thought it would be equally effective as applied to steam-boiler protection. If Mr. Boehm, of the Fidelity and Casualty Company, never knew of an explosion of a boiler being due to an inefficient safety valve, then the speaker did not know what the agitation of the evening was about, but doubtless that is a view which is subject to modification.

A. A. CARY

agreed with Mr. Carhart that the small-lift motion spring is certainly the safest. He called attention to his discussion in the December, 1901, meeting of the society, of the subject of springs, and said that the diameter of the spring should be to the diameter of the wire about as 7 to 1, and may possibly be reduced as 5 to 1, but that is not good practice for pop safety-valve springs. He saw no good reasons for using wire of square section and thought the round section safer. An extension spring would be safer than a compression spring.

Care should be used in safety valves for use with superheated steam to see that they are not subjected to temperatures above 450 degrees. In the Cary process, invented by his father, the spring was subjected to a temperature just above that point (the point of recalescence), and it would hold the shape to which it was bent. All of the "set" must also be taken out of the spring before it is put into use.

A. D. RISTEEN

of the Hartford Steam Boiler Inspection and Insurance Company, indorsed Mr. Rockwood's suggestion of an experimental laboratory for the underwriters of boiler risks, and pledged his influence to that end, but when Mr. Rockwood suggested that they try to lay down the law to the manufacturers and owners of boilers, he thought he had suggested a task from which the insurance companies might shrink.

F. L. DUBOSQUE,

of the Pennsylvania Railroad Company, congratulated the company upon the fact that if they had not learned anything else that evening they had learned the reason for the adoption in the United States laws of a formula that has caused marine engineers more trouble than anything else for the last few years. From the fact that one of the speakers of the evening had laid so much stress upon this formula, and from the fact also that it was exhibited among the formulas thrown upon the screen, it may be looked upon with confidence. He hoped no one would be deceived by it; it was the poorest formula ever established.

He had had a little experience with it a short time ago. The formula as incorporated in the United States laws leaves in the hands of the inspector the decision as to how much coal shall be burned per square foot of grate. In determining the size of the safety valve he knew from actual experience that a particular boiler could not burn more than 16 pounds of coal per square foot of grate area. He figured accordingly that it required a [illegible]-inch safety valve. They sent their plans forward to the inspector and he said: "You are wrong; this boiler will burn [illegible] pounds of coal per square foot of grate area and it requires a [illegible]-inch safety valve, and the nearest size is [illegible] a valve fully 50 per cent. larger than is actually required to be used on the boiler."

L. D. LOVEKIN,

the author of the formula, assured Mr. DuBosque that he had had quite a little to do with boilers in the design of boilers for different steamships in the United States service and had interviewed hundreds of engineers, all of whom, with the exception of Mr. DuBosque, had complimented him upon that formula. Everybody knows that any boiler safety valved on 1 square inch of valve for 3 square feet of grate for a Scotch boiler and 1 square inch of safety valve for 6 square feet of grate area for a water-tube boiler is both ridiculous and absurd. Whenever he had said a boiler would evaporate so much water and submitted the design, he had never had an inspector return the boiler for additional safety valves. The United States Navy authorities, with all their experience, together with several prominent authorities abroad, have agreed upon a lift of 1/8 of the diameter of the valve.

In the present discussion there seems to be a misconception as to what constitutes high lifts. He did not think there was a safety-valve manufacturer in the room who cared to see a safety valve lift 1 inch, no matter how large it is. His rule was based on the proportion which the lift bears to the diameter and it falls on 1/8 of an inch for a 4-inch valve, and, therefore, the largest valve approved for naval work, 4½ inches, would not have so excessive lift under that formula.

DR. LUCKE

in response to Mr. Rockwood's request said that he had never seen the pressure rise in a steam boiler in the way to which he had referred, and did not believe that it could rise in that manner, but that if it does so rise the effects described will be those so produced; he had seen it arise from other causes.

MR. CARHART

thought that there is one way in which safety valves should not be rated and that is by the area of the disk or of the inlet connection, for in every case the outlet discharge depends in proportion to the circumference of the valve seat and the circumference will, of course, increase in proportion to the diameter while the inlet and disk areas will increase in proportion to the square of the diameter. The lift [illegible]

[illegible] assumed to be sufficient to lift [illegible] valves, with [illegible] considerations; [illegible] is the actual performance in practice. If there is any appreciable difference in specific cases it will generally be found that the larger valves lift less than the smaller ones. This is as it should be from the general point of view, for prompt and quiet action, durability of the valve and safety of the boiler. The larger valves have less weight of moving parts, less momentum, less heat, springs of more tractable proportions, and may safely lift higher.

Valves should not be rated in discharge area alone. The discharge area would be different for every pressure and would be dependent upon the care taken in maintaining the resiliency of commercial springs. It would be at best a theoretical amount arrived at by a formula which might be amended by any designer or salesman to suit the exigencies of every contract, price or specification of capacity. This would introduce formulas confused by odd sizes and leave the engineer at the mercy of the representations or misrepresentations of selling arguments. The standard sizes, familiar by practice to all engineers, now denote the size of the inlet-pipe connection which must be provided on the boiler. If different designs of valve have different apparent or claimed efficiencies, allowance can be made for this in the judgment of the engineer. The actual lift or discharge areas of valves should be determined and reported upon after impartial tests, conducted by competent and disinterested engineers, under conditions of scientific accuracy and fair precautions, where each valve is intelligently regulated to work within its proved intended limits.

FREDERICK SMITH

In rating a valve by its diameter, do you use the small diameter of the inside or the larger diameter on the outside of the seat?

MR. CARHART

We always use the small diameter of the inlet equal to the same pressure when the valve is closed.

PHILIP G. DARLING

Mr. Mac said that the Franklin Institute committee [illegible] in the adoption of their rule by a method of [illegible] [illegible] of the French people who introduced the rule. That is, he [illegible] they made their rule [illegible] [illegible] was right theoretically, and then they increased it by 50 per cent. and after that they considered it to be right as a factor of safety. It seems to me that [illegible] of the two [illegible] after [illegible] rules that have considerations.

NATHAN PAYNE

pointed out that the only profound issue in this discussion is that there has been no standard measurement of any safety valves probably to date, and whether we take a high-lift valve or a low-lift valve what we should do is to get some formula therefor measuring what one is offering when he offers a "4-inch" valve, what it will do and whether it is good for a 100-horsepower boiler or a 200-horsepower boiler.

The Shunted Ammeter

BY CECIL P. POOLE

The simple series-connected ammeter, the winding of which is merely inserted in one leg of a circuit and takes the full current, is readily understood by the average engineer. The current flows through the winding just as steam or water flows through a valve or other device inserted in a pipe. The shunted ammeter, however, is not so readily understood by beginners in electrical work, as indicated by numerous letters of inquiry received by the editorial department of this journal.

Fig. 1 is an elementary diagram of the connections of a shunted ammeter and its shunt. The latter consists of a conductor *S* of accurately known resistance, usually fastened to two relatively massive terminal blocks; the circuit wire in which the current is to be measured is cut and the two ends attached to the terminal blocks of the shunt; consequently the shunt forms a part of the circuit carrying the current to be measured. Also attached to the terminal blocks are two small flexible conductors, the other ends of which are connected to the terminals of the instrument; these conductors are twisted together, forming the flexible cord used with portable incandescent lamps, voltmeters, etc., although the diagram shows widely separated leads from the shunt to the instrument.

The instrument, though called an ammeter, is really a voltmeter of small range, usually around 50 millivolts; that is to say, an electromotive of 50 millivolts or fifty one-thousandths (one-twentieth) of a volt applied to its terminals will carry the needle to the extreme limit of the scale. The scale of the instrument, however, is marked in amperes instead of volts, the shunt being proportioned to suit the desired range.

Suppose, for example, that the instrument and shunt are designed for a "full scale" reading of 50 amperes. This means that when 50 amperes flow in the main circuit, the voltage at the terminals of the instrument must be 50 millivolts, in order that the needle may be deflected to the end of its scale. Ignoring the resistance of the "ammeter," which is relatively high in most cases, the resistance of the shunt conductor *S* must be one-thousandth of an ohm in order to show a difference of potential of 50 millivolts at its terminals when 50 amperes pass through it, because

Volts ÷ Ohms = Amperes,

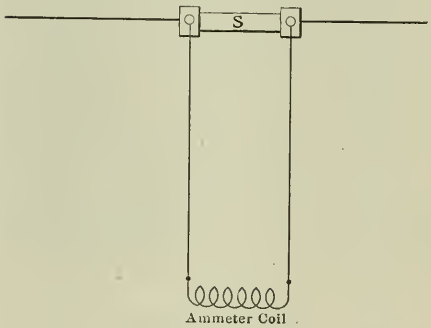
and consequently

Amperes × Ohms = Volts.

In the case mentioned, therefore, when 50 amperes pass through the circuit, there will be 50 millivolts at the instrument terminals and the needle will be carried to the end of the scale; this point is marked 50 amperes, instead of the 50 millivolts which the instrument is really measuring. When 25 amperes flow through the shunt, the voltage at its terminals will be

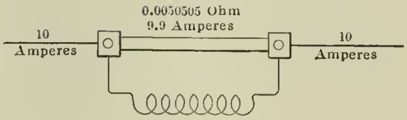
$$25 \times 0.001 = 0.025$$

volt or 25 millivolts, and the needle will point to "25" on the scale, and so on. In this case the scale would be marked exactly as it would be to indicate millivolts, because the number of amperes in the main circuit would always be exactly



Power, N. Y.

FIG. 1



Power, N. Y.

FIG. 2

the same as the number of millivolts at the terminals of the instrument.

No matter what the range of the instrument in amperes may be, however, the voltage at its terminals will be 50 millivolts when the full current is passing. The same instrument may be used, therefore, for any current range by changing the shunt and the scale on the instrument. For example, suppose the maximum current "capacity" were 1000 amperes. Then the resistance of the shunt would have to be 0.00005 ohm in order that Amperes × Ohms should equal 0.050 volt at "full scale" current in the main circuit. With 1000 amperes flowing, therefore, the potential at the terminals would be $1000 \times 0.00005 = 0.050$ volt or 50 millivolts, and the needle would be deflected to the end of the scale, which would be marked "1000," instead of 50 as in the first case; with 500 amperes, the potential would be $500 \times 0.00005 = 0.025$ volt or 25 millivolts, and the needle would stand at the point which was marked "25" in the previous case, this point being marked "500" on the scale now used. So on, through the whole list of "ammeter" capacities. The relation between the current in the main circuit and the deflection of the needle is determined entirely by the resistance of the shunt conductor.

The resistance of a millivoltmeter requiring 50 millivolts for full scale deflection is from ½ to 1 ohm, according to the design of the instrument. When used to indicate currents of 100 amperes or over, the resistance of the instrument is so high with relation to the shunt that it is ignored. For smaller ranges, however, the resistance of the instrument is considered by the more careful manufacturers. For example, if the full scale reading is 10 amperes and the instrument requires 50 millivolts for full scale deflection and is of ½ ohm resistance, the resistance of the shunt conductor should be 0.0050505 ohm; the joint resistance of the shunt and the instrument winding would then be 0.005 ohm, and with 10 amperes flowing in the main circuit the voltage at the terminals of the shunt and the instrument would be 0.050 volt, or 50 millivolts, as required. Of the total current, 9.9 amperes would flow through the shunt and 0.1 ampere through the instrument. This set of conditions is represented diagrammatically in Fig. 2. If the resistance of the instrument were ignored in this case and the shunt were made of 0.005 ohm resistance, the joint resistance of the two would be 0.00495 ohm and in order to get a full scale deflection the current in the main circuit would have to be 10.1 amperes instead of 10. This is an error of only 1 per cent., and would not be very serious. It is too large, however, to satisfy a maker who strives for as high a degree of accuracy as is commercially practical, and such a maker would probably make the shunt of 0.00505 ohm resistance. Then the joint resistance of the instrument and the shunt would be 0.0049995 ohm (assuming perfect connections and other conditions) instead of 0.005, and the error would be insignificant.

The resistance of the flexible cords leading from the shunt to the instrument is so low that the error caused by it cannot be measured by ordinary instruments. In many shunted ammeters of low range the shunt is mounted in the case which contains the meter mechanism and winding; separate connections are therefore unnecessary. When the shunt is separate, however, as indicated by the simple diagrams herewith, it is necessary that the flexible cord connecting the instrument to the shunt should be very firmly secured at both ends; any looseness of connections will cause the instrument to indicate falsely by reason of the increased resistance of the branch circuit passing through the instrument, the error being of the nature of indicating a smaller current than is really flowing in the main circuit.

Some Useful Lessons of Limewater

How Coal Burning Makes Carbonic-acid Gas; Why Fire Must Be Lighted before It Will Burn; What Causes Fire Heat; Expansion and Contraction

BY CHARLES S. PALMER

Coal Burning Makes Carbonic-acid Gas

Here is a clean, common fruit jar. Pour into it some filtered limewater and shake it up. There is no especial change, for the air in the inside of the jar is much the same as that on the outside of the jar; although if you let the limewater stand in the jar for a few minutes, you will see that its surface becomes covered with that thin white skin, or "pellicle," of plain insoluble carbonate of calcium. You can observe this better if you pour out several tablespoonfuls of the limewater into a common glass tumbler and let it stand on some dark surface, say a piece of black paper. Soon the thin white skin of plain carbonate of calcium will form over the surface, and this will remind you that the air about us carries some of this carbonic-acid gas, about one part by volume in three or four thousand of the air. When considerable of the plain carbonate of calcium has formed by exposing the filtered limewater to the air, just clear it all up with a drop of hydrochloric or nitric acid; if you look carefully, you may see a little bubbling, as though you were treating some bits of marble with the strong acid.

Now, rinse out the jar, and hold down into it a burning common wood splinter. In a few moments remove the burning splinter and pour into the jar a few tablespoonfuls of filtered limewater. Clap over the mouth of the jar a piece of common cardboard for a cover, and shake it well. You will note the same white, milky precipitate of plain carbonate, and you will be ready to study it with new questions and answers.

Now repeat the experiment of the last lesson, where you tried to find out the parts of the air, and where you used sulphur or phosphorus; only in this case use shavings, paper and the like. You will find that the experiment will work, but it will be slower than in the case where you used the phosphorus, or the sulphur, or the match ends. The products of burning the shavings or the paper will not absorb nearly as readily as the burnt products from the phosphorus or the sulphur. Indeed, although there is the same loss of bubbles of air, at the first, from the same expansion by heating the air in the jar, and although there is about the same amount of oxygen burnt out of the air, yet the absorption by the water in the jar in the case of the paper or shavings is not nearly as great as in the case of the sulphur or phosphorus. But if you replace the plain water in the wash dish with a solution of filtered limewater, then you will get about the same results as you got in the case of burning sulphur or phosphorus over plain water. The reason is, of course, that the acid-like stuff from the burning of sulphur or phosphorus is easily soluble in plain water; and the stuff from the burning of the shavings or paper, while not soluble in plain water, is nevertheless easily soluble

FIG. 1

in limewater. Try all this and you will get the facts. Now for the explanation.

The Union of Things Unlike

We have seen that in general unlike things unite with each other. Thus acids unite with bases and bases unite with acids; but bases do not unite with bases, nor acids with acids. It is much like the marriage of male with female and of female with male, but with the comparative indifference of male for male and of female for female. It is this principle of the union of unlike things that guides us in chemistry. Now to go back to the experiment: you could test the limewater with litmus, and you found that it turns it blue; that is all right, for the limewater is an alkaline base. You also found that the water solution from the burning of the sulphur or the phosphorus, or the match ends, turns litmus red; and that is also all right, because the substances formed are acid-like.

But, in the case of the carbonic gas from the burning of wood, paper or coal (we call it carbonic-acid gas, although it affects litmus very feebly), we have to reason back to prove that the carbonic gas is an acid. We reason this way: Limewater is a base. Carbonic gas unites with limewater and is therefore unlike limewater; consequently, it is an acid, carbonic-acid gas. But there is also another side to this proof. That is that acids will displace acids and bases will displace bases. We find that this principle works well, for we can drive off the carbonic-acid gas which has been absorbed by the limewater, by any strong acid, such as hydrochloric acid or nitric acid. It will be well for you to make quite a quantity of this same plain carbonate, by blowing your breath (which is the burnt carbonic-acid gas from the body furnace) into some filtered limewater; let it settle, and then pour off—"decant off," the books say—the liquid from the sediment. Then take the sediment and treat it with a few drops of hydrochloric acid; the chlorine of the hydrochloric acid will displace the C-O-two (CO_2), carbonic anhydride, or carbonic-acid gas from the plain carbonate of calcium, making calcium chloride ($CaCl_2$), C-a-C-l-two. So by reasoning backward and forward, we can prove that as this carbonic gas unites with bases like lime, and as it is displaced by acids like hydrochloric or nitric, [illegible] therefore it is an acid, carbonic-acid gas.

Where the Carbonic-acid Gas [illegible]

But we have had [illegible] still more about this colorless gas [illegible] which black coal gives on burning, and where it hides itself. Here is a tall jar; a large fruit jar will do. Pour into the bottom some powdered marble, or some common cooking soda (each are "salts" of this same carbonic acid, one with the base lime, or calcium oxide, and the other with soda proper, the oxide of the metal sodium). Now prepare several bits of candle strung on a wire like that shown in Fig. 1. [illegible] the jar (one candle can be cut into several pieces). Now pour in some strong acid, like hydrochloric acid. You will see the lively foaming, or "effervescence," as the books call it. That is the giving off of the invisible carbonic-acid gas. Now this is a heavy gas; that is, heavy as compared with the air, which, of course, is and must be the standard gas, because the air always surrounds us, and we are much like human fish walking about in this invisible ocean of atmosphere. As the carbonic-acid gas comes off in the jar, being a full-fledged gas it displaces some of the air from the jar. But being a heavy gas, it displaces it from the bottom first; and so, if you are successful with your experiment, you will see the lowest candle go out, because it cannot burn in this carbonic-acid gas. Then the next higher candle will go out, and so on to the top. If you have enough marble dust, or soda, and acid, you can literally flood the candles in order from the bottom to the top.

But this is only the beginning of what you can do with this heavy gas. You treat it as though the jar were full of a light invisible liquid. Thus you can take out the candles strung on the wire, light them again, and set them in another clean and empty jar. Now take up the first jar, which is full of the invisible carbonic-acid gas, and pour it slowly (Fig. 2), for it will not pour quickly like water, into the second jar with the relighted candles. You will see them flicker and tremble as their flames are choked or drowned by the inpouring heavy gas. If you have ordinary luck, you will extinguish some of the lower candles, and you will clearly prove to yourself that this gas is a heavy gas which follows the laws of heavy liquids insofar that it displaces the lighter air. Later, when we get to the study of the very light gas, hydrogen, you will try that the other way, and you can pour it *upward* in the air, from one jar to another; and in that case you will test it by the flame, for hydrogen burns in the air.

Now there is one more test that you want to try again, if you have not done so already; for you will devise many experiments for yourself, and try your own ideas all the time. The test is to see what litmus, red and blue, will do in some strong water solution of carbonic-acid gas, like the "fizz" water or common "soda water." You will find that the litmus will probably turn red; but if you take the litmus paper out of the water and let it dry in the air, the volatile carbonic-acid gas will be driven off from the litmus by the nonvolatile red acid of the litmus, and the litmus will probably go back to blue. But it is possible that only *one* of the slips of litmus paper will go back to blue; because, if one of the slips was already red when you put it into the solution of carbonic-acid gas, and if it was colored red by some strong acid, such as sulphuric or nitric, or hydrochloric, then such a slip of red litmus paper may remain red in the strong solution of carbonic-acid gas, and may still remain red when taken out of the water; while the other slip of litmus paper, which was blue to start with, but which was turned red by the carbonic-acid gas solution, will probably turn blue again on standing in the air. This is only to show that no fixed rule can be given to the exclusion of the free use of one's brains. We must think in all things, and while the principles given may be accurate and correct, yet their use and application may require some thinking.

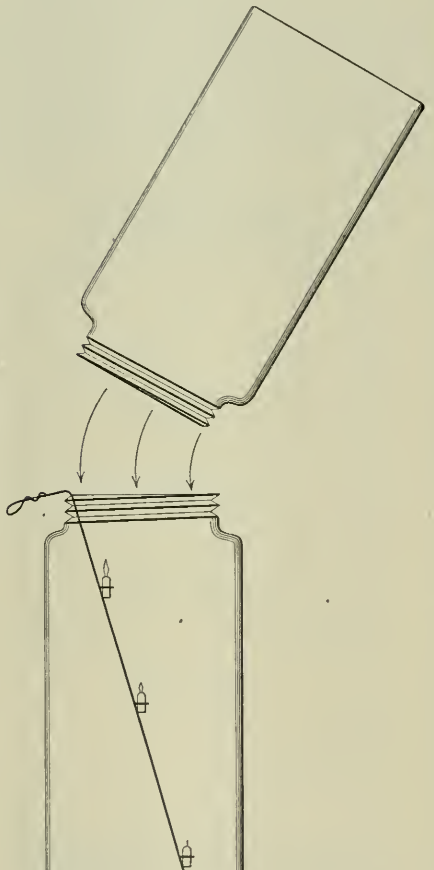


FIG. 2

But we have learned that the gas from the burning of coal, wood, or paper is mostly carbonic-acid gas; and that it comes from the union of the carbon of the coal, wood or paper, with the oxygen of the air.

Why a Fire Must Be Lighted Before It Will Burn

The fact that you may have the grate of a stove or furnace well cleaned out, that you may have the fire materials laid in order, from the shavings and kindlings and the wood to the coal, that you can have all this with the draft open and the free-flowing air all about ready to seize on the fuel, and yet there is nothing doing in the way of real fire, is a matter of everyday experience. In fact it is so common that its meaning and significance may easily escape the attention which they deserve. Why does fire material have to be *kindled* before it will burn? That is the question. It must be connected with the heat given off, because when the fire is once hot, we can kindle any amount of fuel from it.

The explanation of this curious necessity for kindling any combustible, from the match that we light by the slight friction heat of a quick stroke to the gas that burns with a hot flame, or to the still harder coal, is that all matter is made up of *groups* of chemical units. The group is called a "molecule;" and the chemical unit is called an "atom." Thus, the molecule of hydrogen is written H_2, and is called H-two; that is, there are two chemical units or atoms of hydrogen in the molecule group H-two. Similarly, the gas that comes from heating coal, and which burns with a blue flame, is called carbon monoxide (carbon one oxide), CO, and read C-O; that is, there are in the molecule group one atom of carbon and one atom or chemical unit of oxygen. Similarly, in the air the oxygen is found as molecule groups of O_2, called O-two, and the nitrogen as N_2, called N-two. Some molecule groups of chemical units or atoms contain two, some three and some four, five, six, or many more of the atoms or chemical units.

What Causes the Heat of Fire

Now, the heat from a fire is caused by the atoms of the various molecule groups falling together to make new molecule groups; and yet, before the chemical units, or atoms, can fall together in the new combinations, they must be free to come together. It is a case of "off with the old love, before on with the new." So it takes quite a degree of heat to shake the atoms loose from the old molecule groups before these same atoms can be free to fall together into the new molecule groups.

If you should ask how it is that we know that matter is made up of these molecular groups and that these molecules are themselves made up of still smaller atoms or chemical units, it would take some time to give all the proof. But you can begin to convince yourself right here that all matter has a "grained" structure. Thus, think what it means that common salt, for example, can be dissolved in water, can be passed through the pores of the finest filter paper, and can be evaporated down to dryness and recovered—all this shows that the lump of salt is made up of very small pieces which separate from each other in the solution in water, and which pass in droves through the pores of the paper and come together again; and yet in all this we have not got into the inside of the molecular groups of common salt, each of which is made up of NaCl, read N-a-C-l;

that is, each molecule of common salt consists of one atom or chemical unit of sodium (the metal back of all the soda compounds) and one atom of chlorine. But the molecule, salt, is a thing by itself, and it consists of atoms; and similarly every kind of matter consists of atoms united into molecules. The study of these unions of the atoms of each element as they make up the molecules of this and that substance is analysis. Analysis is called "qualitative" if it tells us *what* the *kind* of atom is in each substance, analysis is called "quantitative" if it tells us *how much* there is of each substance. You see that one is led to the study of the molecule and the atom from this fundamental fact that fuel ready to burn will not burn until the atoms of the molecular groups are torn asunder from the old molecules and made "free" to unite with the oxygen atoms, which must be also torn asunder from each other to burn the fuel, in making new molecules. Thus, the very fact of kindling a fire implies a difference between molecules and atoms.

Expansion and Contraction

It will be some time before we can take up very much of the proof for the molecular theory of matter and, beyond that, of the atomic theory of the molecules of matter; but you can be getting your mind in shape to handle some of these curious notions by asking yourself such simple questions as these: What happens when bodies expand with heat and contract with cold or pressure? What happens when any substance expands and contracts? All matter, in general, expands with heat and contracts with cold or pressure; what happens when matter expands? What happens when matter contracts? Whether it is a solid, a liquid, or a gas, the question is the same in kind, but you can think more clearly if you make this simple definite experiment. Take a ball of some metal, iron or brass will do, and then make a ring of metal of such size that the ball at common temperature will just pass through the ring of metal, Fig. 3. It would be better if we could afford to have some metal like gold, platinum or nickel which will not rust nor oxidize on heating; but the iron will show the principle. Now heat the ball so that it will not pass through the metal ring. What has happened to the ball of metal? If you could weigh the ball, cold and hot, you would find that there is no difference in weight, only some slight rusting; but the test has been tried with balls of gold and platinum which do not rust nor oxidize by heating in the air, and it has been found that there is no difference in weight, hot or cold. Then there is no more matter in the ball whether it is cold or hot; heat then neither adds to nor takes from the weight or "mass" of a body. Now if the ball of metal weighs the same cold or hot, if there is no more matter when it has expanded, what is the expansion?

Clearly, the expansion is the separation of small parts that are too small to be seen or felt, but there must be these small parts just the same, and it must be the separation of those small parts which shows on the outside as expansion of the whole ball. Similarly, it is the approaching of these small parts that makes the ball contract. Then the ball, though solid, is made up of small parts, that must be separated from one another by some degree of space; these approaching and receding parts are the molecules, and these molecules are made up of still smaller parts, the chemical units or atoms. It will take you some time to get used to this kind of thinking, but it will pay you for it leads not only to clearer ideas regarding the nature and structure of the kinds of matter about us, but it also leads us to some practical ways of attacking and analyzing the water that goes into your boiler, the fuel that you burn under the boiler, the ashes that you shovel away, the iron that makes up the boiler and con-

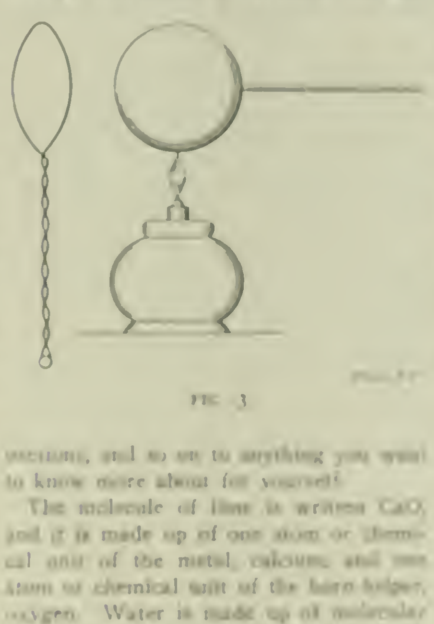

FIG. 3

stituents, and so on to anything you want to know more about for yourself.

The molecule of lime is written CaO, and it is made up of one atom or chemical unit of the metal, calcium, and one atom or chemical unit of the born helper, oxygen. Water is made up of molecular groups, which are composed of the chemical units told in the short form, H_2O (H-two-O); that is, two chemical units or atoms of hydrogen and one atom or chemical unit of oxygen; and so it goes. All this tracing of chemical composition means but one thing, and that is that at the bottom of analysis there must be the atoms, little bodies which have a weight fixed for each element, and hence called the "combining weight" or "the atomic weight." The tables of the atomic weights which are found in every textbook of chemistry will begin to have a new meaning for you, for they stand for the atoms which Mother Nature has fixed for each of the elements. As far as we know, all the atoms of any particular element have the same combining or atomic weight, different from the atomic weight of any other element: 1 for hydrogen, 16 for oxygen, 40 for your friend calcium, 14 for nitrogen, 35.5 for chlorine, 32 for sulphur, and so on. The simple statement of these atomic weights tells a story of its own, but it all was born from that old friend, the quicklime which has got you on the run and which will not let you stop until you learn a little of the special story of calcium and of the larger novel of chemical analysis. This story must be worth learning, for it helps to make "gray matter," and it will put you on your feet a little stronger and make you more ready to hold your own in the procession that starts from your barrel of lime.

Conservation of Natural Resources—Engineering Societies' Meeting

There will be a special meeting on March 24 under the auspices of the four national engineering societies, American Society of Civil Engineers, American Institute of Mining Engineers, American Institute of Electrical Engineers, American Society of Mechanical Engineers, on the general subject of "The Conservation of Natural Resources." The following program will be presented by representatives of the four societies:

"The Conservation of Water," by John R. Freeman, A. S. C. E.

"The Conservation of Natural Resources by Legislation," by Dr. Rossiter W. Raymond, A. I. M. E.

"The Waste of Our Natural Resources by Fire," by Charles Whiting Baker, A. S. M. E.

"Electricity and the Conservation of Energy," by Lewis B. Stillwell, A. I. E. E.

Spring Meeting of the A. S. M. E.

The spring meeting of the American Society of Mechanical Engineers will be held at Washington, D. C., May 4 to 7, inclusive. The local headquarters will be the New Willard hotel, rooms in which may be secured by members two weeks in advance—not later. The detailed program cannot be announced yet. Among other plans it is proposed to furnish members a condensed handbook of the most interesting points in the city with needed information, and excursions will be organized. The University Club of Washington has extended an invitation for the members to [illegible] of its rooms and privileges.

[illegible] April [illegible], inclusive, [illegible] [illegible] exhibition [illegible] Mechanics' Hall, Worcester, [illegible]

POWER
AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for February, 1909, *was (weekly and monthly)* 151,000.

March 2	42,000
March 9	37,000
March 16	37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Coal Weights

A manufacturing concern recently adopted a method of checking its coal weights and found that it was receiving considerably less coal than it was charged for, one barge load being some sixty tons short. The management refused to pay for more than was received, and the coal company brought suit to recover the full amount of its bills. Testimony was offered to the effect that it was the general custom to accept "railroad weights" in billing and settling for coal delivered, after which the attorney for the coal company announced: "Your Honor, the plaintiff rests his case;" whereupon the court immediately responded: "The plaintiff has no case."

Not a word of testimony had been offered to show that the amount delivered agreed with that for which bills had been presented, and if the current practice is anything like that which the attorney for the coal company tried to establish, it will be well for others to put some kind of a check upon their coal receipts.

Safety Valve Formulas

Attention is called to the communication from Philip G. Darling on page 511 of this issue. The formula which he criticizes appeared in our issue of March 9, and assumed that safety valves in general, whatever their diameter, are designed to lift between one-sixteenth and three-thirty-seconds of an inch.

The formula was suggested as an improvement upon that now used by the United States Board of Supervising Inspectors of Steam Vessels, which is based upon the assumption that valves lift one-thirty-second of their diameter, and which gives the result in area instead of directly in the number of inches of diameter required. The bringing out of the fact that large valves lift no more than small ones eliminates the necessity of using the diameter twice, and makes possible the simple expression proposed, in which the result is obtained in inches of diameter without the use of roots or powers or the conversion of areas into linear dimensions.

Mr. Darling's formula also expresses the results in terms of the diameter, is practically as simple and avoids any assumption in regard to the lift by making the lift itself a factor of the formula. This is safer unless the assumption that any valve will lift at least five-sixty-fourths of an inch without dangerous increase of pressure is warranted. Many of the valves which Mr. Darling has tested have not lifted this amount at the popping pressure.

It was not intended, in the editorial proposing the simplified formula, to detract from the credit due to Mr. Lovekin, the author of the formula now in use. His formula is rational, and would be correct if the assumption upon which it is based, that the lift varies in the chosen proportion to the diameter, were true. The papers and discussion at the meeting of the mechanical engineers seemed to show that the assumption was unwarranted. It was a common assumption in the engineering bodies which had given the subject the most attention, even greater proportionate lifts being assumed by responsible official boards, and Mr. Lovekin is entitled to the credit of having substituted a rational formula for the archaic and inadequate one based only upon grate surface in use at the time.

Receiver Drop

It has been aptly said that the facts evolved by practice would fulfil the predictions of theory—if the theory were right—and the facts correctly stated.

The theory must, however, be complete as well as right. One does not condemn as a scientific lie the academical demonstration of Carnot that the most efficient diagram for a heat engine to make is one in which expansion is carried to the back pressure, and compression to the initial, although few engineers would try to carry out the cycle so suggested in the real cast-iron cylinder, with its heat-absorbing properties, with compression processes which are of considerably less than one hundred per cent. efficiency, and with an investment which must be made to yield the utmost per unit of interest and overall charge.

It is also quite true, from a thermodynamic standpoint, that the greatest amount of work will be got out of a pound of steam when there is no free expansion, as in the receiver of a compound engine, i.e., when the diagram from the high-pressure cylinder ends in a point. That this is found to be not the fact when it is tried should not upset one's confidence in the academical demonstration, which is plain and incontrovertible, so far as it goes, but should set one to looking for the disturbing cause. One does not deny the universality of the law of gravitation because a penny falls faster than a feather, but mentally clears the situation of all disturbing influences, such as air resistance, before he applies the law.

What the causes and conditions are which produce results at variance with the abstract truth that free expansion results in loss we do not know. Here are a couple of facts:

Some years ago an engineer operating a pumping engine with fixed cutoff discovered that when the receiver pressure was changed there was also a change in the speed of the engine. Reducing the receiver pressure increased the speed and increasing the pressure reduced the speed.

In another instance, with a horizontal cross-compound condensing engine with fixed cutoff on the high-pressure cylinder, a reduction of pressure in the receiver from fifteen pounds to three pounds was accompanied by an increase of about eight per cent. in the amount of work done by the engine.

Cast Steel Flanges

A correspondent asks if there is any standard for cast-steel flanges. We do not know of any. The diameters and drilling are usually in conformity with the standard for cast-iron flanges described on page 796 of our issue of May 19, 1908. Those who use cast steel to save weight and material will make them lighter; those who use it for greater strength will usually use the same patterns that they do for cast iron.

Buying Coal on the B.t.u. Basis

How do you buy your coal? Do you buy it on its past reputation, or upon the advice of some other user? Do you accept as absolute truth the assurances of the selling agent as to the number of B.t.u. contained per pound and the percentages of ash and volatile matter? Do you have a "proximate" or perhaps a quantitative analysis made? Do you buy it on the basis of the highest number of heat units per dollar, or do you make evaporative tests and select a coal giving the highest evaporation per dollar?

Of these various ways of determining what coal to buy, the two last enumerated may be considered as the really practical methods. What is wanted is a coal which will evaporate the largest possible number of pounds of water per dollar's worth and leave the least possible amount of ash to be carried away. Evaporative tests should give this information and the results obtained should, with careful work, be approximately accurate, more especially as the sample coal is burned under the boiler and on the grates on which the purchased coal is to be fired. In this regard, however, much depends on the fireman and a great deal upon maintaining the same boiler conditions throughout two consecutive tests. The load on the boiler, the draft and the condition as to cleanliness of the heating surface are very irregular, and a variation in any one of the three, or in the thickness of the fuel bed, might easily make a considerable difference in the results of the test.

Buying coal on the B.t.u. per pound basis would appear to be a step in advance, just as practical as and more accurate than the evaporation method, as it obviates all the errors entering into a practical boiler test. Besides, taking a small sample of coal and burning it in an atmosphere of oxygen in a bomb calorimeter is much simpler and easier than to conduct a test requiring several hundred pounds of coal and extending over a considerable period of time. From the data obtained in the calorimeter test, which are the readings of the thermometer, the B.t.u. per pound of coal can be most readily computed, and the result is in practical form, giving in a nutshell the exact information wanted by the busy man. For instance, the engineer, in reporting an engine test to the manager, does not give him the diameter of the cylinder, length of stroke, number of revolutions per minute and mean effective pressure and leave it to his judgment as to whether or not the engine is overloaded. He may give him these data, but the indicated horsepower is by all means incorporated in the results, and this one figure is exactly what is wanted, as it is really a summation of all the other data, and means more to the manager and engineer as well. Much the same may be said of the British thermal unit when used to express the commercial value of a fuel. The busy manager or engineer has not the time to delve into the hydrogen, nitrogen and carbon contents of the fuel or, perhaps, the percentage of ash and moisture, and in some cases may lack the ability to read an intelligent answer in these figures. The B.t.u. put the whole or greater part of the facts in concrete form and give something tangible by which to compare the various coals.

It cannot be claimed that the B.t.u. method is perfect, for like most other methods it has its faults. The sample taken may not fairly represent the coal, but in any case a poorly taken sample will give dissatisfaction no matter how complete an analysis is made. Another objection which might be raised is the higher price usually demanded when coal is bought on this basis. The mine owner is not sure that his coal will have a uniform value throughout the year, even when taken from the same mine, and as a sinking fund to make good any forfeit he may be obliged to pay if the quality should drop below contract specifications, the price is raised ten to twenty-five cents per ton. This addition to the price is not exorbitant, and if the mine owner can afford to take the risk for so small a sum, why cannot the buyer?

Some precaution is necessary, however, in using this method. Two coals may contain nearly the same number of B.t.u. per pound and one may not evaporate nearly as much water as the other, due to its high volatile content. For instance, Pocahontas coal, which is high in carbon and low in volatile, and contains about 14,700 B.t.u. per pound, will evaporate approximately ten pounds of water; Illinois coal of 11,000 B.t.u., which is high in volatile, will evaporate but little over six pounds of water. Consequently, a comparison by the B.t.u. method would not truly determine the relative values of the two fuels. Restricting the comparison to the same or similar coals would obviate this objection, that is, this method could be used with accuracy to compare different grades of Pocahontas or Illinois coals, and either one of these two coals might be compared with others of similar quality. With hard coals the B.t.u. comparison should be even more accurate, as the hydrogen content bears a small ratio to the total combustible, and there is no such necessity of distinguishing between the heating values of carbon and hydrogen.

It would then appear that the chief trouble with the B.t.u. method is to obtain a representative sample. There is no good reason why the sample should not fairly represent the coal to be delivered, and just as soon as the sampling is put on this basis and the mine owners can be induced to adopt this method of selling without raising the price materially, the B.t.u. basis, on account of its simplicity and accuracy, is likely to be generally adopted.

New York's Opportunity

Speaker Wadsworth, of the New York Assembly, in a recent address on "Forest Preservation and Conservation of Water Supply," had the following to say about New York State's opportunity:

"The report of the water-supply commission proceeds to show that with complete utilization of all storage possibilities an eventual development of horsepower would be attained exceeding the present development by 100 per cent., and this without taking into consideration the Niagara and St. Lawrence rivers. And they estimate that as a result of the failure of the State to install a comprehensive system of water storage, twelve million dollars' worth of energy is running to waste annually in this State, and the great bulk of that in the rivers rising in the Adirondack region.

"I submit that it is unreasonable, short-sighted and absurd to allow four-tenths of one per cent. of the State's forests to stand in the way of this great increase of prosperity which lies ready at our hands. In my judgment the State should build these storage reservoirs recommended by the water-supply commission, and should absolutely control them for all time; and I am of the further opinion that a plan can be devised by which the State can derive an income fairly sufficient, in a comparatively short space of time, to pay the cost of constructing the dams and reservoirs and have a considerable surplus to go into the State treasury for the support of the general government. The "U. S." Tube Blower

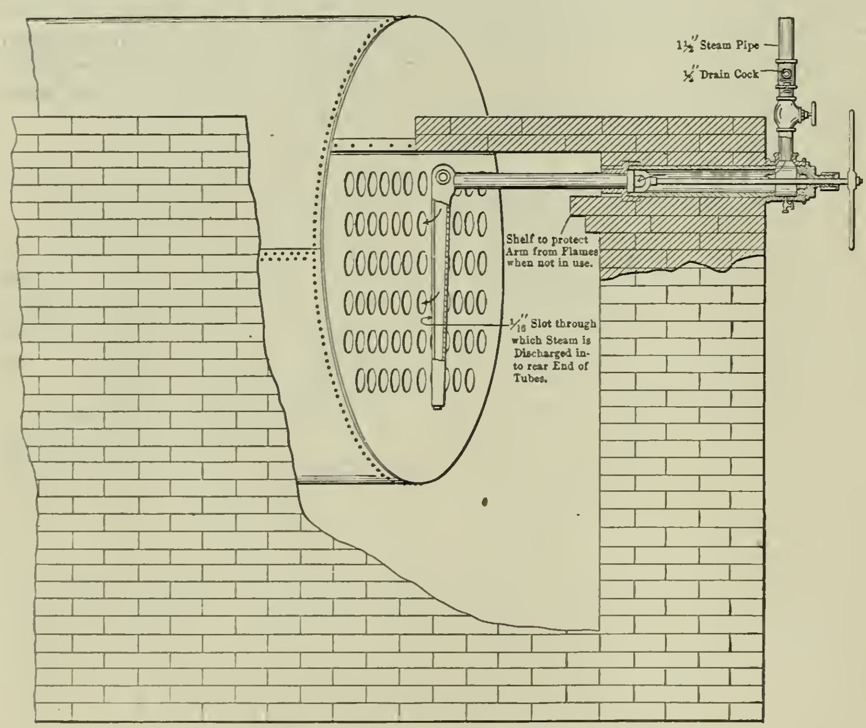
This is a device for blowing soot out of boiler tubes *with* the draft. A casing passes through the rear wall of the boiler setting, and a T-shaped cast chamber outside the wall receives a 1½-inch supply pipe. Directly under this pipe in the chamber is a drain cock to dispose of the condensation, and on the end of the chamber is a stuffing box, through which the handle rod passes to an inner tube which just fills the casing.

On the end of this tube is a hollow cast-iron arm, one-half the diameter of the boiler in length, having a 1/16-inch slot its entire length on the side toward the boiler. By pushing the rod endwise this arm is pushed close to the rear end of the tubes into which the steam is delivered in a thin sheet. By means of a handle secured to a rod the arm may be revolved so it reaches all of the tubes.

The blower can be used while running, and when not in use the arm is pulled back and placed in a horizontal position on a shelf, where it is not exposed to the heat.

This tube blower is manufactured by the U. S. Specialty Manufacturing Company, People's building, Pittsburg, Penn.



POSITION OF U. S. TUBE BLOWER WHEN IN USE

"Anti-Rust"

A preparation which has been successfully used for preventing rust is known commercially as "Anti-Rust," prepared for the market by F. L. Melville, 192 Front street, New York City. This product is semiliquid in form, easily applied and not affected by changes of temperature, it is said. It is readily removed from the surface treated without resorting to the use of benzine or other cutting agents. "Anti-Rust" is said to have given good results under all manner of severe tests, notably in the protection of iron from the corroding influence of salt water and in long continued open-air tests.

Little Giant Tube Cleaner

The "Little Giant" tube cleaner, which is made by the Poole Manufacturing Company, 310 Broadway, Albany, N. Y., is shown herewith. It is a mechanical cleaner, the head of which is driven for-

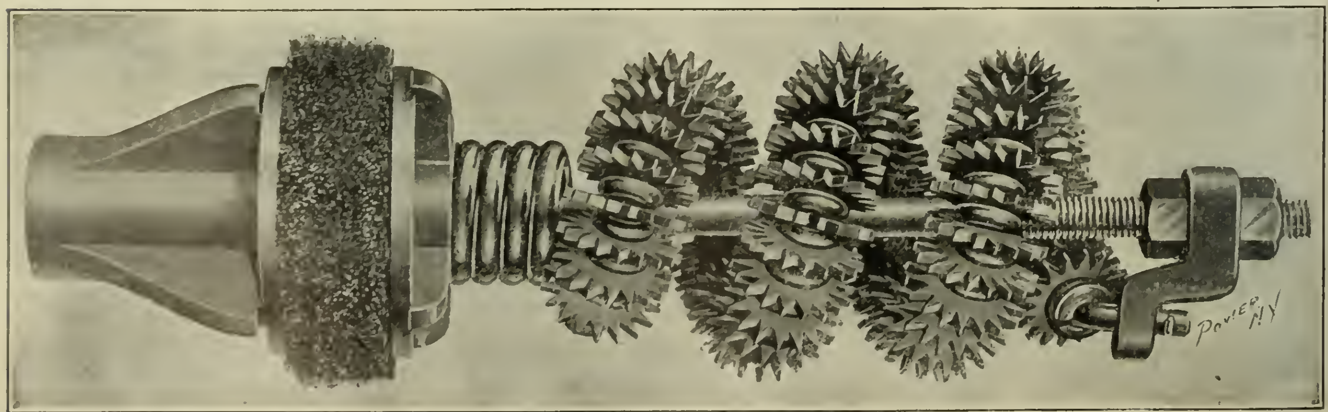


FIG. 1. TYPE OF CLEANER USED IN FIRE-TUBE BOILERS

ward by a spline shaft set in the hollow shaft of a rotary engine.

Fig. 1 shows the type of cleaner used with fire-tube boilers. The spiral portion is composed of small cutters which cut the scale, while the brush at the inner end pushes the loosened deposit out of the tube.

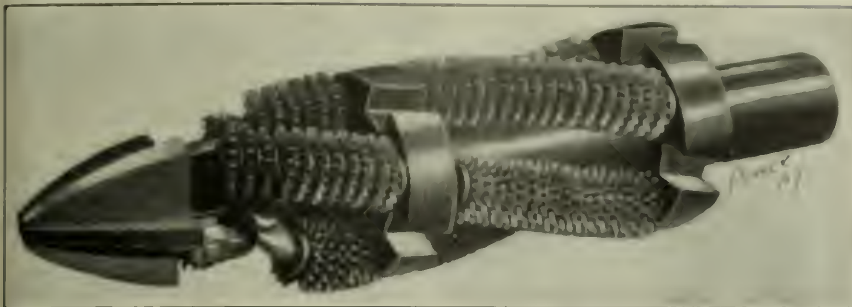

FIG. 2 CLEANER USED FOR WATER-TUBE BOILERS

Fig. 2 shows the cleaner for water-tube boilers. This cleaner is composed of a number of cutting wheels, and a cutting head. The cutting wheels, as they are revolved in the tube, remove the scale or accumulation by coming into direct contact with it. It is claimed that this cleaner does its work in a remarkably short time and is very effectual in its operation.

Ames Alloy Sheet Packing

A new kind of high-pressure sheet packing has been placed on the market, known as the Ames alloy high-pressure sheet packing, manufactured by the United States Indestructible Gasket Company, 16 South William street, New York City.

This packing, as its name implies, is ordinarily made in sheet form in thicknesses of 1/64, 1/32, 1/16 and 1/32 inch and up to 48 inches wide, but other thicknesses may be had. It is suitable for use on flanges, valves, steam chests, etc., or where the ordinary type of sheet packing is used.

It is claimed that this packing does not melt under about 700 degrees Fahrenheit and that it has been tested up to 6000 pounds pressure, which would make it suitable for the highest steam or hydraulic work. It is claimed that it does not stick to flanges or patches when the joint is broken, and that it will not disintegrate, dry out nor crack if subject to months or years of standing in stock or service. It is also claimed that it is suitable for use in contact with oils, acids, heat, gas fumes and steam, and is waterproof. It is easily cut, it only being necessary to make a pin scratch on each side of the packing which, when bent, easily breaks to the desired shape.

The Zenith Rear End Flue Blower

Herewith is illustrated a new flue blower to be attached to the combustion chamber, and which is arranged to be withdrawn from the influence of the hot gases when not in use. The device is made by the Zenith Manufacturing Company, of Duluth, Minn., and its construction is shown in Fig. 1.

It consists of a hollow casting with a packing nut at each end through which passes a hollow rod having a handle attached. The inner portion of the rod, which has a length equal to the radius of the tube sheet, is perforated with holes corresponding to the tubes of the boiler and swings on a steam-tight joint. The steam enters the joint to the hollow rod and, by turning the handle, all the tubes are cleaned by a jet of steam, and the soot is blown out in the same direction as the draft in the boiler.

Fig. 2 shows the blower in operation on a return-tubular boiler, and Fig. 3 shows it withdrawn from the combustion chamber. When not in use all parts of the apparatus are removed from the influence of the heat and gases, and a disk on the end of the blower closes the aperture through which the swinging joint is inserted. F. M. Harmon, 80 East One Hundred and Seventeenth street, Cleveland, O., is agent for the Zenith blower.

Ladies' Night in Brooklyn

Brooklyn Association No. 8, National Association of Stationary Engineers, held a social session on Saturday evening, March 6, to which the ladies were invited, in the rooms of the association; and as many more of the fair sex came than were expected the rooms were overcrowded. The next ladies' night should be held in a larger hall. Frank Martin acted as master of ceremonies and introduced the following entertainers: "Bert" Self, Frank Corbett, "Joe" McKenna, "Billy" Murray, "Jack" Armour, "Dan" Quinn, Harry Elder, "Joe" Matier, Charles Kronland, "Jack" Tracy, N. H. Kenney and G. J. Sullivan. Refreshments were served.

James O. Westberg was chairman of the committee of arrangements.

Business Items

The Ohio Blower Company, of Cleveland, Ohio, includes among its recent sales three oil separators, eight steam separators and six cast-iron exhaust heads.

The American Fire Brick Company, Spokane, Wash., has given an order to the Minneapolis Steel and Machinery Company for a 20x42 heavy-duty Twin City Corliss engine, to be installed in its new plant at Mica, Wash.

Recent large orders taken by the Crocker-Wheeler Company, of Ampere, N. J., include eight generators of various types, with capacities ranging frm 50 to 800 kilowatts; eight motors for printing presses, three for elevators and a 40-horsepower induction motor.

"High-grade Petroleum Grease Lubrication" is the title of a 4-page (with stiff paper covers) pamphlet just issued by the Keystone Lubricating Company, of Philadelphia. It is devoted to contrasting some of the advantages, or disadvantages, in the use of oil for lubrication with those of grease.

The engineer of the Schauss Manufacturing Company, Toledo, Ohio, W. F. Brubaker, writes to the Buckeye Boiler Skimmer Company, South End, Toledo, Ohio, and says: "The floating skimmers you placed in our McNaull boilers are certainly all right. I ran six weeks without cleaning, and on opening the boilers I was surprised to find clear water in the bottom of the front water leg, which I expected to find half full of mud. The boilers were absolutely clean all through."

The DuBois Iron Works, manufacturer of DuBois gas engines and steam and power pumps, has been awarded the contract for the complete equipment and installation of the pumping station for the Clarion water works, Clarion, Penn., the machinery purchased consisting of one 150-horsepower Du Bois tandem natural-gas engine geared to a million-gallon pump, one 50-horsepower unit for driving the air compressor and one centrifugal pump, together with the necessary fittings, etc. The plant is an auxiliary to the present steam-pumping equipment, which will eventually be replaced by a duplicate of the new gas-engine-driven unit. The engines and pumps will work against a head of 685 feet, pumping through 4000 feet of 10-inch main to the standpipe. A complete new power station is being erected. The DuBois works has also been awarded the contract for a 160-horsepower Twin tandem gas engine, direct-connected to 100-kilowatt generator, for the lighting plant of the seventy-fourth regiment armory at Buffalo, N. Y.

The sales organization of the Northern Electrical Manufacturing Company has, for the purpose of economy, been consolidated with that of the Fort Wayne Electric Works, Fort Wayne, Ind. The Northern company has in the past confined itself to the manufacture and sale of direct-current apparatus, while the business of the Fort Wayne company has consisted very largely of alternating-current apparatus. In putting these two lines of product into the hands of one combined sales organization they are adding greatly to the efficiency and capability of each salesman, and are also making it more convenient for the public. They wish to make it particularly clear that the manufacture of present designs will be continued and that particular attention will be given, as in the past, to manufacturing and carrying at Madison a large stock of repair parts as well as completed machines. They confidently expect the result of this arrangement will be greater satisfaction to their joint customers and a steady increase in the volume of business of the respective plants.

New Equipment

A. H. Deiters and B. Davis, owners of the electric-light plant at Dickinson, N. D., are considering plans for erecting an addition and the installation of two more boilers.

The Terre Haute, Indianapolis & Eastern Traction Company, Terre Haute, Ind., is planning to increase the output of plant. New steam turbine boilers, etc., will be installed.

The Albert Lea (Minn.) Light and Power Company has planned extensive improvements at its plant which will include installation of new generator, transformers, boilers, etc.

Help Wanted

Advertisements under this heading are inserted for 25 cents per line. About six words make a line.

AN ENGINEER in each town to sell the best rocking grate for steam boilers. Write Martin Grate Co., 281 Dearborn St., Chicago.

WANTED—Thoroughly competent steam specialty salesman; one that can sell high-grade goods. Address "M. M. Co.," POWER.

WE WANT REPRESENTATIVES to handle metallic packing in Pittsburg, Cleveland and Cincinnati. National Metallic Packing Co., Oberlin, O.

WANTED—For the engineering department of a manufacturing establishment building hydraulic machinery, a young man, college graduate with one or two years' shop and drawing room experience; one that will develop into an engineering salesman. State age, experience, education, wages to start, and send samples of drawings. Box 9, POWER.

Situations Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

MANAGER, sales manager or traveling commercial engineer; 20 years' experience electrical and mechanical lines. M. F. Harwood, 20 Howard Place, Jersey City, N. J.

POSITION WANTED anywhere by engineer with Massachusetts license; experienced hotel and power station work, a.c. and d.c. generators, absorption and compression ice machines. Box 10, POWER.

YOUNG MAN, four years' technical college training in department of mechanical engineering, wishes to hear from consulting engineers' establishment desirous of such a man to enter their services. Box 8, POWER.

Miscellaneous

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

WANTED—Second-hand, 60-cycle, single phase motors, ½ to 5 H.P., 110 or 220 volts. The Edgerton Electric Lighting System, Edgerton, Ohio.

PATENTS secured promptly in the United States and foreign countries. Pamphlet of instructions sent free upon request. C. L. Parker, Ex-examiner, U. S. Patent Office, McGill Bldg., Washington, D. C.

IN ORDER TO SETTLE an estate, an attractive opportunity is open to a party with $150,000.00 competent to fill responsible position either in the scales or manufacturing department, to purchase an interest in a well and favorably known, profitable machinery manufacturing plant located in Pennsylvania, with an office and established trade in New York City. Address "Executors," Box 3, POWER.

For Sale

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

150 HORSEPOWER tandem compound Corliss engine in good order; 16' wheel; 24-in face. F. W. Iredell, 11 Broadway, New York.

FOR SALE—One 9x12 Armington & Sims automatic high-speed piston slide valve engine. Can be seen in operation until April 1. Studer Bros., Apple Creek, Ohio.

FOR SALE—20x48 Wheelock engine and two 72"x18' high pressure tubular boilers in good condition cheap. Address "Engineer," Box 2, Station A, Cincinnati, Ohio.

SECOND-HAND MACHINERY FOR SALE—Engines, milling, linseed and cotton seed oil mill machinery. Write us for description and prices. Indiana Machine and Supply Co., 203 Ingalls Building, Indianapolis, Ind.

ONE 14x36 Vilter Corliss engine, with 7 tandem air compressor; one 14x36 Nagle Corliss engine. Can be seen under steam. Guaranteed in first-class condition; selling on account of change in equipment. Ontario Silver Co., Muncie, Ind.

Characteristics of the Turbine Pump

A Study of the Design and Operation of Centrifugal Pumps by Means of Curves Characteristic of the Head, Power, Efficiency and Speed

BY FREDERICK RAY

The modern centrifugal pump has taken a position of ever-increasing importance among the various types of pumping machinery of the world, and in the last few years its field of usefulness has increased from one of limited extent and small importance to one that embraces almost every pumping service. While as already stated, the recent achievements of the centrifugal pump have been great, there is every reason to believe that the future holds in store still greater ones than have yet been recorded.

Since the modern centrifugal pump is the growth of a very few years and is the result of scientific design on the part of a few engineers, among the general engineering public there is still to be found a great deal of ignorance as to the real merits, capabilities and limitations of this type of pump.

CHARACTERISTIC CURVES

It is the purpose of this article to bring out and discuss various points in the design and operation of centrifugal pumps that must be clearly understood in order properly to select the most suitable type of pump for any particular service and to operate it most efficiently when in service. The operation of almost any type of machine can be most easily illustrated and understood by means of plotted curves showing the relations between the variables entering into the problem under consideration. With the centrifugal pump [illegible] tion between capacity and power, and one between capacity and efficiency.

Fig. 1 shows such a set of curves derived from the test of a [illegible] single-stage turbine pump operating at the constant speed of [illegible] revolutions per minute, a photograph of which is shown in Fig. 4. In this case the curve marked "Head" shows the variation of total head, which is the sum of the heads on the suction and discharge of the pump as the capacity is increased [illegible] up to the maximum quantity of water that can be forced through the pump with the discharge wide open. The curve marked "Brake Horsepower" shows the variation in the power required to [illegible] the pump [illegible] as the output is increased, while the curve marked "Efficiency" shows the variation in the efficiency of the pump under the same conditions.

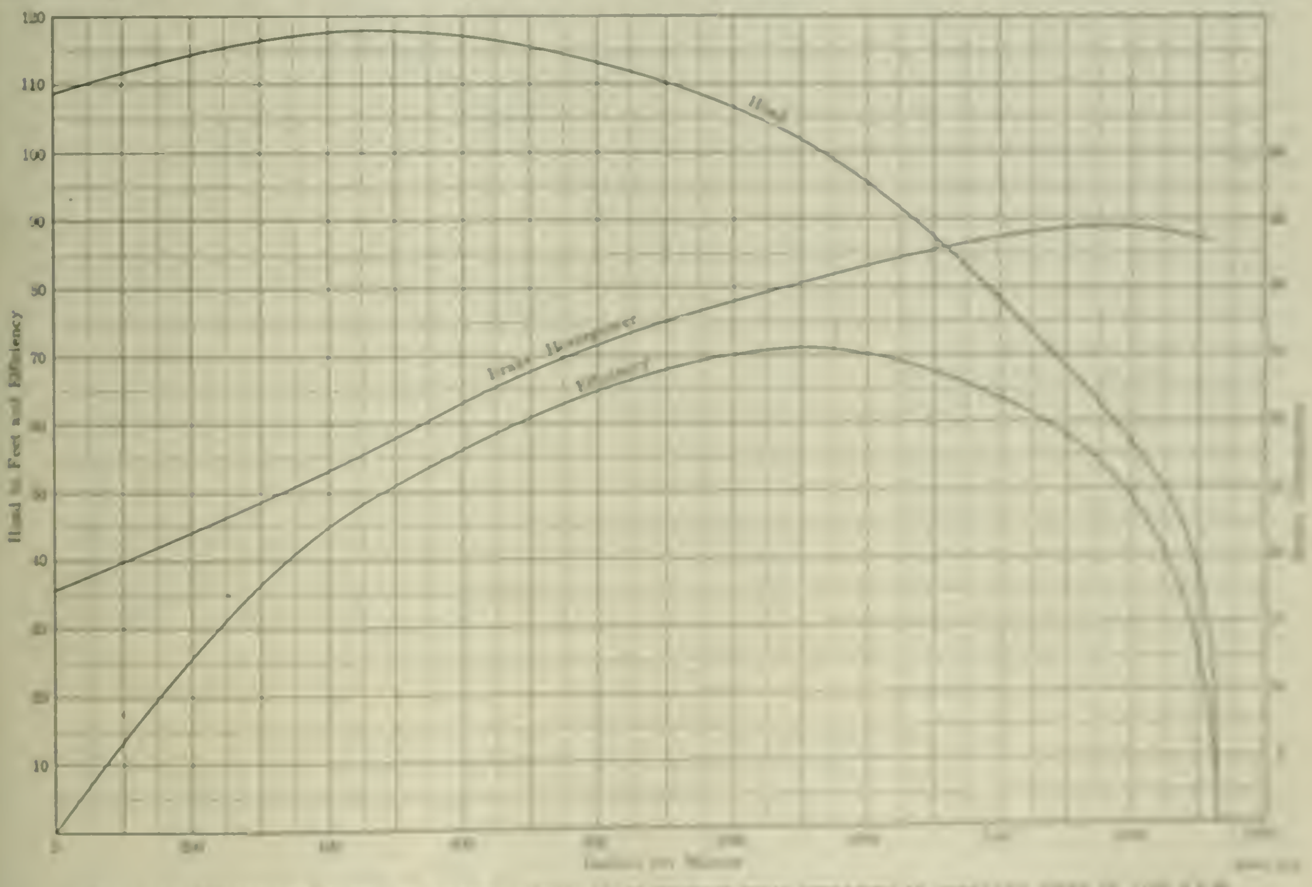

FIG. 1. CHARACTERISTIC CURVES OF [illegible] SINGLE-STAGE TURBINE PUMP OPERATING AT CONSTANT SPEED OF [illegible] R.P.M.

Head Curve—From this curve can be obtained the total head against which the pump is capable of delivering any given quantity of water when operated at a speed of 1125 revolutions per minute, and conversely, if the pump was operated at this speed and gages on the suction and discharge were read, it would then be possible to determine the amount of water being pumped. In addition to this, directly below the point on the curve representing the head would be found a point on the curve of brake horsepower giving the power being consumed; and in the same vertical line a point on the efficiency curve would show the efficiency with which this power was being utilized. It is thus plain that if a pump can be tested in the shop or elsewhere, where suitable apparatus is available, and a similar set of curves plotted from the results, a complete guide is obtained for the efficient and satisfactory operation of the pump in actual service.

Examining the head curve, it is seen that with the discharge closed, when the water in the pump is simply being revolved around, the head generated amounted to 109 feet. As the discharge valve was gradually opened, this head increased until at a capacity of 500 gallons per minute the head amounted to 118 feet, and from there on it gradually decreased until at 930 gallons per minute it again amounted to 109 feet. Thus for every point on the head curve between these limits, there are two different capacities at which the pump can operate.

From the foregoing it might appear that there would be some unstableness about the operation of the pump within these limits, and so there would be if it was not for the balancing action of pipe friction, which usually amounts to a considerable part of the total head. It is readily seen that if the pump was discharging directly into a large standpipe, so that the pipe friction was negligible, and the top of this standpipe was gradually raised until the total head became slightly over 118 feet, the discharge would immediately cease, and it would be impossible again to start it until the head was reduced below 109 feet. If, however, the static head was less than 109 feet, then by introducing friction into the discharge, by throttling, until the head became 118 feet, there would be no such sudden decrease in the capacity, as this friction head being a function of the capacity, automatically maintains a running balance, and by adjusting the throttle it is possible to operate the pump at any point on the curve with absolute stability. As the proper head to operate this pump against is about 100 feet, where the maximum efficiency is obtained, there would consequently be under such conditions none of the above difficulties.

On following this curve still farther, it is seen that the head drops to zero when a capacity of 1730 gallons per minute is reached, at which point the whole of the head generated by the pump is consumed within the pump itself and none is available for useful work.

Power Curve—This is also of great importance as the efficiency of the pump and the cost of operation depend directly upon the power consumed. In addition to this the power curve furnishes the data from which a proper selection of the driving motor can be made, and shows the load that the motor will have to carry under any condition.

In Fig. 1 the power curve shows that it required 18 brake horsepower to drive the pump at a speed of 1125 revolutions per minute with the discharge entirely closed, and from this point the power gradually increased, as the capacity was increased, in nearly a straight line until it reached a maximum of 44.5 brake horsepower at a capacity of 1550 gallons per minute. It then decreased slightly to 43.5 brake horsepower at the full capacity of the pump. From this it may be seen that it would be impossible to overload a motor of 40 or 50 horsepower to any great extent, by either a stoppage or breakage of the discharge pipe. Since at all points below 1550 gallons per minute the power decreases with a decrease in capacity, power may be saved by throttling the discharge so as to allow no more water to flow through the pump than actually required. Beyond the point of maximum power it would be more economical to let the pump discharge as much as possible, but as this point is rather beyond the proper operating conditions and the gain or loss in power is slight, this point would not be of much importance in this case.

There are, however, some designs in which the power curve would reach a maximum at a point corresponding to the normal working capacity, or even less, and under these conditions a power curve might be of considerable importance as a guide to economical operation.

Efficiency Curve—The efficiency is generally the one point about a centrifugal pump which receives the particular attention of the purchaser, with the result that most manufacturers are using every effort to produce pumps of the very highest efficiencies. High efficiency is naturally a desirable feature, but the other characteristics are often of nearly equal importance.

In Fig. 1 the efficiency curve starts from zero, at zero capacity, which must always be the starting point, as the pump does no useful work until it discharges water, although it consumes power which is entirely wasted in friction. As the capacity increases, the efficiency gradually increases until it reaches a maximum of 71 per cent. at a capacity of 1100 gallons per minute and then decreases to zero again at the full capacity of the pump, where again there is no useful work performed, as the head against which the water is pumped is zero. This particular curve shows many desirable features

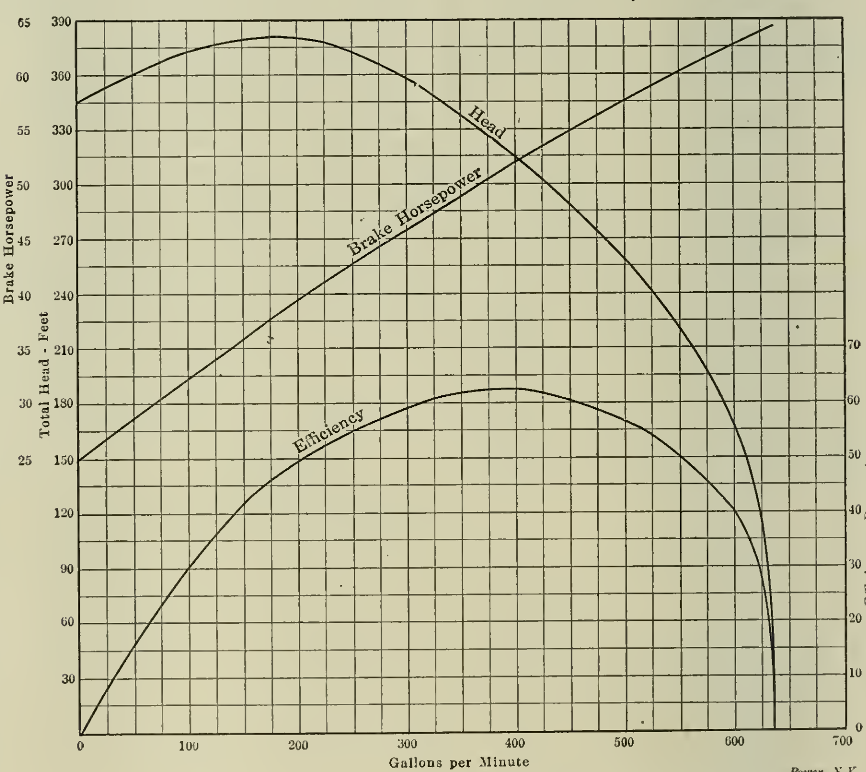

FIG. 2. CURVES FROM 5-INCH THREE-STAGE PUMP WITH SPEED OF 1788 R.P.M.

in its general form inasmuch as it has a steep inclination at its beginning with a flat top and a steep ending, and incloses a large area. Steepness at the beginning shows that the efficiency comes up quickly as the capacity increases, while a flat top and a steep ending show that the efficiency is maintained high over a wide range. Since the average efficiency is obtained by dividing the area below the curve by the length of the base, it follows that the greater the area for any given length, the greater is the average efficiency. The average efficiency in this case is 50.6 per cent. which is considered by the writer to be considerably above the ordinary for these conditions.

each at a pressure of nearly [illegible] pounds; and it would even be possible to get three very good streams at a pressure of [illegible] pounds. Such a range as this should certainly be sufficient to meet the conditions that would be apt to occur at any fire, and is much superior to what could be obtained with a positive displacement pump of the same normal capacity, especially if driven by a constant-speed motor. In addition to this the power curve shows that the motor could only be overloaded 7 per cent. if all the hose lines should burst, and the head curve shows that if all the nozzles were shut off no injurious pressure could result. The efficiency of 62.5 per cent. obtained with this pump,

[illegible] per cent. while the other characteristics retain a desirable form.

Fig. 5 shows the characteristics of the standard [illegible]-inch two-stage Underwriter pump which has a normal capacity of [illegible] gallons per minute against a pressure of [illegible] pounds. In this size of pump the efficiency is over [illegible] per cent., but otherwise the curves show the same general form. Fig. 6 is a photograph of this pump direct-connected to a [illegible]-horsepower direct-current motor, and shows the fittings furnished with the pump as called for by the Underwriter specifications.

These curves, which have been plotted from actual tests, show clearly that the centrifugal pump is well suited for fire

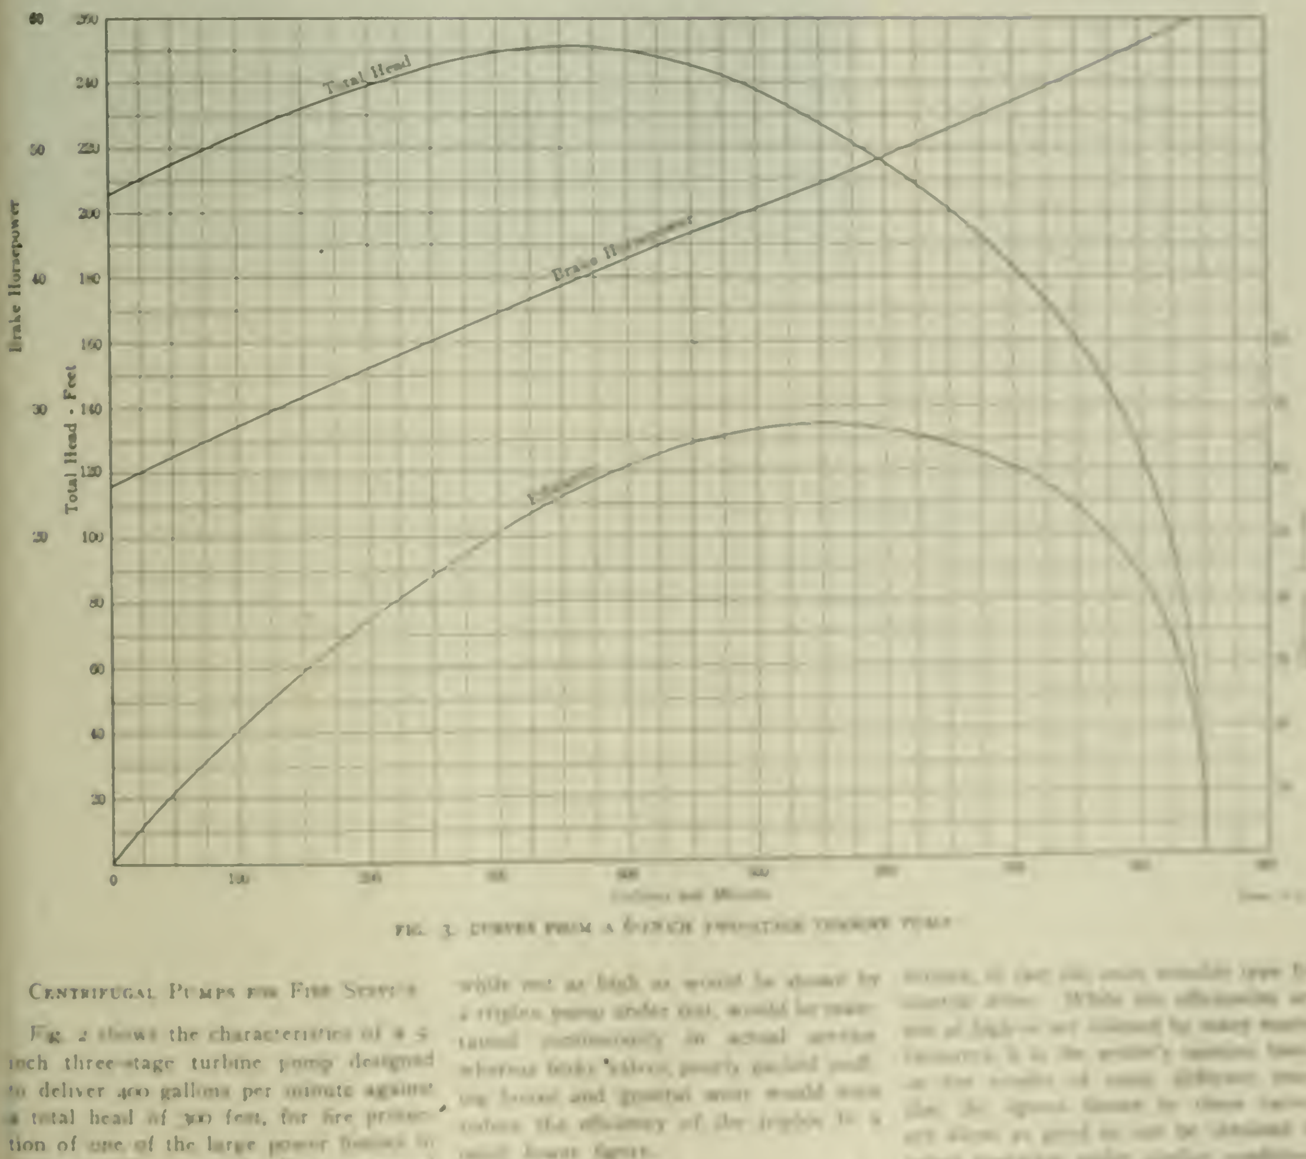

FIG. 3. CURVES FROM A [illegible] TURBINE PUMP

CENTRIFUGAL PUMPS FOR FIRE SERVICE

Fig. 2 shows the characteristics of a 5-inch three-stage turbine pump designed to deliver 400 gallons per minute against a total head of 300 feet, for fire protection of one of the large power houses in Chicago. The pump is direct-connected to a 60-horsepower 60-cycle induction motor, operating at a synchronous speed of 1800 revolutions per minute. The head curve of this pump shows that it would deliver one fire stream of 250 gallons per minute at a pressure of 160 pounds, two streams of about 200 gallons per minute each at a pressure of 125 pounds, two streams of 250 gallons per minute

while not as high as would be shown by a triplex pump under test, would be maintained permanently in actual service, whereas leaky valves, poorly packed stuffing boxes and general wear would soon reduce the efficiency of the triplex to a much lower figure.

Fig. 3 shows the characteristics of a 6-inch two-stage turbine pump designed for [illegible] gallons per minute, against a pressure of [illegible] pounds, for standard Underwriter conditions for this size of pump. Fig. 4 is a photograph of this pump direct-connected to a [illegible]-horsepower motor. From Fig. 3 it may be seen that the maximum efficiency has increased to

[illegible] While the efficiencies are not as high as are claimed by many manufacturers, it is the writer's opinion, based on the results of many different tests, that the figures shown by these curves are about as good as can be obtained in actual practice under similar conditions [illegible]

The [illegible] of the centrifugal pump for fire service was [illegible] several years ago [illegible] sign and installation of pumps for this service, with the result that centrifugal pumps whose design and manufacture have been passed on and approved by the Underwriters are accepted by them for fire protection on an equal basis with any other type of pump. This has led to a considerable demand for such pumps, and from present indications it will not be many years before the centrifugal will be the leading type of Underwriter pump.

With the exception of Fig. 1 all the curves shown are taken from pumps that were designed for fire service, but they are equally applicable to the usual design of pump for similar conditions. They are all very similar in their general form and represent a design of impeller that is well adapted to give high efficiency under the usual conditions that have to be met by such pumps. It is often necessary, however, to meet special conditions where sometimes the maximum head must be kept to within a few per cent. of the normal working head and at other times just the reverse is wanted, and by suitable design either of these conditions can be readily fulfilled. A pump designed to meet the first of these conditions would in general have a greater maximum capacity and a power curve of greater steepness and range than those illustrated. The point of maximum efficiency would also be apt to occur at a greater capacity. For the second condition the

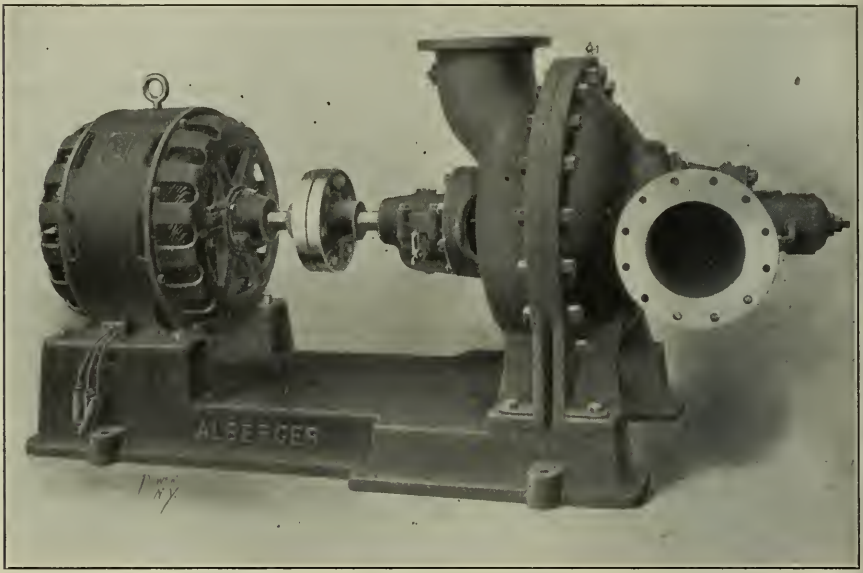

FIG. 4. ALBERGER 10-INCH SINGLE-STAGE TURBINE PUMP

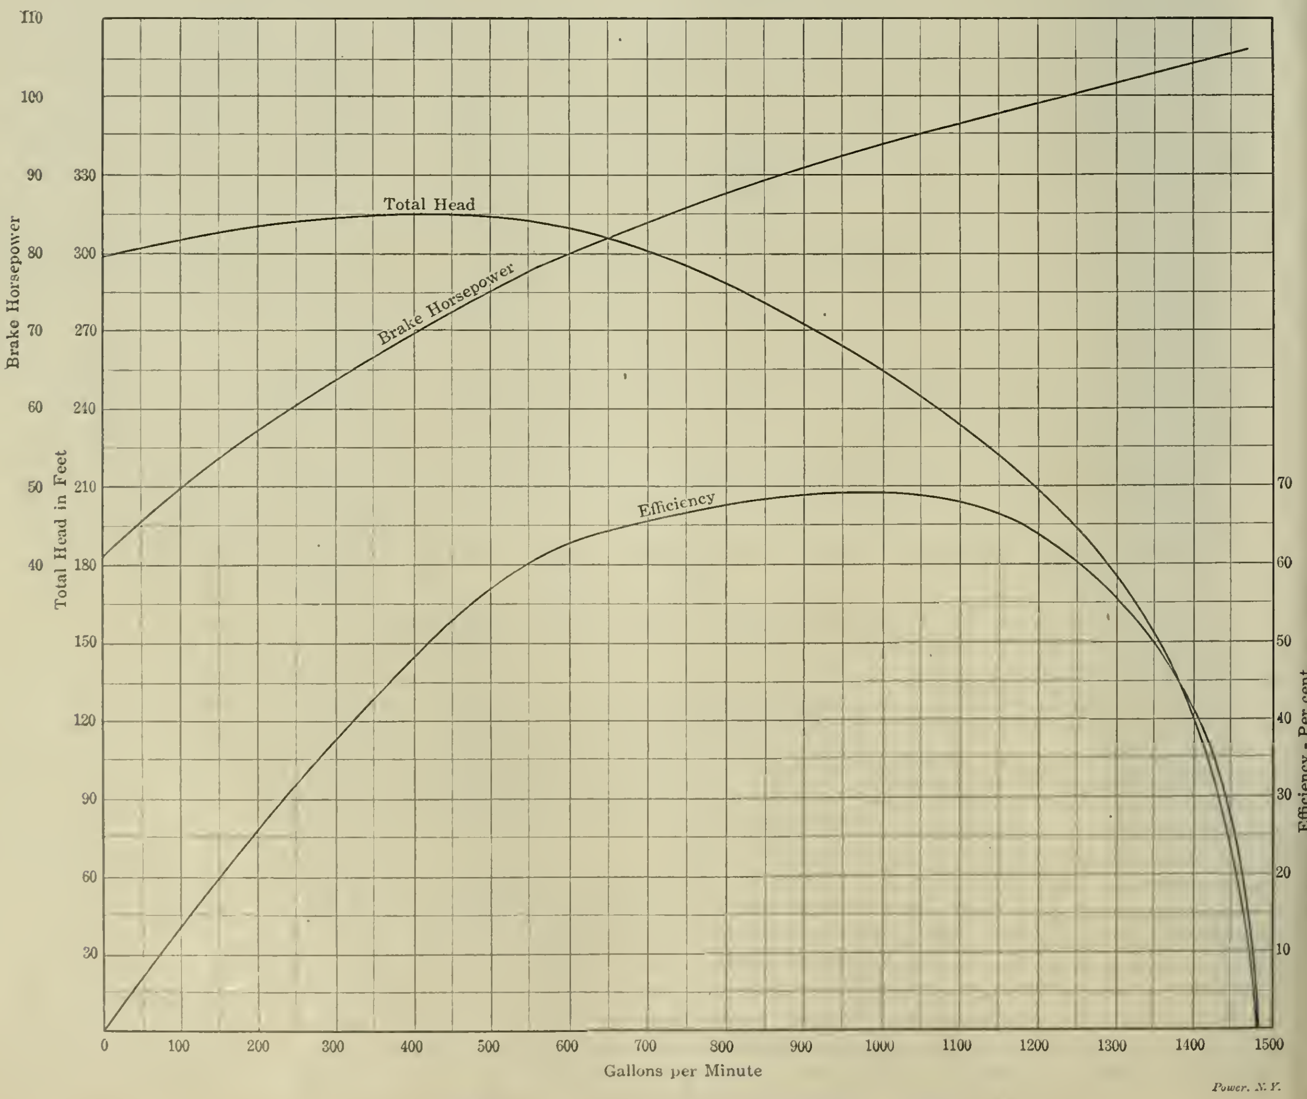

FIG. 5. CURVES FROM 8-INCH TWO-STAGE PUMP WITH SPEED OF 1400 R.P.M.

maximum capacity would be less, the power curve would become more nearly horizontal, showing a greater consumption of power at zero capacity and less at maximum capacity, while the point of maximum efficiency would occur at less capacity. From this it is seen that a horizontal head curve means a steep power curve, while a steep head curve results in a horizontal power curve.

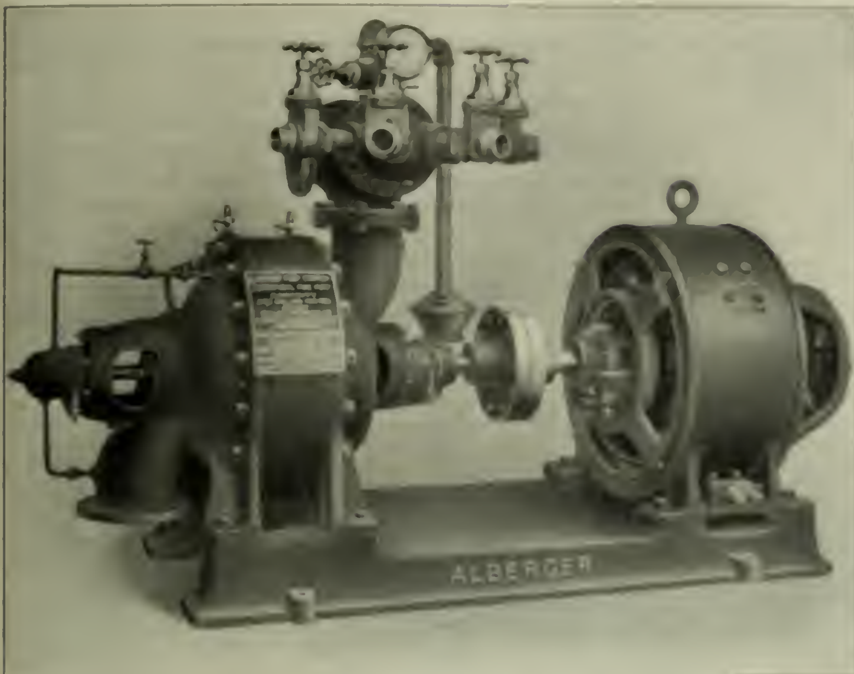

FIG. 6. TWO-STAGE 8-INCH UNDERWRITER FIRE PUMP

REGULATION OF CAPACITY AND HEAD

Another point of great importance is the regulation of the capacity and head of a centrifugal pump. There are three methods of doing this: by varying the speed, by throttling the discharge and by varying the number of stages. Varying the number of stages in a single self-contained pump is the most complicated and troublesome to work out in a satisfactory manner, and is practically used only in connection with mine-sinking pumps which are used under widely varying heads. This method is very satisfactory where the additional stages are contained in a separate pump independently driven, and is much used for city water-works service where increased pressure is required for fire service. Where the extra stages are contained within the same pump, it is almost impossible to make the design so that the idle impellers will not be churning in water, and without accomplishing this, this method of regulation is not of much value.

Throttling the Discharge—The results to be obtained by throttling are

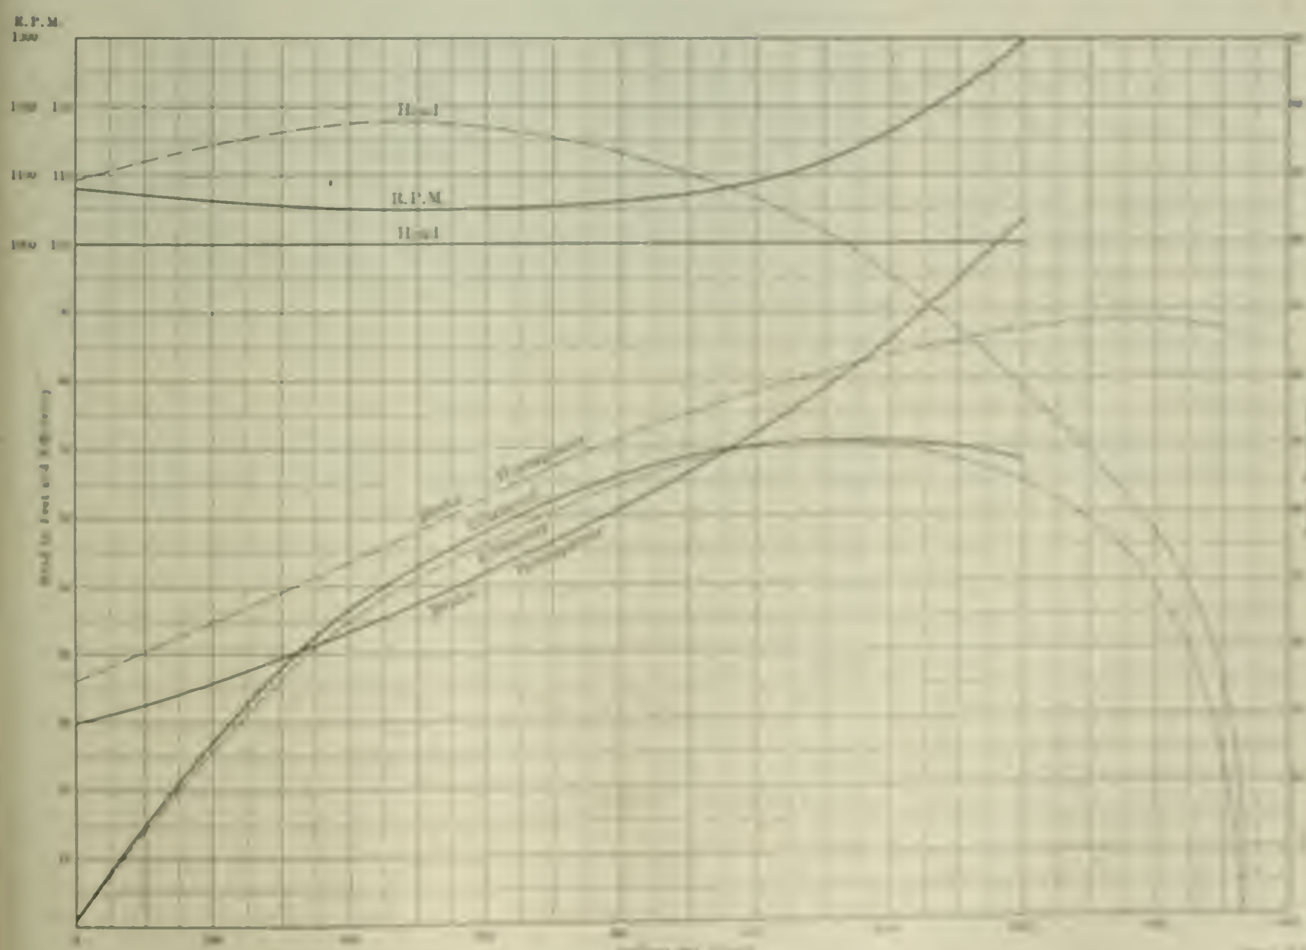

FIG. 7 [illegible]

shown by the curves already given. Thus for any given speed the power used depends only on the quantity of water flowing through the pump, since the head that the pump generates depends only on the quantity being pumped. This head can be utilized or wasted in the throttle valve as may be necessary, but whichever way the head is utilized the action of the pump is the same. If all the head is utilized the efficiency with which the water is being pumped is given by the corresponding point on the efficiency curve, but if any of the head

$$0.65 \times \frac{100}{113} = 57.5 \textit{ per cent.}$$

This same result can be obtained by calculating the water horsepower of 800 gallons per minute against 100 feet and dividing by the corresponding brake horsepower from the curve. By making similar calculations on the several curves that are illustrated it can be readily seen that the objection to this method of regulation is the considerable loss in the efficiency of pumping that results therefrom.

mark instead of the curve shown in Fig. 1. There has also been introduced a new curve marked "R.P.M." which gives the revolutions per minute required for any given capacity against the constant head of 100 feet. The power and efficiency curves are also changed, as is apparent by a comparison with the original curves reproduced in dotted lines.

On looking at the speed curve, it is evident that to generate a head of 100 feet without delivering any water requires a speed of about 1080 revolutions per minute. As the capacity is increased the

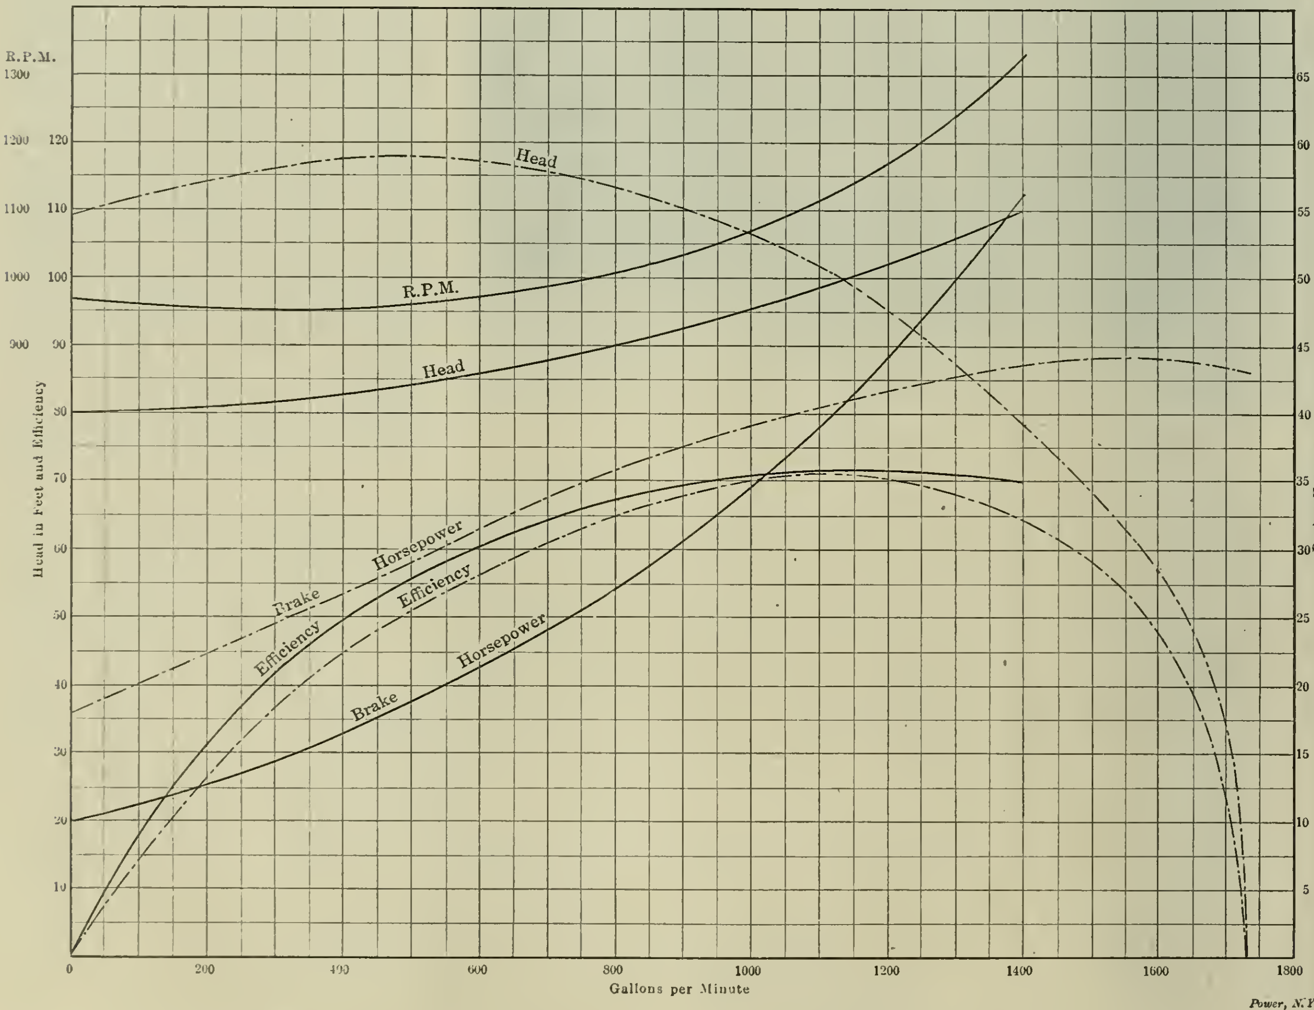

FIG. 8. SINGLE-STAGE 10-INCH PUMP OPERATING AGAINST A COMBINED STATIC AND FRICTION HEAD

is being wasted in the throttle valve the above efficiency must be multiplied by another factor whose value is the ratio of the total head utilized to the total head generated. To illustrate this point with an example, take Fig. 1 and assume that this pump is operating against a steady head of 100 feet and that it is required to find the efficiency with which it is possible to pump 800 gallons per minute. From the curves it will be seen that the efficiency of the pump itself is 65 per cent. and the total head generated is 113 feet. Consequently the efficiency of pumping is

Speed Variation—Undoubtedly the best method of regulating the capacity of a centrifugal pump is by means of speed variation, and as the proper selection of the method of control is of great importance, it seems well worth while to discuss the matter thoroughly.

Fig. 7 shows the characteristics for the same pump as those in Fig. 1, derived from the results there illustrated on the assumption that the total head remains constant at 100 feet while the capacity is varied by varying the speed. On this assumption the head curve becomes the horizontal straight line at the 100-foot

speed required gradually decreases until it reaches a minimum of 1050 revolutions per minute at a capacity of 450 gallons per minute, which also corresponds with the point of maximum head under constant-speed operation. From this point on, the speed gradually increases until at a capacity of 1130 gallons per minute it has reached a value of 1125 revolutions per minute, at which point the original head curve crosses the 100-foot mark, as would be expected. As the capacity is still further increased, the required speed increases at a more rapid rate until at a capacity of 1400 gallons per minute it becomes 1300 revolutions per minute and would continue to increase in the same curve until the maximum capacity of the pump is reached, beyond which it would be useless to go farther as it would be impossible to pump more water at any speed whatsoever.

The power curve is seen to have changed its form materially, becoming much steeper, so that the power at capacities less than 1130 gallons per minute is considerably less than at constant speed, while at greater capacities it increases rapidly. Below the intersection with the former power curve the power required is less, due mostly to the fact that less work is being done by the pump, but also due to the better efficiency with which the work is done, as is shown by the efficiency curve. Beyond this intersection the increase in power is entirely due to the increased output of the pump, since from the efficiency curve it may be seen that the efficiency under these conditions is considerably better than at constant speed. It is seen by comparing the new with the old power curve that it would take as much as 25 per cent. more power at some points to drive the pump at constant speed and decrease the capacity by throttling than would be necessary to secure the same capacity by means of speed regulation. The efficiency curve is flatter with as high or higher efficiency at every point and consequently includes a larger area, thus giving a greater average efficiency throughout the range of capacity of the pump.

The conditions illustrated in Fig. 7, which were based on the assumption of a constant total head, are the least adapted to show a saving in power by means of speed regulation, and they are also conditions that practically never occur in actual practice inasmuch as there must always be some frictional resistance to every pumping system making use of pipes to convey the water. In fact in the usual installation the pipe friction generally amounts to at least 10 to 20 per cent. of the static head at normal capacity, and for many services the total head is composed entirely of frictional resistance.

As an illustration the curves in Fig. 8 have been drawn from the data of Fig. 1 based on the assumption that the total head is 100 feet at a capacity of 1130 gallons per minute and that this head is composed of 80 feet static head and 20 feet friction head. Since the frictional resistance varies as the square of the capacity, the head curve can be drawn at once as shown. Having the head curve the speed curve can be drawn and it may be seen that for capacities less than normal the speeds are lower than required for the conditions in Fig. 7. For capacities greater than normal the speeds are higher. The power curve is of the same general shape as in Fig. 7, but steeper, showing that at capacities less than normal still less power is used, while for greater capacities more power is necessary. Under these conditions it is seen that nearly 60 per cent. more power would be required at some points to drive the pump at constant speed and regulate the capacity by throttling. The efficiency curve shows as good or better efficiency at every point and a higher average efficiency throughout.

When the head is entirely of friction, regulation by speed variation becomes even more important if economical results are desired. Under these conditions when the capacity is zero, the head is also zero and the speed required is likewise zero. It will also be found that the capacity will increase directly as the speed, and the head generated by the pump and required to overcome the friction varies as the square of the speed. The efficiency will be found to be nearly constant at all speeds and consequently the efficiency curve would be nearly a horizontal straight line. Therefore, if the frictional resistance is known at any capacity, the head curve can be drawn at once. The speed curve follows immediately, and if an efficiency curve has been determined at any constant speed, the efficiency curve for those conditions can be constructed. The power curve can be derived from these curves, and it will be found that the power varies as the cube of the speed. Since the head varies as the square of the speed and the capacity as the first power of the speed, the output of the pump in work varies as the cube of the speed and is directly proportional to the power input.

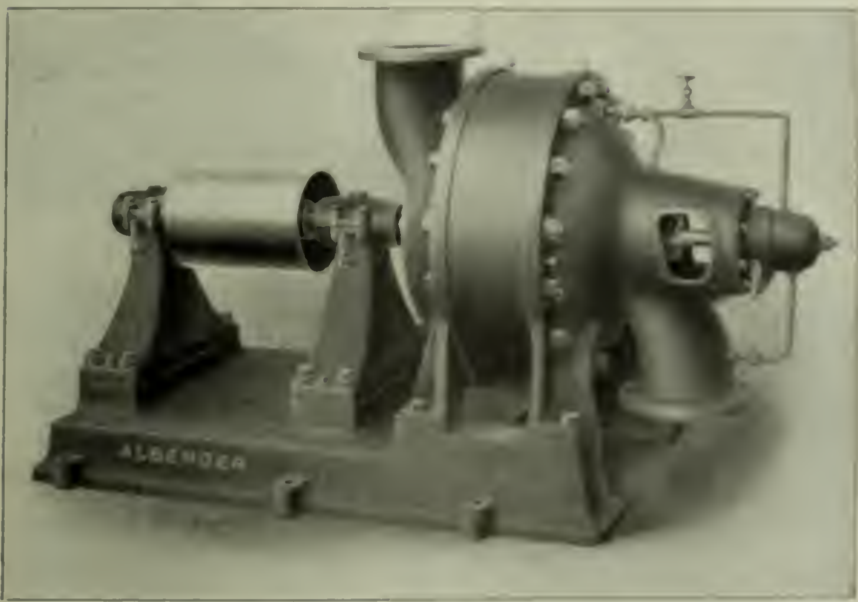

FIG. 9. BELT-DRIVEN PUMP

From the previous illustrations and examples it would appear that the most efficient method of capacity regulation of a centrifugal pump is by means of speed variation. Even in the case where the number of stages is varied, the variation in head or capacity resulting therefrom can only occur in jumps or steps and speed variation is necessary to obtain regulation between these steps. For conditions similar to those illustrated in Fig. 8, which are representative of the majority of cases, a speed variation of 10 per cent. above and below normal will be found to be ample to give all the regulation that is required. This amount of variation can usually be obtained at very slight expense with either electric-motor, steam-turbine or steam-engine drive, and the power saved would in most cases pay for the additional outlay in a very few months of operation.

There are also other reasons which make it desirable to have some variation in the speed permissible, the principal reason being the difficulty of accurately estimating the friction loss in one [illegible] system. There are so many variable factors entering into this problem, such as age of pipe with the resulting incrustations in the interior, effect of elbows, bends and other fittings, that no one can hope to calculate the friction exactly. The average run of engineers who have had no particular experience in this line almost invariably underestimate the friction loss, while those of more experience estimate the results so closely [illegible] not allow enough to insure being on the safe side.

The result of the first method is that when the pump is installed it is found to be short on capacity which on the application of gages to the suction and discharge is found to be due to the head being greater than that for which the pump was designed. If the speed cannot be increased, the only way out of the difficulty is to design a new impeller for the pump, and in some cases where the first impeller was as large as could be used in the pump, it might be necessary to purchase an entirely new pump.

The second method tends toward a pump designed for a head greater than actually exists, with the result that on installation the pump discharges too much water, the motor consumes too much power and the efficiency is low. The pump designer generally aims to be safe on capacity so that usually the pump is a little over capacity at the required head. In designing a centrifugal pump it is difficult to obtain results within a few per cent. of the calculated, and in fact two pumps made from the same design seldom operate the same, owing to differences in castings and machine work. Generally the error from this source, in a standard pump with which the designer is perfectly familiar, would not be serious, and an error of 5 per cent. or less either way in the capacity at the stipulated head should be considered satisfactory for commercial work. These errors are entirely eliminated by a small variation in speed either way from normal, and on this account alone, provision for speed regulation is well worth the expense of procuring.

Mechanical Features

While it is of great importance that the characteristics of any given centrifugal pump should be suitable for the work it is to do, it is of equal importance to have the mechanical design properly carried out. The most important mechanical features of a centrifugal pump are probably the shaft and bearings. The shaft must first be of sufficient size to transmit the necessary power from the coupling to the impeller. As it is also required to support the impeller or impellers in practically a central position at all speeds, it must have the necessary stiffness, so that neither the weight of the impellers nor the centrifugal forces due to their slightly unbalanced masses will deflect it to any appreciable extent. It must also be properly supported in bearings of such design and size that perfect rotation of the shaft will be maintained for a long period of use. Such bearings must be entirely separated from the water passages of the pump, as otherwise it is impossible to maintain lubrication and prevent the grit and sand carried by the water from entering the bearings.

A thrust bearing should also be provided on every centrifugal pump, as no matter how perfectly the thrust is balanced in the design, it will be found in practice that there will always occur a slight thrust one way or the other, and as wear on the impeller occurs this thrust is apt to increase. A properly designed marine type of thrust bearing will easily take care of any such thrust. In fact out of several hundred pumps designed by the writer during the last three years, all of which were similar to the illustrations and provided with the marine type of thrust bearing, there has yet to occur a single case of thrust difficulty.

Another part requiring particular attention is the stuffing box. This should be of ample depth and diameter, so that at least six to eight rings of good-sized packing can be accommodated. The stuffing box on the suction side should always be water-sealed, as otherwise it is impossible to prevent the entrance of air if the pump has much suction lift.

The impellers and diffusion rings in pumps operating under high heads should always be of bronze, as the action of even the purest water on these parts when made of cast iron soon corrodes them away. This action seems to be a chemical one, as it generally occurs at points where no erosion whatever is shown, and furthermore the water has practically no effect on bronze, which would not be the case for ordinary wear.

Flexible couplings should be used between the driving motor or engine and the pump, as otherwise a slight lack of alinement between the two will cramp the shaft so that the bearings will heat and cut out, or they may even bind the shaft tight. Even with flexible couplings the shafts should be in absolutely perfect alinement, as otherwise in time more or less needless wear will be caused on the bearings. Flexible couplings also allow the motor armature to take its proper position in the magnetic field, while any thrust on the pump is taken care of by itself. In addition to these various constructive details, the general design of the pump should be as pleasing and symmetrical as possible without sacrificing any point of utility.

New Power Plant of the L. S. Starrett Co., Athol, Mass.

The recently completed power plant designed by Charles T. Main, mill engineer and architect, Boston, Mass., for the Starrett company comprises a boiler room and coal pocket in one building and engine, generating, condensing and feed-water heating equipment in another. Between these buildings is a small pond, the water level maintained by a concrete dam which practically connects the two portions of the power plant. Through the dam is a tunnel, 170 feet in length, which serves as a duct for carrying both steam and water piping, the steam being carried 400 feet from the boilers to the engines.

FIG. 1. THE NEW STARRETT POWER HOUSE

FIG. 2. COAL POCKET

The boiler room and coal pocket occupy a building triangular in shape and measuring approximately 220 x 150 x 115 feet. The boiler room extends across the end and is about 47 feet in width with a clear hight of about 35 feet. The coal pocket occupies the rest of the building with the exception of the space required for the feed and fire pumps, feed-water well and chimney.

The boiler equipment consists of four Babcock & Wilcox 500-horsepower boil-

[illegible] horsepower primary heater, and back to the boilers. These pumps draw their water from a well which is fed from the pond through a [illegible]-inch pipe fitted with a sluice gate operated from the well-room floor. The fire pumps are also supplied from this well. When necessary, water may be drawn from the city mains at [illegible] pounds pressure.

The engine-room equipment comprises a Brown [illegible]-inch horizontal cross-compound condensing engine direct-con-

[illegible]

The Plunger Hydraulic Elevator

Hand-rope Control for Freight Elevators; Pumps and Connections Used with "Safe Lifters;" Locking Device for Plunger Elevators

BY WILLIAM BAXTER, JR.

Hand-rope Control

Regarding plunger elevators controlled by a simple hand rope and valve there is little information to give except in the matter of manipulating the rope. The valve proper is made substantially the same as this type of valve for other forms of hydraulic elevator, but the distance through which the hand rope is pulled to make a start or stop is slightly greater for the high-speed cars than it is with cable elevators. The reason why the hand rope has to be moved through so great a distance is not, as may be supposed, that the effort necessary to move it may be reduced, but that the valve may not be closed too rapidly by the movement of the elevator car as it approaches the upper or lower landing. In slow-running elevators the stretch of the hand rope upon which the stop balls are fastened passes through the car and by manipulating this rope the elevator is controlled. In high-speed cars both stretches of the hand rope pass through the car and both are handled to control the movement. The advantage of this latter arrangement will be made clear by reference to Fig. 309, which is a vertical elevation of a fast-running plunger freight elevator. The stretch *B* of the hand rope is the one ordinarily used to operate the car, and this is pulled down to cause the car to ascend, and pulled up to cause the car to descend. It will be obvious, however, that if the rope has to be pulled down, say, 15 feet to make the car run upward at full speed, the operator would have a hard time doing it unless he were extremely quick in his movements; the first pull of the rope might not draw it down more than 3 or 4 feet, which would be sufficient to set the car in motion at a fair rate of speed, but not at the maximum, and the operator would have great difficulty in pulling the rope down farther because the car would be running upward. By starting the car by the aid of the stretch *C* of the hand rope the case will be very different, because this side must be pulled upward to make the car run upward; therefore, all that is necessary is to give the stretch *C* a slight upward pull, and then hold on to it until the car attains full speed. To prevent moving the rope too far a stop is fastened on the stretch *C*, and this runs between two stationary stops set at the proper points; hence, if in starting the operator desires to run up at full speed all he has to do is to pull the stretch *C*

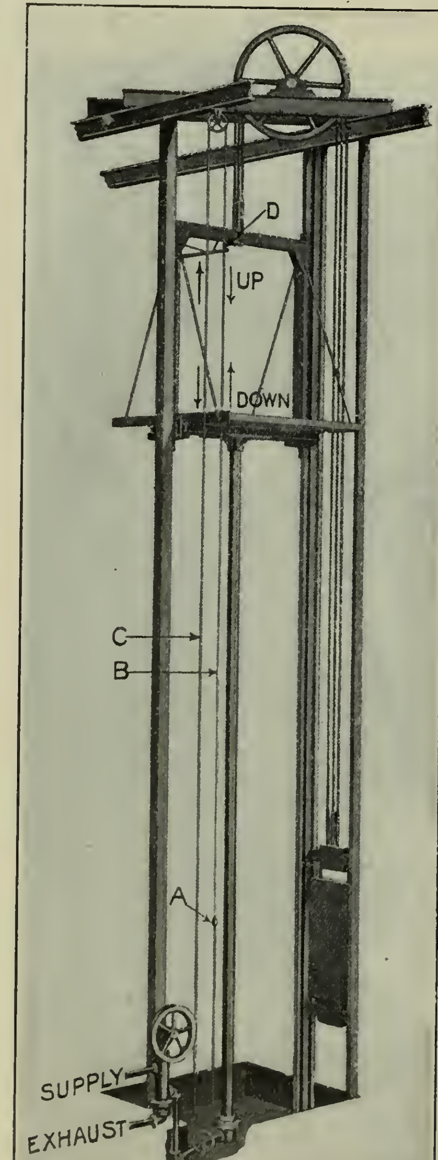

FIG. 309

up far enough to open the valve and then hold it until the stop on the rope strikes the stationary stop. To make a stop at any floor going upward the operator grasps the stretch *B* and holds it until the car stops. On a down trip the operation is reversed, that is, in starting, the stretch *C* is pulled down slightly and held until the desired speed is obtained, and to make a stop the stretch *B* is grasped and held, just as in stopping on the upward trip. The stationary stops that limit the movement of the rope when the stretch *C* is held are set apart a distance equal to the combined distances through which the stop balls on the rope *B* move at the top and bottom of the well to stop the car. Thus if the top ball moves 15 feet and the bottom ball 10 feet, the stationary stops that limit the movement of the stretch *C* will be set 25 feet apart, and the stop ball on *C* will be 15 feet below the upper stationary stop when the car is standing at any floor.

"Safe Lifters"

In all large buildings one of the elevators has to be designed to lift extra heavy loads, ranging from about 6000 to 10,000 or 12,000 pounds, according to the size of the building or the character of the business done by the occupants. This elevator is generally called a safe lifter, as the heaviest loads it carries are usually safes. If it were intended to carry such loads all the time it would be arranged precisely the same as the other elevators in the building except that the cylinder and the main valve would be made as much larger as might be necessary to lift the heavier load. But this elevator is only called upon occasionally to lift extra-heavy loads and it is therefore made of the same normal lifting capacity as the other elevators, but with parts sufficiently larger than normal to give it the proper strength to carry the extra load; the increased lifting power is obtained by increasing the pressure of the water that operates it, when used to lift heavy loads. The common practice with all types of hydraulic elevator used for safe lifters is to provide a small high-pressure pump that is capable of developing the pressure required to lift the load, and this is connected directly with the lifting cylinder, so that when a heavy load is handled, all the parts of the elevator excepting the lifting cylinder and the pipes directly connecting with it are cut out of service, and are not subjected to the high pressure. The way in which the Standard plunger elevators are arranged when used as safe lifters is illustrated in Fig. 310, which shows an elevation and a plan view. In the elevation the high-pressure pump, used to lift the heavy load, is moved some distance to the right, so as to bring it out from behind the main valve and the automatic stop valves. The true position of the pump and the pipe connections between it and the lifting cylinder is shown in the plan view. The high-pressure suction pipe taps into the main discharge at the bend *D*, and the delivery pipe from the high-pressure pump connects with the pipe *A* at the upper end. At the places marked V^1, V^2, V^3 and V^4 are located hand valves for the purpose of disconnecting the main valves from the cylinder and from the tanks. The valves V^5, V^6, V^7 and V^8 are located in the piping of the high-pressure pump, and are for the purpose of operating the elevator when used to lift extra-heavy loads. When such a load is to be lifted the valves V^2, V^3 and V^4 are closed to prevent high-pressure water

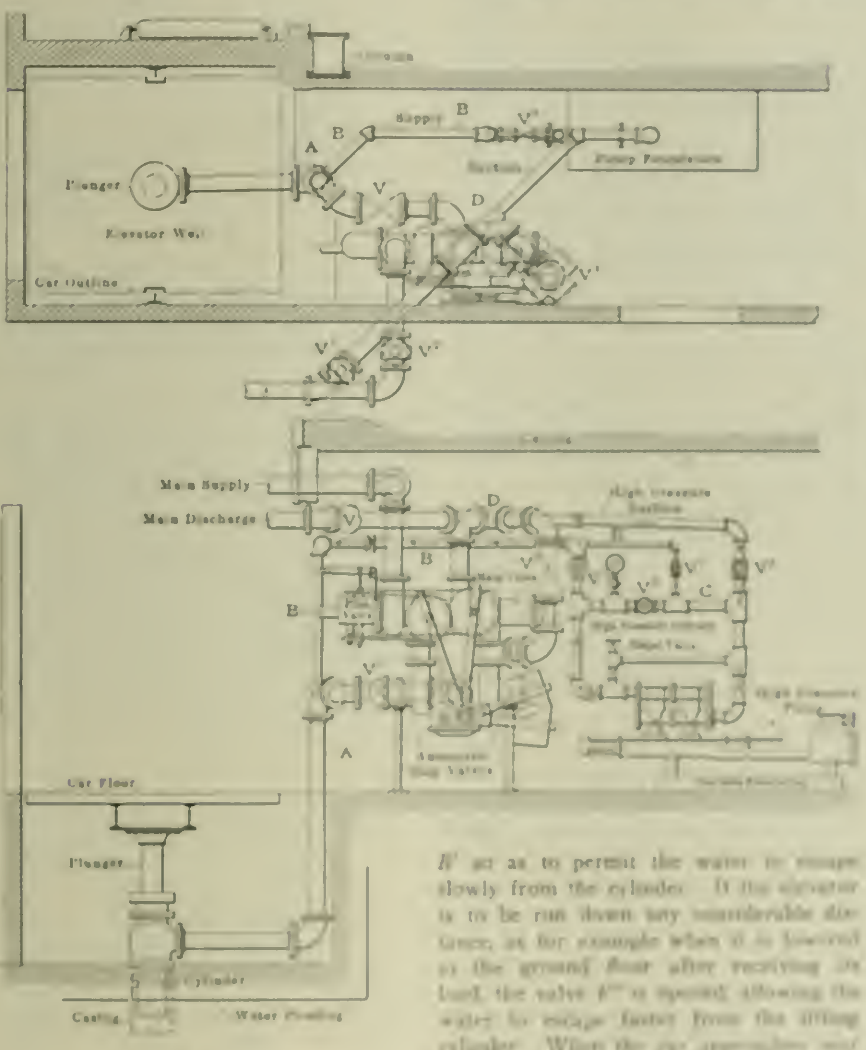

FIG. 310

from reaching the main operating valves. The high-pressure pump is started when the load is to be raised, and the valves V^9 and V^8 are opened; then water is drawn into the high-pressure pump through the high-pressure suction from the main discharge pipe, and from the high-pressure delivery pipe it passes through the valve V^6, and thence into the pipe *B* through the pipe *A* to the lifting cylinder, forcing the plunger and car upward.

As long as the pump is kept running the elevator will rise, and when the stopping place is reached, the pump is stopped. As the movement of the car is controlled entirely by the running of the pump and the manipulation of the valves V^5, V^6, V^7 and V^8, communication of some sort must be established between the car operator and the man at the pump. This is generally done by means of electric bells or a telephone. With this method of operating the car, accurate stops at the floors of the building cannot be made at the first trial, so that the general practice is to stop the car a short distance above the floor, and then to lower it slowly to the proper position by opening the valve V^{10} in the pipe *B'* so as to permit the water to escape slowly from the cylinder. If the elevator is to be run down any considerable distance, as for example when it is lowered to the ground floor after receiving its load, the valve V^{11} is opened, allowing the water to escape faster from the lifting cylinder. When the car approaches near enough to the lower floor, the valve V^{11} is closed and the car descends the remaining distance at a greatly reduced speed, as the water can escape only through the small pipe *B'* and the valve V^{10}. By properly manipulating this latter valve the descent of the car can be made as slow as desired. When the car is being lowered the high-pressure pump is not operated.

When an elevator is used to raise or lower a heavy load that requires some time to place upon the car, it is not advisable to depend upon the lifting cylinder to hold the car in position while the loading is going on, because during this time the car might settle enough to cause some trouble, if not to do actual damage. Owing to this fact it is customary to provide an elevator used as a side lifter with a locking device at each floor that will hold the car immovable while it is being loaded. This device is thrown into action after the car has been run up a short distance above the floor, and then by opening the valve V^{10}, as already explained, the car is permitted to settle gradually upon the locking device. When the load is in position the first thing to do is to run the car up far enough to free the locking device, then this is drawn out of the way and the car is started for its destination.

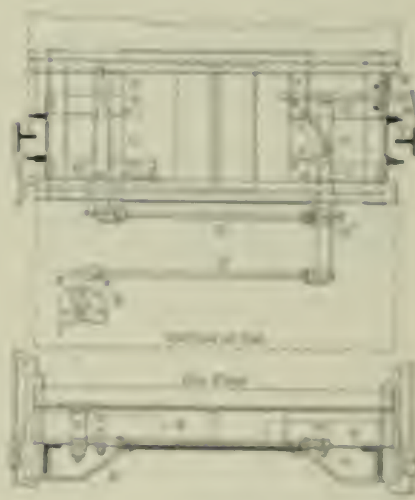

FIG. 313

FIG. 314

LOCKING DEVICE FOR PLUNGER ELEVATORS

The type of locking device used with the Standard plunger elevators is shown in Figs. 313 and 314, the former giving a plan view and a front view of the apparatus and the latter a side view. At each floor of the building strong supports *A*, *A'* are secured in the proper position upon the guide rails *Y*, *Y'* to hold the car level with the floor. Under the car are mounted sliding bars *B*, *B'* which are pushed out over the supports *A*, *A'* by means of levers connected with a vertical shaft *F* located in the car floor at one corner and so arranged that it can be turned by a pocket wrench. The flat lower end of this shaft is [illegible] a crank [illegible] a rod [illegible] links the crank to a lever *C*, which is pivoted at [illegible] and at its end engages with a [illegible] mounted on the back bar *B*. A connecting bar [illegible] is connected with the lever [illegible] by a [illegible] and through this connection any movement of [illegible] imparts motion to the lever C which is pivoted at H and moves the lock bar B' through the stud connection H'. If the shaft F is turned counter clockwise, the lock bars B, B' will be moved outward over the stationary supports A, A'. In Fig. 311 the lock bars B, B' are shown very close to the supporting pieces A, A', but when they are in their normal position they are drawn in far enough to prevent accidental striking of the stationary supports. The position of the levers C, C' is such that the shaft F can be rotated clockwise as well as in the opposite direction, and then the bars B, B' will be drawn in toward the center of the car.

When a plunger elevator is used to lift safes the compression stress on the plunger is greatly increased, as no additional counterbalance is provided to offset the weight. This extra stress is not serious in elevators of moderate rise, but when

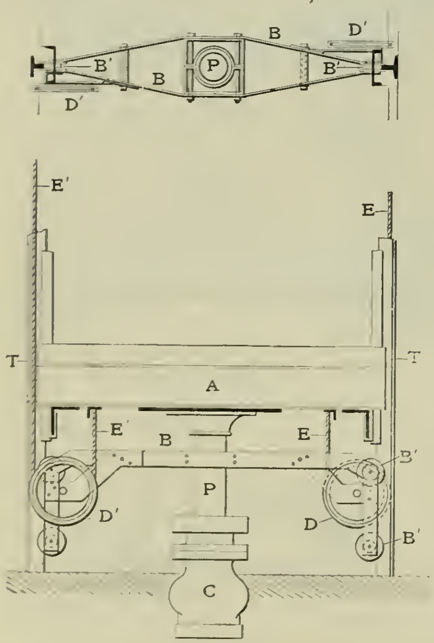

FIG. 313

the rise is fairly great, say between 200 and 300 feet, it is necessary to provide a stiffener to reinforce the plunger and avoid liability of buckling it. The stiffener used with the Standard plunger elevators is shown in Fig. 313, which gives a side elevation and a plan view. It consists of a frame B carrying at the center a guide through which the plunger P slides and at its ends guide wheels B', B' that run on the elevator guides T, T. The frame also carries two sheaves D, D' under which pass two ropes E, E', fastened at one end to the under side of the car and at the other end to the beams at the top of the elevator well. As the elevator runs upward, the rope ends attached to it are drawn upward, of course, and pulling the frame B upward just one-half as fast as the car moves, so that at all times the frame will be at a point midway between the bottom of the well and the car, and will brace the plunger at the central point of its exposed length.

The plungers of these elevators are made as nearly water-tight as practicable, but they are liable to be leaky sometimes. If a plunger leaks, the effect will be that the load to be raised will be increased by whatever the water in the plunger may weigh. In extreme cases, in very high buildings, the accumulation of water in the plunger may be sufficient to prevent the elevator from lifting its maximum load. If the plunger leaks, it is not an easy matter to make it tight, but it is a very simple thing to remove the water, and this should be done. The best way to do it is to drill a hole about ¼ inch in diameter in the lower section of pipe, just above the end casting, say 2 feet above the lower end of the pipe, and draining the water out. After the water is out the hole must be plugged up. This is easily done by tapping the hole and screwing in a brass plug, which should be filed off flush with the plunger surface and smooth.

Operating Direct Current Generators and Rotary Converters

By Norman G. Meade

When a generator or rotary converter is put into operation, the attendant should always be sure that the connections are tight, the brushes in the proper position and the oil wells properly filled. When first starting, rub the commutator of a direct-current generator or a rotary converter with a cloth having a few drops of oil on it, until the commutator obtains a dark gloss. If sparking occurs, the brushes should be shifted backward and forward until a point is found where there is no sparking under normal load. When a machine is first started it is advisable to change the oil in the bearings two or three times in the first few days; after that the oil may be left in about three months, adding enough occasionally to make up for loss. The machine should be watched closely at first, say for two or three days, to see that the brushes do not grind and that the oil rings revolve freely.

Any machine should be kept clean and dry, and no bolts, nuts, screws, etc., should be left around, as these may be drawn into the revolving part when the field magnet is excited and the machine running.

The armature of a belted machine should oscillate endwise in its bearings while running under load, as this will lengthen the life of the commutator and the bearings. Precautions should be taken never to break a field circuit suddenly, as the voltage of the inductive discharge is always many times higher than the operating voltage, and may puncture the field insulation; care should also be exercised not to open a switch in a circuit carrying a large current; trip the circuit-breaker first, then open the switch. The operator should make sure that all switches, circuit-breakers, etc., are open when the machine is not in operation, and always close the circuit-breaker first, then close the main switch.

The ends of brushes should be fitted to the commutator so that their whole end surfaces make contact; this can be done by putting each brush in its holder and grinding it with a piece of sandpaper slipped between the brush and commu-

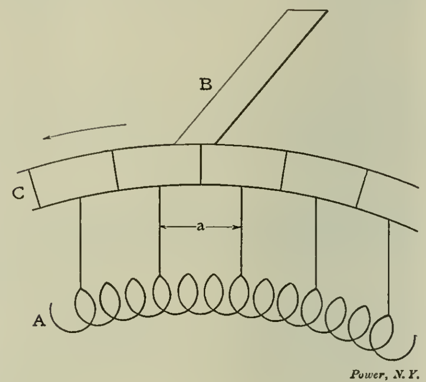

FIG. 1

tator until it fits the curvature of the commutator surface. If the brushes are copper-plated their edges should be slightly beveled, so that the copper does not come in contact with the commutator.

Care of the Commutator

To keep a commutator clean will ordinarily require only a daily wiping off with a piece of canvas; if this is done regularly so as to keep the commutator surface and end free from dirt and oil, in the majority of cases the commutator will require no other attention. In service the ideal appearance of a commutator is a polished, dark-brown surface. Sandpaper or other abrasive should never be used

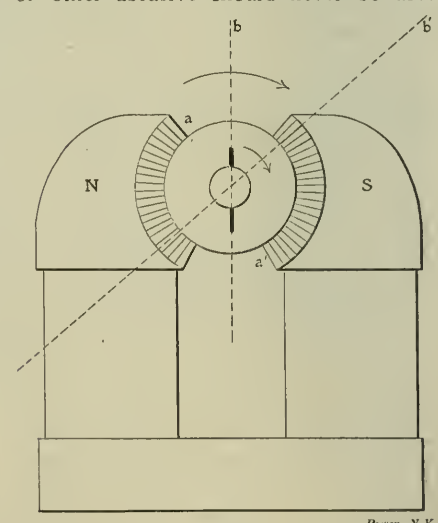

FIG. 2

on a commutator which is taking on a polish and shows no signs of roughness. Commutators which do not take on a polish, but show signs of roughness, should be smoothed off with a piece of sandpaper, and if quite rough a piece of sandstone may be used. Flat spots on commutators are usually caused by excessive wear, or a soft bar, or too much end play, by a loose commutator, a bad belt splice, or a flash produced by a short-circuit on the line. When a commutator becomes out of true from uneven wear it should be turned down. If the machine is of small size it is better to put the armature in a lathe, but if of large size a turning gear should be attached directly to the machine. Special care must be

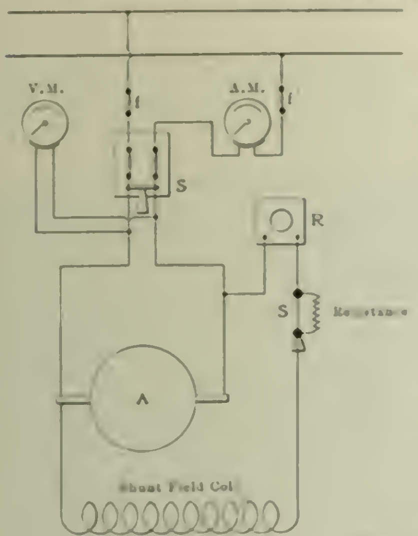

FIG. 3

taken that the cutting tool does not gouge into the commutator, as when an engine is running very slowly, which is necessary when turning off a commutator, its speed is liable to vary considerably during each revolution.

A small amount of lubricant may be applied to a commutator while in service. A lump of paraffin rubbed across the surface once a day is sufficient. Lubricant should always be applied sparingly and never in sufficient quantities to collect on the surface and about the brushes and

FIG. 4

leave them in a gummy condition. Excessive noise from the brushes may frequently be remedied by the application of a small amount of lubricant.

A commutator bar which projects above the others may be detected by a jumping motion of the brush-holder arms, by a pencil point held on the commutator surface and, in some cases, by a short intermittent spark at the brushes. If the commutator is found to have a high bar the fault should be corrected at once.

Too much tension on the brush springs will cause heating and excessive wear of the commutator; about one pound tension will be found generally satisfactory. The tension can be determined by a small spring scale. Place the hook under the lever or spring-end resting on the brush and pull on the scale until the finger is just raised from the brush; the scale reading will indicate the spring tension.

If on starting a generator it fails to generate, all connections should be examined carefully. It will generally be found that a poor joint is the cause of the trouble.

Sparking

Sparking will occur if the brushes are not set in the proper position. Each time a brush touches two commutator segments the coil connected to them is short-circuited, as represented in Fig. 1, where *A* represents the armature winding, *B* a brush and *C* the commutator. At the particular instant in the revolution of the armature the coil *a* is short-circuited. To maintain sparkless commutation the short-circuited coil must be under the influence of a field so that there will be generated in it during the instant of short-circuit an electromotive force that is in the same direction that the current will flow when it leaves the brush. In order to obtain this result a slight forward lead of the brushes is generally necessary as the load increases, because the armature reaction shifts the flux of the magnetic field, causing it to crowd at the trailing pole tips *a* and *a'*, Fig. 2, and to thin out at the leading pole tips. In the sketch the line *b* represents the theoretical position of the brushes during light load, and the line *b'* the position under heavy load.

Sparking at the commutator of a rotary converter may be caused by hunting, although this is practically eliminated in modern machines by the use of copper grids imbedded in the face of the pole shoes. Hunting is caused by an oscillation set up by changes in frequency in speed and in some generators or between a rotary converter and the supply circuit. The converter operates as [illegible] [illegible], and if the frequency of the supply circuit suddenly increases, the speed of the converter will increase, and in the sudden effort to gain synchronism will pass that point, owing to the momentum of the armature, and will oscillate backward and forward from synchronous speed until the right point is reached. During this oscillation above and below synchronous speed, excessive currents will flow backward and forward between the rotary and supply circuits, causing the neutral point of the commutator to shift, with resultant sparking.

To Start and Stop a Shunt- or Compound-wound Generator

Throw resistance in the field rheostat *R*, Fig. 3, and bring the generator *A* up to speed; then adjust the voltage to normal by means of the rheostat. Close the circuit-breakers and throw in the main switch *S*. If for any reason it is imperatively necessary to stop a machine suddenly from generating, open the field switch *S*. To stop a single machine, first trip the circuit-breakers, then open the main switch and increase the resistance in the shunt-field circuit by means of the

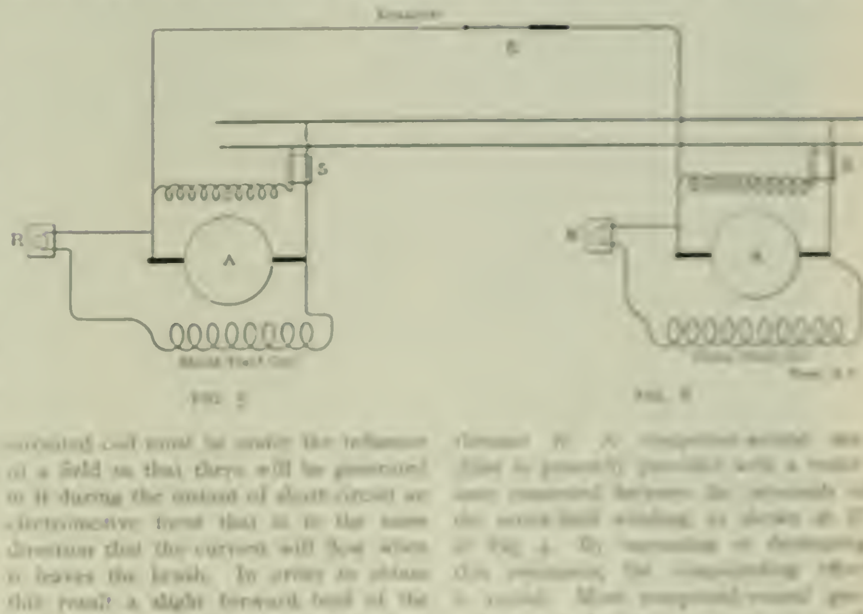

FIG. 5 FIG. 6

rheostat *R*. A compound-wound machine is generally provided with a resistance connected between the terminals of the series-field winding, as shown at *R*, Fig. 4. By increasing or decreasing this resistance, the compounding effect is varied. Most compound-wound generators are designed to over-compound, that is, give a higher voltage at full load than at no load, this is to compensate for the increased drop in potential in the line which occurs at heavy loads.

To operate two or more generators in parallel requires some skill in connecting the machines together. Suppose, for example, the generator *A* in Fig. 5 is in operation, and it is desired to start the generator *B*, Fig. 6. Before starting the latter the equalizer switch *E* would be open as well as the circuit-breakers on the machine and the main switch *S*. Bring the machine *B* up to speed and adjust the voltage as usual; then close the equalizer switch, then the circuit-breakers and finally the main switch *S*. The two machines will then operate in parallel, each taking its share of the load.

Supernatural Visitation of James Watt

The "Shade" of the Old-time Inventor Attempts to Throw Light upon Several Matters which Have Interested a Great Many of Us

BY WARREN O. ROGERS

Since relating my experience concerning a supernatural visitation of James Watt, a few weeks ago, grave misgivings at first beset me as to the wisdom of continuing the narration of similar manifestations. Naturally, there have been those who have not hesitated to deny that such happenings could have occurred; others have declared that it must have been the production of a fanciful brain, whatever that is, while still others attribute it to an attack of acute indigestion. I might have concluded that the visitation in question was purely visionary had it not been for the two empty glasses and numerous cigar stubs found on the table the next morning by the maid who cleaned up the room. Not only this, but a number of similar experiences of more recent date have left no doubt in my mind as to their genuineness. In fact, I am so firmly convinced of their reality that I have decided to publish an account of the various visitations I have received from my distinguished friend, and others, be the consequences what they may.

I did not feel in the mood for a second visitation for some days, preferring, as may be easily understood, to dwell on what I had already seen and heard. In fact, it was more than a week before I experienced a desire to engage in another chat with Watt, and should not have cared to then had it not been for a peculiar influence which I could hardly withstand; for, to tell the truth, wonderful though the first experience was, it was almost too uncanny for mortal enjoyment.

The second visitation of Watt was almost identical with his first, as far as the manner of accomplishment is concerned, except that I did not experience any uncomfortable sensations. I sat before the fireplace, idly musing and watching the flames as they shot upward trying to see which could reach the highest. The evenings were cold, and the warmth and soft, mellow light of the blazing wood gave one a sense of comfort and contentment. Thus, in the semidarkness I experienced a desire for another visit from my former midnight companion.

Concentrating all my energy to accomplish that end, I awaited his coming. The first indication was a faint body shadow, which rapidly developed into the form of James Watt. We shook hands and, passing the cigars, I invited him to be seated and make himself comfortable.

"Well, James," said I, as he accepted a chair, and extended his transparent hands toward the blazing fire, stating at the same time that he was cold, a fact I had noticed as we shook hands, "how have things been going with you since your last visit?"

"Oh, in a circle; you know that is all we have to do, just prance around in a particular circle until we obtain perfection for the requirements of that circle, when we are promoted to another, but easier one, which gives us more liberties. As soon as I get to the next circle, I can come to you whenever I like, day or night, rain or shine, and then we will hit the 'pike'," and James gave me a poke in the ribs, after a manner that indicated that he would not be at all "slow" when it came to seeing the town.

When James had warmed his hands and feet, he lit his cigar, and settled back in solid contentment. After permitting him to enjoy the "perfecto" for a reasonable time, I said:

"James, tell me how you happened to stumble onto the idea of your condensing engine."

"Well," replied James, as he closed his eyes in ghostly fashion and wrinkled his snow-white forehead as if to recollect memories of the dim past were a difficult operation, "while I was monkeying around the college, I got interested in old Newcomen's engine, and I will give him the credit of having the best and most advanced type of engine on the market at that time, but I decided that it could be made considerably more efficient.

"It was an awful steam eater, and was only used for pumping out mines. I'll never forget the first one I saw. Newcomen was a blacksmith by trade, you know, so what could you expect? I have always maintained that he did a better job than most blacksmiths could under the circumstances.

"You see he didn't have the machine shops to do the work that the present generation have, and, when an engine cylinder was put in a lathe no one knew what the exact shape would be after it was bored out. He not only had poor machines to work with, but the workmen were not skilled, seeing none of them had ever made a decent engine before. In fact, they were hostile to the notion, declaring that they had something better to do than to throw away their time on an idiotic idea."

"But tell me, James—you have been in the spirit world and have had a chance to find out—was Newcomen the inventor of his engine or did he steal it, as so many ideas have been stolen since?"

"No," replied James, as he leisurely puffed at his cigar, "Newcomen did not steal the idea. The engine that bore his name was the result of his own effort. I know that Savery got out his patents in 1705, or two years before Newcomen, but that was because he had a pull with the government; and by the way, his was the first patent issued by the government. I met Savery the other day, and when I put the question to him point blank, he admitted that Newcomen had his idea first. Savery still is in the outer circle, and from the way he cuts up I don't believe he will ever get into another." James gave a little grunt of satisfaction as he said this, which indicated that, although he was a spirit, and a progressive one, he still had one characteristic of mortals. James seemed to think he had been a little indiscreet in giving way to his spiritual animosities, and hastened to change the subject by adding, "I meet plenty who are worse than he is, though."

"How about Savery's and Newcomen's difficulties, did they have a lawsuit or was it settled out of court?"

"Oh, it was settled out of court," replied James, with greatly increased huskiness in his tones, I thought. Wishing to prevent any interruption of his interesting conversation, I rang for a little "Scotch" and soda to act as a lubricant, the which, by the way, was a decided success, as the huskiness immediately disappeared, and when James left me at daylight he rounded out two or three verses of "Auld Lang Syne" in a rather hilarious manner.

"Newcomen's invention was altogether different from Savery's," went on James, after he had creakingly crooked his elbow, and smacked his transparent lips. "Savery, you know, thought he had tumbled onto something new when he found out that the sudden condensation of steam made a vacuum, and he used the idea to draw up water; but this pump was never any good. It was so crude he had to place it in a mine out of sight. You see," said James, as he gave a hacking cough, "old 'Newk's' (Newcomen's too long to bother with in this age of progress) engine had a cylinder that stood on end in a vertical position under one end of a beam, but was open at the top.

The steam pressure in his time was only a little higher than the atmosphere, and it was admitted to the cylinder at the bottom."

"Well, I don't see how even a blacksmith could expect to get work out of such a contrivance as that," I remarked, just to draw James' attention from the decanter which seemed to have a fascination for him.

"Well, it wasn't so bad for an old codger like 'Newk.' In fact, the other night I took a little trip around New York just as the river steamers were putting fresh one. "The idea is the same, only there has been a slight improvement in the general construction of the engine which, by the way, is the outgrowth of my idea.

"In 'Newk's' engine, when the steam was admitted to the bottom of the cylinder, it allowed the piston to be pulled up by an equal weight or a counterpoise at the other end of the beam. The pump plunger was attached to the weighted end of the beam, and as the beam worked up and down the pump was operated. The power of the steam in the cylinder was idea, but didn't know how to use it. [illegible]"

"How did Newcomen happen to use the idea of condensing the steam?" I interrupted.

"Why, 'Newk' used Papin's cylinder and piston and Savery's principle of condensing the steam. I saw Papin the other day and he was still fussing about 'Newk' using his idea. He was so mad he would have gnashed his teeth if they hadn't all fallen out long ago. He had fussed so much about the matter that he is nothing but a walking skeleton.

HE ACCEPTED A CHAIR AND EXTENDED HIS TRANSPARENT HANDS TOWARD THE BLAZING FIRE

out and I noticed that they are still using the same idea of transferring the power in the steam to the shaft of the engine."

"Oh, you will be the death of me," I said, as James looked at me to see how I was receiving his argument. "Why, 'Newk' never had the ghost of an idea as to the power and magnitude of these river steamer engines. I'll—"

"Now you just shut your throttle," interrupted James, as he threw the butt of his cigar into the fireplace, and lit a transmitted to the pump by means of the beam, just as today it is transferred to the shaft of the beam [illegible]. The engineers of today are not such [illegible] as you think."

It will be observed that James had a tendency to be sarcastic at times, which is a [illegible]

"Why, you see 'Newk' had the [illegible]

[illegible]

the steam and then condensing it, and so transferred the heat into mechanical motion.

"'Newk' finally rigged up a cylinder having what you today term a water jacket," resumed James after wetting his whistle, "and I supposed he always would have used it if he had not found out by accident that there was a better way. One day the engine started up two or three revolutions faster than usual and 'Newk,' getting scared, shut it down and didn't know whether it was best to run it again or not. After fussing round awhile he got some 'lumpers' to take off the cylinder head, when he found that a small hole had appeared in the cylinder from the water jacket, allowing a stream of water to run in on top of the piston. This condensed some of the steam and also made the piston steam-tight. After that he abolished the water jacket and injected the water for condensing purposes through a pipe in the bottom of the cylinder."

"Very interesting," I remarked, as James ceased speaking and relit his cigar.

"Interesting nothing," replied James, in a disgruntled voice; "that is the kind of an engine they make so much noise about and say I got hold of, and that I got all my ideas from 'Newk' and other old fossils, and all that. I did get an old model of 'Newk's' engine to monkey with, but I can tell you it was a total failure. It had a sort of valve gear for operating the valves. It is said that a boy by the name of Humphrey Potter got up this idea, and from what I know of 'Newk' I would as soon think 'Hump' worked out the idea as that 'Newk' did."

"Well, how about your condenser?" I asked. "We started to discuss that question at the start and I don't know any more about it now than I did before."

"Well," replied James, as he arose and rattled his bones in his attempt to stand steadily, for truth demands the confession that he had begun to show signs of a state not altogether supernatural, and at times sang softly a few verses of the latest catchy songs, although where he got them I don't know. "Well," repeated James in a thickening voice (I determined then and there to have the mixture weaker for his next visit), "I take it that we had better let matters stand for a time. It is about sun-up and this staying up all night ain't what it is cracked up to be. I will tell you about my condensers next time. So long."

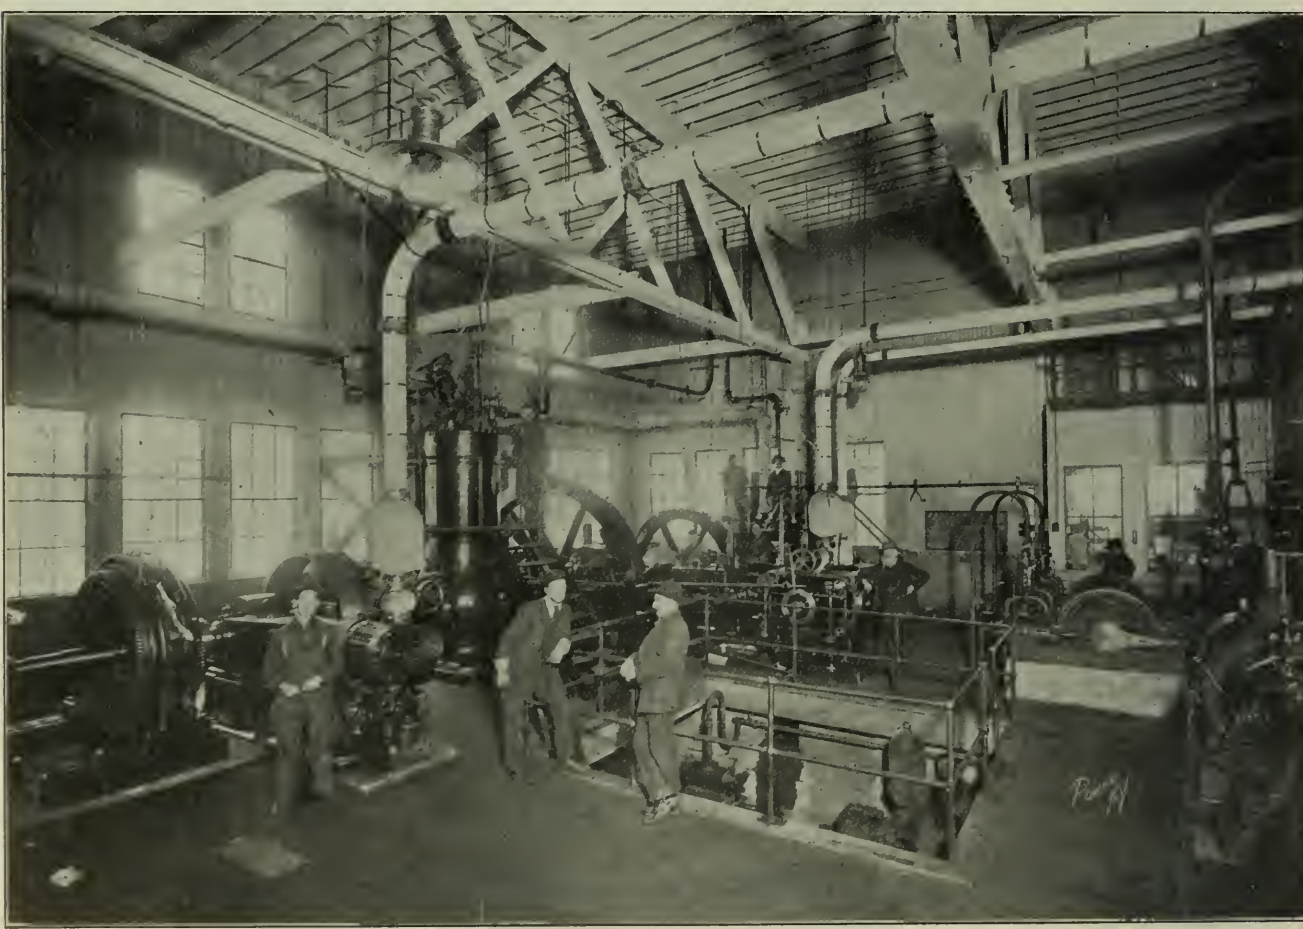
He reached out his cold, bony hand to shake goodby, and as I extended my own the morning sunlight streamed in through the window and in the twinkling of an eye the phantom vanished.

Power Plant of Miller & Lux

By Nelson Dean

Some years ago I chanced to be in southeastern Oregon, when I made up my mind to take a trip to Texas on the hurricane deck of a bronco. One of my friends suggested that I make the trip by way of the Miller ranches. I secured a map and, with his aid, marked out a route that was to take me to the heart of the cattle plains of Texas. During a trip of six months I traveled over several thousand miles and only once slept on anyone else's property.

At one of the ranches I met and made a friend of an engineer, Mack Lyon, whom I chanced to meet a short time ago on Market street, in San Francisco. He invited me to visit the plant at "Butcher Town," which is located south of the city by San Francisco bay. I found the place so interesting that I went to the trouble



INTERIOR OF POWER PLANT OF MILLER AND LUX of securing the accompanying photo showing the plan of the main machinery.

The engine room comprises 3166 square feet. The view taken shows to the left a 135-kilowatt two-phase 60-cycle Fort Wayne generator, operated at a speed of 275 revolutions per minute, and direct-connected to a 14x14 inch "Ideal" engine. Naturally, the chief electrician tried to hide the engine by getting in front of it. Next to the right is the central point of interest in the form of a Larsen-Baker ice machine of 100 tons capacity, with an 18x36-inch steam cylinder and a 15x25-inch ammonia cylinder, driven at 60 revolutions per minute and direct-connected to a Bates-Corliss engine.

Next may be seen the 30-ton ice machine, with a 12x32-inch steam cylinder and a 10x20-inch ammonia cylinder. The ice machines are packed with Garlock ammonia packings. Next come two 7½ and 8 by 9-inch duplex air pumps fitted with special regulating governor. The work of these pumps is to bring water from three 14-inch wells, 150 feet deep, located half a mile from the plant. To the extreme right are two electrical exciters. The larger is a 25-kilowatt 200-ampere 125-volt generator direct-connected to an American blower engine, with a 6x6½-inch cylinder, running at 370 revolutions per minute. The small exciter is a 7.5-kilowatt 52-ampere 145-volt machine, direct-connected to another American blower engine, with a 5x5-inch steam cylinder, driven at 375 revolutions per minute.

It will be noticed that all the steam mains head toward the right-hand side of the print, showing the location of the boiler room, which has 2070 square feet of floor space. Here are three 300-horsepower Atlas water-tube boilers and one 10-horsepower vertical boiler carrying 175 pounds superheated steam pressure. In this room there are also two 7½ and 4½ by 10-inch boiler feed pumps, one 400-horsepower Cochrane heater and purifier, and one 12 and 7½ by 18-inch salt-water fire pump connected with a modern sprinkler system. The foremost figure in the picture (my friend, Mack Lyell) acted as installing engineer and is now chief engineer. He is facing the imperturbable Mr. O'Brien, superintendent of the packing house.

The pit in the foreground contains two large water pumps used in connection with the air compressors. The cooler is equipped with 33,000 feet of 2-inch direct-expansion pipe and 10,000 feet of ammonia pipe. There is 650 feet of live-steam pipe and 600 feet of exhaust-steam pipe, used for heating purposes; also 2000 feet of water pipe used about the buildings. Oil is used as fuel, being stored in two 15,000-gallon tanks, 275 barrels being used daily.

The cost of the power plant stands at about $300,000, there being $100,000 to be used in installing new machinery in the near future. The total cost of the packing house is about $1,750,000. This particular plant is one of several that handle the output of the Miller ranches. All of its products go to supply our navy department on the Pacific coast and everything is rigidly inspected by United States inspectors.

An Instructive Experience with the Tirrill Regulator

By W. Nelson

In an hydroelectric plant of 20,000-kilowatts capacity, where there are two 200-ampere 125-volt exciter units, the exciters are sometimes operated in parallel on account of heavy overload, as this gives better voltage regulation. There is in use there the Type TA Form F4 Tirrill regulator, which has three secondary contacts shunted across each exciter-field rheostat. Under normal load with one exciter the instrument gives excellent regulation, but with about 25 per cent. overload on the station there is excessive sparking at the contacts, when the power factor is low.

ELEMENTARY DIAGRAM OF EXCITERS AND SECONDARY CONTACTS OF REGULATOR

To avoid this wear on the contacts and for better regulation the exciters are run in parallel during the peak-load period. There are no equalizing rheostats in the circuits; the exciters are [illegible] and although of the same type and size, with the field rheostats in the normal running positions and the commutator brushes on the neutral points, exciter No. [illegible] it would take about 40 per cent. more load than No. 1.

At first the load was equalized by cutting resistance out of No. 1 exciter field rheostat. This caused excessive sparking at one of the three contacts on No. 1 side of the Tirrill regulator, as the rheostat was out of its normal running position.

Method of Equalizing the Loads

After several trials a method was devised to equalize the loads and still keep the exciter field rheostats in their normal running positions, and without the expense of installing equalizing rheostats. As the exciters, when in parallel, carry only 50 to 60 per cent. load at most, the brushes could be shifted a little about the commutator without sparking. The brushes of No. 1 exciter were set as far back and those of No. 2 as far ahead as possible. The load was not then evenly divided, but the division was improved.

Now the normal secondary contact spacing of the Tirrill regulator is given as 1/32 inch, but as the exciters were being run at little more than half load this spacing could be varied slightly without affecting the action of the regulator. It was found that by setting the contacts of No. 2 side of the regulator at a little more and those of No. 1 side at a little less than 1/32 inch, the excitation of No. 1 exciter was increased enough to make it keep its share of load with the exciter field rheostats in their normal running positions.

The explanation of this is that although the contacts all operate at the same instant due to the action of a common magnet, they open (break) by individual coil springs and the contacts on the No. 1 side of the regulator closed an instant before those of the No. 2 side because they had less travel; the resistance of the rheostat of the No. 1 exciter was therefore shunted longer than that of No. 2.

It has been proved after running this type of regulator for some time that 1/32 inch is the best spacing for the secondary contacts. Wider spacing will cause excessive sparking at the contacts and cause variation in the voltage, while with closer spacing there is little or no sparking but the contacts, which are of platinum-silver alloy, will weld rapidly and have to be cleaned about once a day. With 1/32-inch spacing there seems to be just enough spark to keep the contacts clean of oxide and with frequent [illegible] of the contacts through the [illegible] by means of the [illegible] the contacts will work in excellent condition and give no trouble. It was only on account of running the exciters on light load that any variation in spacing could be made. The regulator is a delicate instrument and should not be [illegible] with [illegible] the [illegible] [illegible] to get best results.

Proper Treatment of Boiler Feed Water

Data from Plant Which Reduced Maintenance Charges $160 per Month by Analyzing Feed Water and Treating with Soda Ash and Lime

BY A. J. BOARDMAN

Owing to the widespread interest that is being shown as to the proper treatment of boiler feed water it might be of interest to relate the experiences of a plant that has managed to place its treatment on a substantial, scientific basis. Previous to January, 1907, this plant had a great deal of trouble from boiler scale owing to the large quantity of scale-forming matter in the river water. The plant is located at Indianapolis, on White river, which flows through a limestone country. The analysis shows a total of 25.30 grains of scale-forming and suspended matter per U. S. gallon.

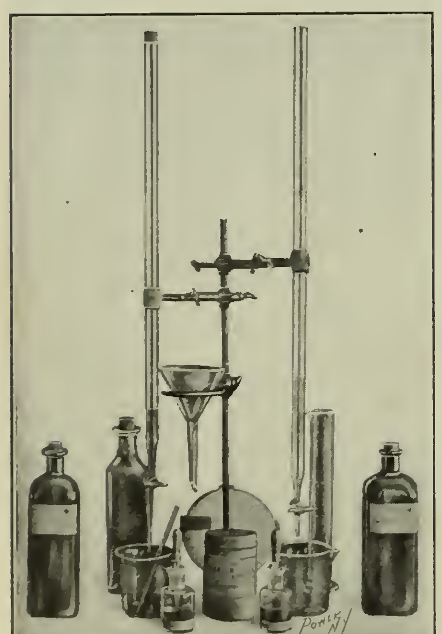


FIG. 1. TESTING OUTFIT

TABLE I.

	Grains U. S. Gallon.
Calcium carbonate	4.30
Magnesium carbonate	1.01
Magnesium sulphate	0.96
Sodium sulphate	0.71
Sodium chloride	0.88
Iron and alumina	0.19
Carbonic acid	0.78
Silica	1.21
Alkalinity	5.85
Suspended matter	8.02
Incrusting solids	15.69
Nonincrusting solids	1.59
	25.30

Pounds of incrusting solids in 1000 gallons, 2.24

Before the first of the year several different boiler compounds had been used with very little decrease in the amount of scale. Boiler tubes were still being purchased by the hundred, and the cost of boiler compound averaged $270 a month, or 3.21 cents per 1000 boiler horsepower monthly.

It was then decided to treat the water by using soda ash and lime to throw down the scale-forming matter, and to follow up and check this treatment with feed-water analysis. The basis of the treatment was to analyze the river water for permanent and temporary hardness and treat it accordingly. The feed-water analysis is the more accurate of the two, and by using it to check up the treatment very satisfactory results were obtained. At the same time the boiler-room records, which are of a permanent value in any plant, were started.

Testing Outfit

The expenditure for a testing outfit was not over $10, and the operations required for the complete analysis are extremely simple. In fact there are automatic feed-water analyzers on the market today. The apparatus consisted of two 50-cubic centimeter burettes, one square pint bottle with rubber cork, one pint standard N/50 HCl solution, one pint standard soap solution, three 500-cubic centimeter beakers, one funnel, 100 filter papers No. 2, one 100-cubic centimeter phenol-thalein indicator, one 100-cubic centimeter methyl orange indicator, one 100-cubic centimeter graduated test tube, 10 ounces barium chloride, stirring rod, burette support, stand, etc. It is necessary to have HCl exactly correct. Normal HCl is 98.7 parts hydrochloric acid, and can be obtained from any chemist. Phenol-thalein and methyl orange are chosen owing to the distinct color effects when the reactions take place.

The burettes mentioned above are graduated test tubes with a glass stop cock in the bottom. The soap or hydrochloric-acid solution is poured in and the hight of the liquid is read on the glass. Suppose the initial reading to be 18.5 cubic centimeters. Then after the operation is completed, shut the stop cock and make the last reading, say 25.7 cubic centimeters. The difference between 25.7 and 18.5, or 7.2 cubic centimeters, is the amount which has been used.

River-water Analysis

The directions for river-water analysis for permanent and temporary hardness are as follows: Hard water may be defined as water containing in solution mineral compounds that curdle or precipitate soap; generally the salts of lime, magnesia, iron, etc. In the United States hardness is generally stated as parts of calcium carbonate per million, i.e., the number of parts by weight of calcium carbonate that would have to be added to a million parts by weight of water to produce the specified degree of hardness. To convert grains per gallon to parts per million multiply by 17.18. The standard soap solution is obtained by dissolving pure castile soap in alcohol. It can also be obtained from any analytical chemist.

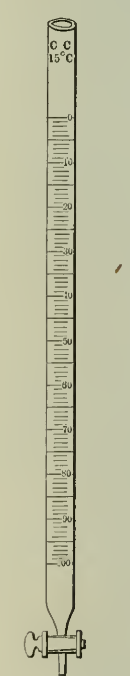

FIG. 2. TYPE OF BURETTE USED

Total Hardness—In testing for total hardness in river water, 25 cubic centimeters of the water to be tested is diluted with 75 cubic centimeters of distilled water. This is to be titrated with the standard soap solution in a square pint bottle provided with a rubber stopper. One cubic centimeter of soap solution is added at a time until there is some evidence of a permanent lather. Then add one-half cubic centimeter and decrease to one-fourth at a time until the lather is permanent, when the bottle can be laid on its side for three minutes with no decrease in the lather. The bottle must be well shaken after each addition of soap solution. In Clark's Table of Hardness* opposite the number of cubic centimeters of soap solution used will be found the degree of hardness in parts per million.

Permanent Hardness.—This is obtained by subtracting the degree of temporary hardness, that due to the bicarbonates and lessened by boiling, from the total hardness. The result is expressed as before in parts of calcium carbonate per million parts of water.

Temporary Hardness.—Each cubic centimeter of the acid solution used indicates [illegible] of a grain of calcium carbonate per million. In testing proceed as follows: Twenty-five cubic centimeters of raw water is diluted with 75 cubic centimeters of distilled water and two drops of methyl orange indicator added, which will turn the solution a yellowish tinge. Now add the acid solution until the color of the solution turns from a yellowish to a faint pink. Care should be taken to add the acid solution drop by drop. When the color turns it indicates the end of the reaction. Set the result down and multiply by 4. The product will be the temporary hardness expressed as calcium carbonate in parts per million.

*Gill's "Engine Room Chemistry," page 105.

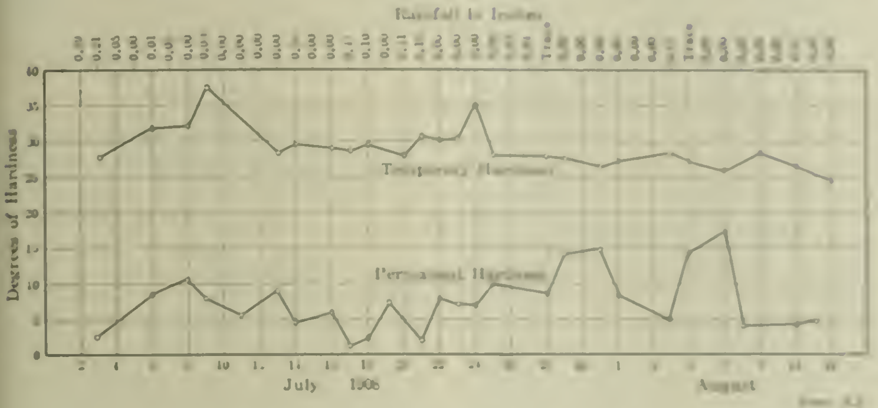

FIG. 3. WATER FROM WHITE RIVER AT INDIANAPOLIS, IND.

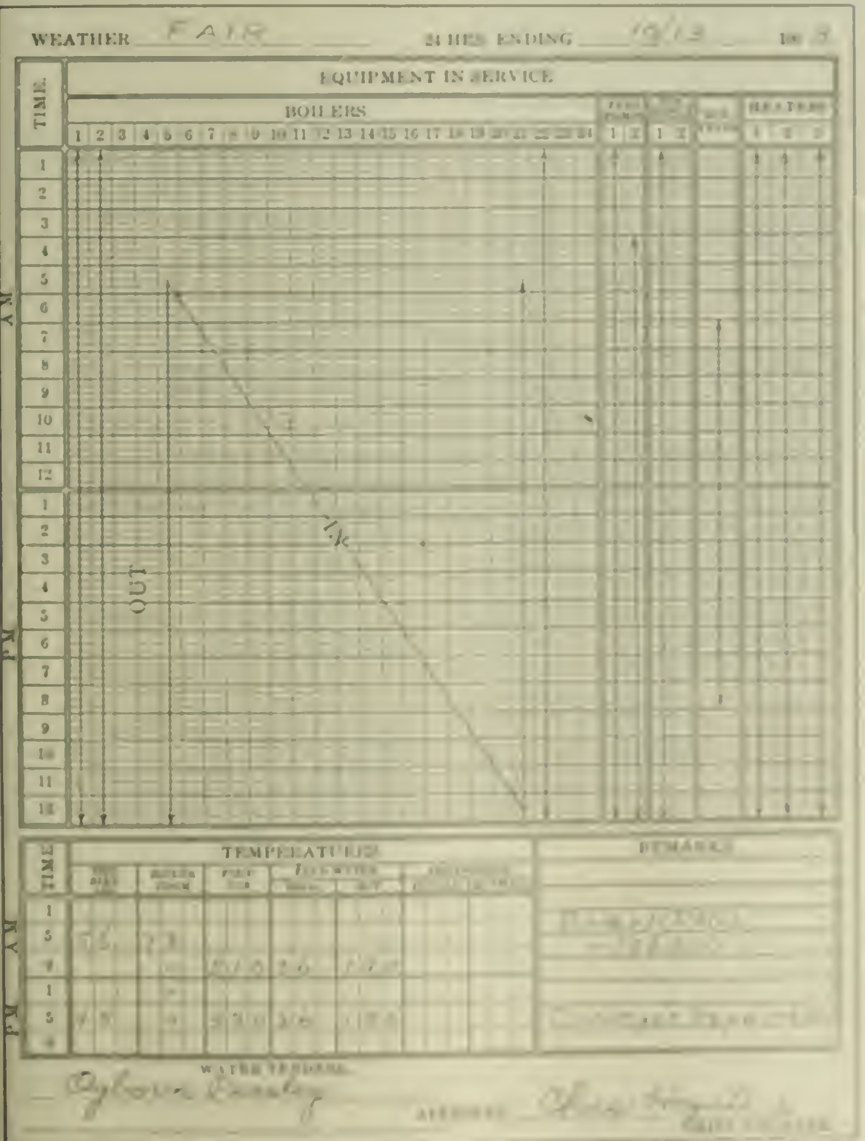

FIG. 4. DAILY BOILER-ROOM REPORT

Analysis of Softened Water

Measure out 100 cubic centimeters of the purified water, put it into a beaker and add a few crystals of barium chloride. The addition of four drops of phenolphthalein indicator will turn the solution purple if there is plenty of lime present. Now add standard acid solution drop by drop to obtain a clear solution. This is analysis for lime. The number of cubic centimeters of acid solution added indicates the amount of lime present, as explained above, and may be read off directly from the graduation on the burette. Measure out another 100 cubic centimeters of the softened water, add four drops of the phenolphthalein solution and titrate with the standard acid solution to obtain a clear solution as before. Call the result in the first operation *B* and the result of the second operation *A*. Then *A* minus *B* in cubic centimeters multiplied by [illegible] equals the number of pounds of soda ash per 1000 gallons; *B* multiplied by [illegible] equals the number of pounds of lime per 1000 gallons.

Use for standard purification [illegible] of a pound of lime and [illegible] of a pound of soda ash per 1000 gallons of raw water. As the results *A* or *B* just differ in value as determined by the standards, to determine the proper correction due to the variations in the reagents, add or subtract the difference in pounds per 1000 gallons.

The soda ash** or sodium carbonate acts on the sulphates of lime or magnesia forming sulphates of soda which are discharged by the blowing-off of the boiler [illegible]. It changes the sulphate into carbonate, transforming what would be a hard crystalline scale into a powdery calcium carbonate which is easily removed from the boiler although it hardens after exposure to the air. The [illegible]

**[illegible] "Engine Room Chemistry," page [illegible]

$$\text{Calcium Bicarbonate } CaH_2(CO_3)_2 + \text{Sodium Carbonate } Na_2CO_3 = \text{Sodium Bicarbonate } 2\,NaHCO_3 + \text{Calcium Carbonate } CaCO_3$$

When injected into boiling water the above gives:

$$\text{Sodium Bicarbonate } 2\,NaHCO_3 = \text{Sodium Carbonate } Na_2CO_3 + \text{Water } H_2O + \text{Carbon Dioxide } CO_2$$

The effect of sodium carbonate on sulphates is shown by the following reaction:

$$\text{Calcium Sulphate } CaSO_4 + \text{Sodium Carbonate } Na_2CO_3 = \text{Calcium Carbonate } CaCO_3 + \text{Sodium Sulphate } Na_2SO_4$$

The precipitation of the above carbonates has a tendency to clarify the water if it is very turbid, carrying mud or clay. In extreme cases a small quantity of iron sulphate can be used.

With the open feed-water heaters in use at the present time the precipitation of the bicarbonates is not complete, as with atmospheric pressure the highest attainable temperature in a heater of this sort would be 212 degrees. The temperatures actually reached are from 190 to 200 degrees Fahrenheit, and the result is that there is precipitation in the feed-water pipe line. In order completely to precipitate the bicarbonates in a closed heater, a temperature of 290 degrees is necessary, which corresponds to a pressure of about 45 pounds gage. The lime is held in suspension by the presence of the carbon-dioxide gas, and no matter how alluring are the promises of the feed-water-heater salesman, no precipitation will take place until this carbon dioxide is removed. The best way to do this is to put the steam connection for one of the auxiliary pumps into the heater above the water level and draw the gas off with the steam. Table 2 shows the percentages of lime thrown down at various temperatures.

8.9 × 4 = 35.6 Total hardness.

Acid.

39.6 c.c. Final.
32.8 c.c. Initial.

6.8 c.c. Difference.
4

27.2 = Temporary hardness.

Permanent hardness = 35.6 − 27.2 = 8.4

Soda Ash—For each degree of permanent hardness, 0.091 pound of soda ash should be used for each 1000 gallons of raw water,

$$0.091 \times 8.4 = 0.7644$$

of a pound per 1000 gallons.

Lime—For each degree of temporary hardness, 0.048 pound of lime should be used per 1000 gallons of raw water,

$$0.048 \times 27.2 = 1.3$$

pounds of lime per 1000 gallons.

The accompanying curves, Fig. 3, show the varying degrees of hardness, both temporary and permanent, for the month of July. It is evident that the permanent hardness will vary with the rainfall, and that the amount of lime and soda ash should also be varied.

Sample Analysis of Softened Water

Soda Ash (Result *A*).	Lime (Result *B*).
29.4 c.c.	25.2 c.c.
25.2 c.c.	24.0 c.c.
4.2 c.c.	1.2 c.c.

Result A — Result B = 4.2 — 1.2 = 3.0 cubic centimeters.

Then, 3 × 0.091 = 0.27 pound of soda ash per 1000 gallons.

By means of Table 3, which was calculated for the 70,000-gallon tanks that were used, it was possible to tell at a glance how to vary the treatment.

TABLE 3.

(Result *A*) Soda Ash. c.c.	Lb.	(Result *B*) Lime. c.c.	Lb.
0.0	+ 5.95	0.0	+ 11.90
0.4	+ 3.92	0.6	+ 9.89
0.8	+ 0.91	1.0	+ 8.54
1.0	— 0.35	2.0	+ 5.17
2.0	— 0.65	3.0	+ 1.82
3.0	—12.95	3.4	+ 0.48
4.0	—19.25	3.6	— 0.19
		4.0	— 1.54
		5.0	— 4.88
		6.0	— 8.25

From the result of the above analysis of softened water, result A = 4.2 cubic centimeters. By looking at the table for

Result *A* at 4.2 cubic centimeters it means to cut the treatment down by about 20 pounds. Therefore,

$$53.5 - 20 = 33.5$$

pounds of soda ash, which is correct. The other result, 1.2 cubic centimeters for *B*, by the table indicates that eight pounds more lime are necessary for the completion of the treatment. Therefore,

$$91 + 8 = 99$$

pounds of lime. New treatment, 33.5 pounds of soda ash, 100 pounds of lime. The analysis the next day checked this up and it was found to be correct.

Cost of Treatment

For September, 1908, this was $103.80 against $270 for boiler compound. The cost of treatment for 1000 gallons at the present market prices for high calcium lime and 58 test soda ash is 66.5 cents. The lime used should be high in calcium oxide, of approximately the following analysis: Calcium oxide, 98.5 per cent.; magnesium, 1 per cent.; iron, alumina, silica, 0.5 per cent.

When properly hydrated it should contain 15 to 25 degrees moisture, as this lime is liable to air slack during the summer months unless the hydration is complete. The ordinary Dolomite lime contains from 20 to 30 per cent. magnesium, which is useless as far as the treatment is concerned and it is best to buy on test and still farther check up the lime by an occasional analysis.

Reducing Boiler Repairs

It should be borne in mind that this analysis is not absolutely correct and that other factors will enter into the treatment. The river water analysis will generally give an overdose of lime and soda ash. This will cause liming and foaming of the boilers, so it is necessary to keep

TABLE 4

Month	Maintenance	B.H.P. Hours	Cost Per B.H.P. Hour, Cents	New Tubes
January	$182.80			31
February	180.12	4,077,180	0.0044	15
March	414.07	7,400,000	0.0056	44
April	208.37	4,976,000	0.0042	16
May	448.96	4,880,000	0.0092	12
June	150.17	4,013,200	0.0037	12
July	64.90	3,200,000	0.0020	6
August	108.08	3,340,000	0.0032	[illegible]
September	103.80	3,487,800	0.0030	[illegible]
October	60.90	3,877,000	0.0016	[illegible]

posted on the conditions of the boilers and the river, etc., for successful results.

Table 4 shows the results of ten months' treatment. The number of boiler tubes replaced has been reduced to a minimum and the expense of maintenance is mostly repairs to brickwork. Take September, for instance; the boiler records show that of the total expense for maintenance, $93.80 was for brick arches, side walls, etc., and the remainder, $10.00, for stoker fuel plates. With the form of boiler records shown in Figs. 4 and 5 it is possible to follow closely the performance, depreciation and repairs to any boiler, and also keep a close check on the renewals of tubes and boiler parts.

The boiler equipment consists of eighteen 400-horsepower and four 250-horsepower Babcock & Wilcox boilers. Total, 8400 boiler horsepower.

It may be noted that during the early months of the year there was only a slight improvement in the condition of the boilers and the number of tube renewals. This was due to the fact that while the importance of the treatment was recognized, there was no one in the office who could systematically follow the treatment from day to day or at least check up the treatment twice a week, owing to other interruptions. The last of June, however, the writer took charge, and the above would indicate that some sort of system is necessary for the best results.

By Table 4 the average cost of maintenance for material was $247.81 for the first six months; the average cost for the last four months was $82.87, a saving of $160 a month for the plant.

The writer is indebted to Charles Hosgate, chief engineer of the power station, for courtesies extended.

Hydroelectric Development at Grand Falls, N. B.

The contract for the construction work involved in the hydroelectric development of the Grand Falls Power Company, on the St. John river at Grand Falls, N. B., has been awarded to the Frank B. Gilbreth organization of New York. The plant is to develop natural horsepower to electric current to be distributed to various cities in New Brunswick and Maine. The falls at this point are the largest in eastern Canada, with a head of 125 feet. They are on the Canadian Pacific railroad about 200 miles north of St. John, N. B., and about 1 mile east of the Maine border. It is expected that the development will cost [illegible]. John B. McRae, of Ottawa, is chief engineer, and Ralph Mershon, of New York City, electrical engineer.

The International Congress of Applied Chemistry, which meets in London, England, May 27 to June 2, will be invited to hold its 1912 meeting in New York City. The cooperation of educational institutions, scientific societies, manufacturing corporations and others interested is being sought in order to render the invitation more effective. The matter is in the hands of a temporary committee, of which the secretary is B. [illegible], [illegible] street, New York.

Polytechnic Mechanical Society Meeting

Members of the Brooklyn Polytechnic Institute student section of the American Society of Mechanical Engineers listened on Saturday evening, March 6, to two excellent addresses. The first speaker, George A. Orrok, mechanical engineer of the New York Edison Company, and secretary of the Gas Power section of the American Society of Mechanical Engineers, discussed the development of the large gas engine in connection with blast-furnace operation, showing slides of interesting lantern slides and explaining the operation of various types of engine running up to 4000 horsepower capacity. The speaker called attention to the fact that among the largest gas-engine builders in the world there should be included the Standard Oil Company, or rather its subsidiary, the National Transit Company. It does not, however, build engines to sell.

Following Mr. Orrok's address, which was frequently interrupted by questions from the audience, evidencing the keen interest taken in gas-power developments, Ernest Bournonville, of the Davis-Bournonville Company, gave a demonstration of the oxyacetylene blowpipe for welding and cutting metals. By mixing oxygen and acetylene the temperature of 6300 degrees Fahrenheit is reached, permitting of the direct welding of metals together with the use of solder or brazing. Mr. Bournonville made several welds of steel and cast iron, and also welded cast iron to steel and steel to copper. By the use of an additional oxygen jet various metals were cut by the flame. A piece of [illegible] steel plate about 7 inches wide was cut in two in less than one minute. A piece of burglar-proof steel, about 3 inches square and 1 inch thick, was severed in an [illegible]. Mr. Bournonville also described welding and cutting operations on a larger scale. The experiments [illegible] [illegible] interest and were continued until a late hour, after which the usual collation was served to the [illegible].

The [illegible] mill of [illegible], near Manchester, England, is driven by a [illegible] [illegible]. [illegible] [illegible] with the [illegible] from the [illegible] generator. [illegible] the [illegible] of the [illegible] [illegible] [illegible] for [illegible] purposes. After passing through the [illegible] it is delivered at a temperature of about 100 degrees Fahrenheit [illegible] [illegible] [illegible] [illegible] [illegible] and returned [illegible] to the mill, where it is distributed in the [illegible]. WE PAY FOR USEFUL IDEAS

Renewing a Valve Seat

Some time ago the valve-chest face of a high-pressure cylinder became so badly worn and scored that a new valve and valve face were necessary. The new valve was finished complete from measurements taken from the old valve and the valve chest. The new seat was machined the exact width, and approximately the proper thickness, allowance being made for some fitting; the ports were also finished to size. This meant that after the old valve seat was removed it would only be necessary to make a templet from the old holes, drill and counterbore the new seat and bed it in position; then the screws being put in, the job would be completed. It sounds quite simple and easy.

For various reasons it was considered expedient to carry the job through on a Friday night, and have the engine ready for work at 6 a.m. the following morning. Accordingly, when steam was shut off at 5:30, operations were begun. The casing door was removed and the valve spindle and valve taken out. After some preliminary cleaning out of the slots in the holding-on screws, the serious part of the work was begun. The holding-on screws were of brass, ½ inch in diameter, with slotted heads. After removing the screws holding the valve seat in place an attempt was made to remove it with steel wedges, but without success; it seemed to be rusted on solid. It was then decided to split it off in pieces. A line of holes was drilled down the center of the valve face and nearly through; the remaining metal was then cut out with a cape chisel. Wedges were inserted in this space and the face wedged off in pieces.

After tapping out the holes for the pins, stout drawing paper was procured and a templet made from the valve chest, ports and holes. The holes were then marked and drilled on the new valve seat, which was then bedded into position. The rust had left the chest face somewhat uneven, but with a judicious use of the chisel and file it was soon pronounced "good enough." A thin coating of red lead was placed between the face and the chest and the screws put in tightly. The new valve and spindle were then placed in position, the door put on and the engine was ready for steam.

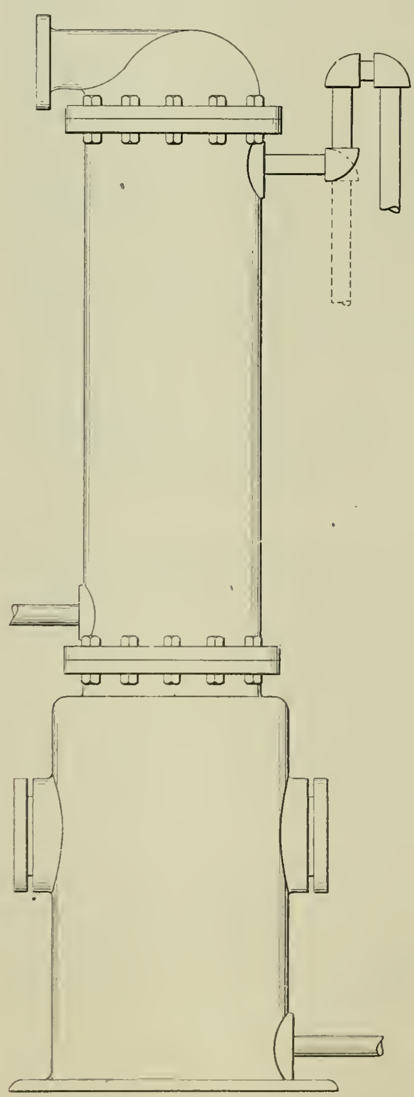
A Gasket Difficulty

A troublesome gasket in a vertical surface condenser recently came under my observation. It was located between the vapor dome and the barrel. The con-



CAUSE OF A GASKET DIFFICULTY

denser is used to condense the hot vapors from a drying oven. Numerous failures of the gasket necessitated the frequent removal of the dome.

It was noted that when the circulating water had been run through under higher pressure than usual for several weeks, the gasket lasted much longer. This led us to the solution. The outlet pipe at the top of the barrel turned downward, as shown by the dotted lines in the accompanying sketch, and prevented the maintenance of a head of water sufficient to come into contact with the tube plate. The loop in the pipe keeps the troublesome surface flushed with water, and obviates a great deal of bothersome work.

Technical Education

Through the engineering journals, at frequent intervals, we see the young technical graduate heated up in the furnace of public inspection and then placed under the steam hammer to be knocked and pounded into shape, or ridiculed by a few prejudiced unbelievers.

Notwithstanding all that has been said to the contrary, there is no person in the world who realizes how little he knows as does the graduate during his first year out of college. He begins to see that he has just got a few principles or foundations by which he may use his brains for useful thinking. For this reason, contrary to Mr. Johnston's assumption that the "ordinary grad" considers himself 100 per cent. efficiency, he joins the ranks of the toilers, and is willing and anxious to pick up the tricks and kinks as they present themselves; and the man who takes the pains to help the poor "tech" on his way finds a warm place in the heart of the latter.

It is admitted that a great many boys have the conceited and bloated feeling, but that does not come after graduation, it is in the fellow when he comes to college, and in the most of our schools it is the purpose to kill this evil by means of that essential to all condensing apparatus, cold water.

A large percentage of the fellows who come from our State universities and other institutions worked their way through by sacrificing a good many things, and they appreciate the value of technical education. Do not condemn the college graduate because he is not expert in some particular thing; he has got only the fundamentals, while you may have worked on this very job for five, ten or twenty years.

Orono, Me.

Do Crank Pins Always Wear Flat?

W. O. Platt, in his article on "Do Crank Pins Always Wear Flat?" in the February 9 number, brings up that question in a direct manner. He has had personal experience with bearings on crank pins where the pin did not wear flat. Some pins wear flat and others do not, depending on several conditions. The first and most important of these is the fitting of the bearing around the pin. If the bearing fits snugly the pin cannot wear flat, while if it does not the pin will surely wear flat, especially in a single-acting engine. This may be illustrated in the following manner.

Take a flat surface bearing on a pin along a single element of its surface and, with the impulse all in one direction, the side of the pin toward the impulse will always wear flat, the flatness depending on the magnitude of the impulse. This will be seen to be the condition when a loose box is placed around a pin, the box only bearing along a very narrow surface.

However, in a well fitted bearing it is impossible for the pin to wear very flat, for to make it wear flat the box must bear harder at one place than at another. As the box fits the pin it must bear hard around one whole half instead of merely on a line. Further, the impulse usually lasts for almost a half revolution of the pin, so that the portion of the pin on which the bearing is forced by an impulse extends almost all the way around the pin. The very slight flatness which may be induced by the resiliencies of the material in the box and pin, and by the small clearance which the box must have in order to run freely, are taken off by the general frictional action removing the high parts first, and also by the force exerted on the "nonwearing" side of the pin by the resistance of the piston moving back to its original position. This last force is also augmented in the gas engine by the compression pressure.

Los Angeles, Cal.

Scaled Pipe Connection

Fig. 1 is a sketch of the piping connected with the feed pumps and hot-water heater in the Criminal Court building, Chicago, Ill. The pumps refused to run at their rated speed, although they did so when installed, their speed gradually reducing until it was evident that something must be done to provide sufficient water for the boilers, tanks, etc. The steam for the pumps was taken from an auxiliary steam main. The exhaust from each pump entered a 4-inch auxiliary exhaust main, thence blowing to the main exhaust and feed-water heater, not shown.

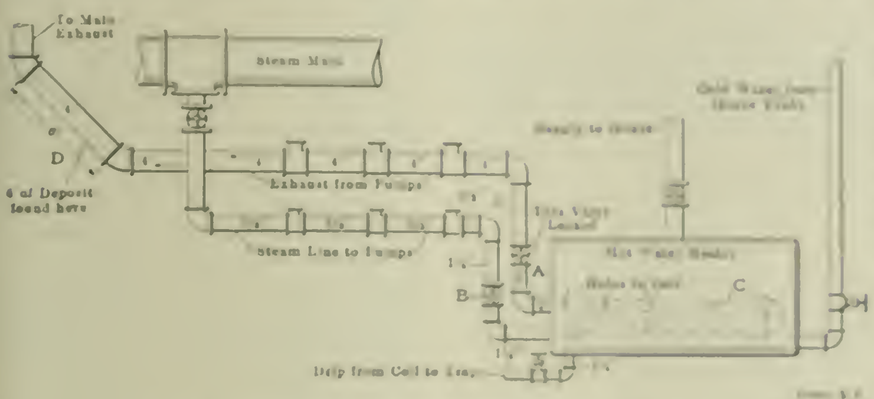

FIG. 1. CONNECTIONS OF FEED PUMPS AND HOT-WATER HEATER

It will be noted that the hot-water house-supply tank is provided with a valve A to heat by exhaust steam, and a valve B, to heat by live steam.

FIG. 2. SECTION OF 4-INCH EXHAUST PIPE SHOWING DEPOSIT

The cause of the trouble was due to the 4-inch coil C in the hot-water tank becoming perforated and the water from the cold-water house tank being forced into the exhaust pipe through the body valve A.

This leak [illegible] was supplemented by a second one, as the water was found to come in contact with the exhaust steam and mingled with some of the [illegible] the pump cylinders, causing the solid matter in the water to precipitate in the interior of the 4-inch exhaust pipe. As this composition was being exhausted toward the main exhaust, it is plain that if any restriction were to be offered to its passage it would occur between the two 45-degree ells. Consequently, I ordered the exhaust main taken apart between these points.

No flange unions being near, we used a large 4-inch pipe cutter, placing it at the point D and cut out a piece about 8 inches long. The condition of the interior of the pipe is shown in Fig. 2; the formation of the different layers of scale is shown by the numerous circles. It was found that this scale, which was as hard as a piece of limestone, reached the entire distance, 6 feet, between the two 45-degree ells.

J. W. Graham.

Chicago, Ill.

Extraneous Supervision of Power Plants

I should like to ask the following questions of the Engineering Supervision Company, of New York City.

To whom do they furnish absolute proof of their ability to decrease the cost of power and maintain or increase the efficiency of the plant without any further outlay or expenditure on the part of the user?

Can they afford to hire a well-trained engineer to operate and keep in repair each individual plant, involving a knowledge of the most economical methods of conducting such work; or do they mean to say that [illegible] a few superficial examinations they can accomplish what some very able and experienced men have often found it difficult to do by working every day and some nights?

Upon whom does the responsibility rest for the safety of the mill property in a plant so conducted? [illegible]

[illegible]

[illegible]

book is to be taken as documentary evidence that all inside the covers may be taken literally by the man who foots the bills?

HORACE L. BRADBURY.

West Everett, Mass.

Removing Broken Studs or Set Screws

There are two methods in general use for extracting a broken stud or a set screw. One is to drill it out with a drill of about the same diameter as the bottom of the threads, and remove the remaining small pieces from the hole with a chisel or other suitable tool; the other method is to take a round-nose or diamond-point chisel and drive the stud around, thus screwing it out, sometimes.

The first method has many drawbacks, as the threads in the hole are often damaged, either by the drill running to one side or during the subsequent operation of extracting the threads; it is also next to impossible to drill out the commercial set screws that are case-hardened all over.

The second method is not always successful and very often does more harm than good, but sometimes very stubborn pieces may be started by employing two chisels, one on each side, and having each man strike in unison.

Fig. 1 illustrates a job I had to do some time ago. The casting weighed several tons, and the only shop within miles was a blacksmith shop, where I borrowed

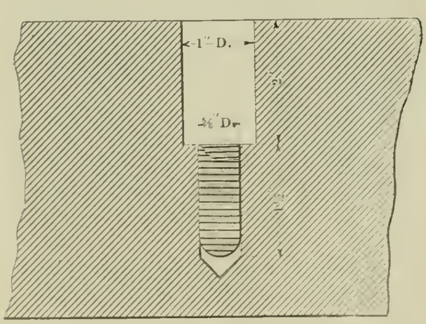

FIG. 1

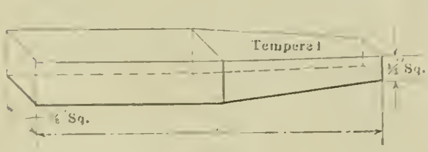

FIG. 2

a breast drill with a 3/8-inch drill and forged a punch similar to Fig. 2. I then drilled a hole 1/2 inch deep in the end of the broken stud, drove in the punch, applied a wrench to the projecting end of the tool and screwed out the troublesome piece.

This method has since proved extremely useful on many occasions, especially when extracting small set screws, as the center of these is generally soft enough to enable a small hole to be drilled with comparative ease. I have also removed taps by the same method, after softening with a torch.

A. J. TAYLOR.

Nanaimo, B. C.

Pressure Vibration in a Steam Main

The accompanying indicator diagrams were taken at one of the power plants of which I had supervision. They are a good illustration of the influence which can be

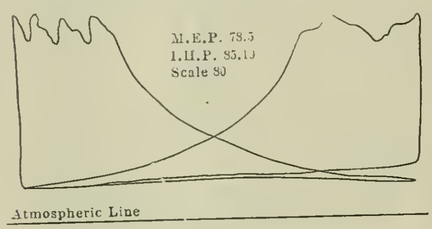

FIG. 1

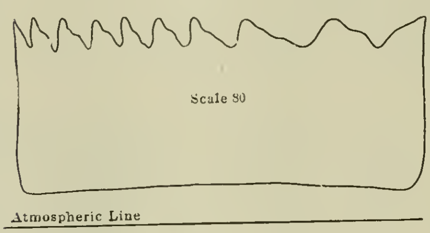

FIG. 2

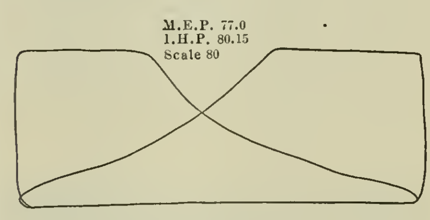

FIG. 3

exerted upon one engine by another fed from the same steam main and standing nearer the boilers.

A 6-inch steam main from a battery of Heine boilers feeds, by means of a branch pipe, a 30 and 52 by 48-inch cross-compound noncondensing direct-connected engine. The pipe then diminishes in cross section and supplies an Ingersoll-Sergeant 16 and 32 by 36-inch cross-compound noncondensing air-compressor engine with Corliss valves.

When the dynamo engine is running, the intake line of the second engine shows considerable vibration; when the dynamo engine is not running, the intake line of the compressor engine becomes straight.

In Fig. 1 is shown a diagram of the high-pressure cylinder taken from the compressor engine when the dynamo engine was running under usual conditions. Fig. 2 shows a diagram taken under the same conditions, but with a 100 per cent. cutoff to show distinctly the characteristic vibration of the intake line on the compressor. Fig. 3 shows a normal diagram of the same cylinder, the compressor working under the same load, all the conditions being the same as in the first case, except that the dynamo engine is not running.

During these trials the dynamo engine made 103.5 revolutions per minute, developing 156 horsepower. The compressor engine made 23 revolutions per minute, compressing 750 cubic feet of free air per minute to an average pressure of 87 pounds.

The second diagram shows nine vibrations. Multiplied by 23, the number of revolutions per minute, gives 207 double vibrations per minute, which exactly corresponds to the number of strokes of the direct-coupled dynamo engine.

A comparison of the energies used in the compressor in the cases of Figs. 1 and 3 gives the following difference in favor of Fig. 3: Fig. 1, high-pressure cylinder, 86.193 horsepower; low-pressure cylinder, 75.33 horsepower. Fig. 3, high-pressure cylinder, 80.154 horsepower; low-pressure cylinder, 74.25 horsepower.

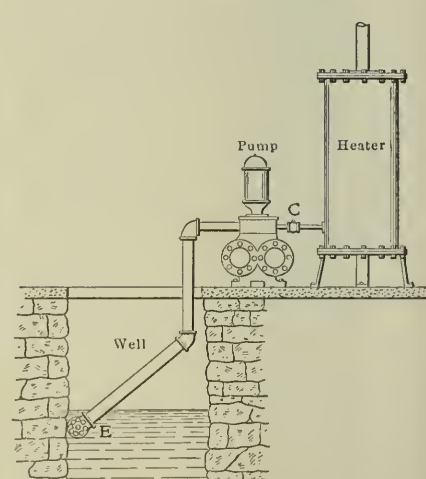
The vibration of the steam pressure in the main in this case causes a loss of about 4.4 per cent. in the efficiency of the compressor engine.

W. N. POLAKOV.

New York City.

Faulty Pump Connections

The arrangement of a new boiler-feed pump that caused trouble is shown in the



FAULTY PUMP CONNECTIONS

sketch. The pump had a lift of 20 feet and was placed quite close to the feed-water heater. When the pump was first started no trouble was experienced, but after stopping and then restarting the pump the failure occurred.

The trouble was caused by the pump being placed too close to the feed-water heater, as the heat from the heater coils prevented the pump from producing a vacuum, consequently the water would fail to rise to the plungers. A check valve *C* was placed in the discharge line from the pump to the heater and no further trouble was experienced. This little failure called an outside engineer from a distance of over 100 miles.

In erecting the pump carelessness had been displayed in placing the suction line, foot valve and strainer as shown, consequently the foot valve failed to work. It was tested by trying to prime the suction pipe, but it could not be filled, indicating that the foot valve was not tight. An examination of the valve disclosed its faulty position.

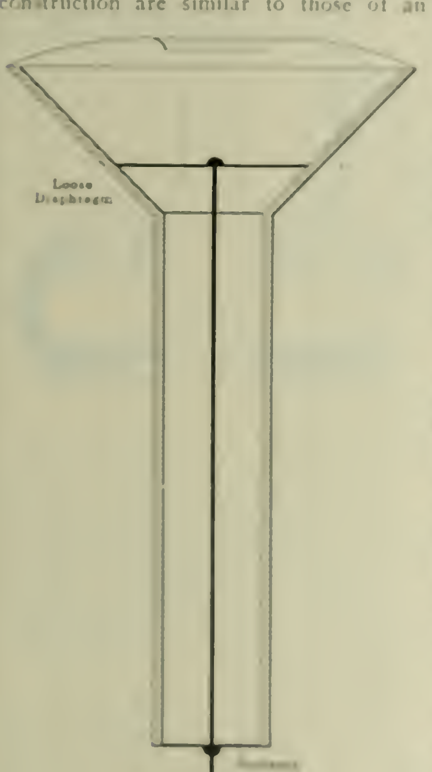
Lynchburg, Va.

Engineers' Knock Detector

The instrument shown in the accompanying cut is an engineers' homemade detector, invaluable for determining the location of knocks, pounds, drips and leaks. A great many of these detectors are used by municipal water inspectors in their "waste and leak" inspections.

The principle of operation and mode of construction are similar to those of an



KNOCK DETECTOR

elementary telephone receiver. A transmitter rod communicates the vibrations to a diaphragm, which produces the proper vibratory effect on the ear. The requisites for construction are some scraps of tin, soldering tools and 6 inches of brass wire about 1/16 inch in diameter. The [illegible] the wire the better.

The cut shows the construction clearly enough to need little description. Make the tube about 5 inches long and 1 inch in diameter. Close the end with a disk punched to allow the rod to project through about ½ inch, and solder the rod to this disk. Make the greatest diameter of the funnel 3 or 4 inches, and leave a ½-inch hole in the cover for the ear. Cut the diaphragm 2 inches in diameter and let it fit loosely under the curved head of the rod.

To use the instrument, place the rod end on the object to be investigated and the funnel end to the ear. Such trouble as loose piston rings, chattering slide valves, water in cylinders, etc., can readily be located. To locate leaks in piping, shut off all valves and then listen for running water in the pipes.

Buffalo, N. Y.

An Engineer Who Is also a Doctor

One of the best engineers on the Boston & Albany railroad leads a dual life, as after his daily run the engineer becomes a doctor. He is a graduate of Brown University and has a medical diploma. His name is H. F. Brackett, and he drives a locomotive because he loves the "iron steed." At certain times during the day he wends his way through the streets of Brighton with an air of dignified reserve and with medicine case in hand. His calls upon patients being over, his silk hat is placed in its bandbox, off comes his white necktie, fancy vest and other stylish clothing, and an hour later Dr. Brackett is speeding over the rails, eyes to front, and his hand firmly clutching the throttle. The clever physician has become the skilled engineer.

For twenty-seven years, and up to the present year, Dr. Brackett ran the big record-breaker "No. 22," which pulled the New York express from Boston to Springfield. In his thirty-eight years of unbroken service as an engineer he has the [illegible] record of never having been [illegible]. He has never killed a person nor destroyed a cent's worth of property through carelessness or inefficiency. With "No. 22" he [illegible] records, but made a name by [illegible] and his daily [illegible] in two [illegible].

As a physician, Dr. Brackett is a member of [illegible] medical societies. As [illegible] he is known to every [illegible] in Boston. He is examining physician for the Brotherhood of Locomotive Engineers and for the New England Order of Protection. He is the physician of the men of the Boston & Albany, and when Dr. Brackett is [illegible] the [illegible] of that road he is [illegible] by the [illegible] and the [illegible]. In his [illegible] [illegible] [illegible].

[illegible], Mass.

An Engine Revolution Gage

In our plant there are two [illegible] [illegible], [illegible] [illegible] [illegible]. It is [illegible] necessary to adjust the speed of the engines from time to time according to the requirements of

ENGINE REVOLUTION GAGE

their loads, we used to have to "feel around" with the governor and then count the revolutions with watch in hand, sometimes [illegible] [illegible] times a day. This made it very inconvenient, so we made the arrangement shown in the sketch.

We screwed a graduated [illegible] made out of a piece of sheet [illegible] on the side of the governor stand, and attached a [illegible] [illegible] [illegible] [illegible] [illegible] through the vertical slot in the stand. The [illegible] was [illegible] down, and we [illegible] that the [illegible] was pointed to the lowest mark on the scale at [illegible] when the engine was stopped. When the engine runs at its highest speed the pointer is at the highest mark on the scale, which is [illegible]. We run at different speeds, [illegible] [illegible] revolutions per minute, and in that way we graduated our scale. We graduated the scale [illegible] [illegible] revolutions by [illegible] the [illegible] [illegible]. All we have to do now is to look at the scale to know at what speed the engine is running.

[illegible]

[illegible], Mass.

Boiler Settings

When called upon to design a new boiler setting the engineer usually recalls the defects in his present settings and endeavors to eliminate them in the new.

Probably the weakest point in the brickwork of a return-tubular boiler setting is the back connection, which is sometimes so small that the tubes can only be reached with difficulty, and often the top row of tubes is so close to the arch that they will not admit an expander. There is no reason why this part of the combustion chamber should not be roomy.

Back arches made up of firebrick will be found to be unsatisfactory and expensive, considering the frequency with which they must be renewed. A slight shrinkage in each of the numerous joints will soon cause the brick to loosen and a bursting tube or an accidental blow when cleaning will bring it down. There are several forms of arches composed of molded blocks of refractory material, which will hold their place and are independent of iron bars or forms for support.

A space of ¾ inch should be left between the head and the back arch to allow free movement of the shell, otherwise the back wall will bulge out and crack. This space should be packed with asbestos after the boiler has been fired up. Usually some of the rivets of the braces will come into this space and if the heads are formed up as they should be will interfere with the free movement of the boiler. This can be overcome by chipping out a recess in the arch opposite each rivet head.

The combustion chamber should be paved with firebrick, starting at a point near the top of the bridgewall, sloping until directly under the end of the boiler and then continue level to the back wall. The clean-out door in the back wall should be set so as to be on a level with the paved floor, which will render it easy to remove the soot. The clean-out door should be of a heavy pattern and fit the frame closely. The frame should be firmly anchored and made tight. More air will usually leak in between the frame and the brickwork or around a warped clean-out door than anywhere else in a setting.

The blowoff pipe should be protected by a firebrick shield, open on the back for inspection. A pier of red brick should be built from the foundation up to near the floor of the combustion chamber to form a firm and independent support for the blowoff shield. The blowoff pipe should be extra heavy and extend from the boiler to an elbow under the paving of the combustion chamber, and then through the back wall. A thimble of 4-inch pipe should be built in the back wall for the pipe to pass through so that it can be easily renewed. The opening between the pipe and thimble can be filled with asbestos fiber.

Care must be taken to see that the brackets have an even bearing on the wall plates. If this is not the case it will cause a serious strain upon the shell. It is customary to specify that the bottom of the brackets be machine finished, and it is just as important that the wall plates be finished on their top surface. Care should also be taken that the rear brackets are properly placed on their rollers and that a space is left around them when bricking in, so as to allow free movement.

It is customary to carry the outside walls considerably above the top of the boiler and to finish with a stone or concrete coping. There should be a space left in the center of the back wall about 2 feet wide, with the bottom on a level with the top of the arch so that soot on the top of the setting can be swept out and collected here. Usually the top of the arch is the bottom of a deep pit which is hard to keep clean. Such an opening will facilitate repairs to the arch.

It will be found very convenient when making tests to have an opening into the combustion chamber back of the bridgewall, also in the back wall opposite the tubes, to insert a pyrometer or to connect a draft gage or gas sampler. This can be accomplished by inserting a 1¼-inch pipe in the wall flush with each side and screwing a cap on the outside. The inner end can be packed with asbestos fiber. A ¾-inch hole drilled in the delivery pipe between the valve and the nozzle will save drilling one by hand when it is desired to insert a calorimeter.

The ashpit should be deep and have a waterproof cement bottom. It should slope back from the ashpit door to a point under the back edge of the dead plate and the cement should be carried up the sides and bridgewall at least 6 inches, to prevent wetting the brick when water is carried in the ashpit. It will also eliminate the corners which cannot be kept clean. Care should be taken that the fire-door arches extend back far enough to protect the front row of rivets and the space between the arch and shell packed with plastic asbestos.

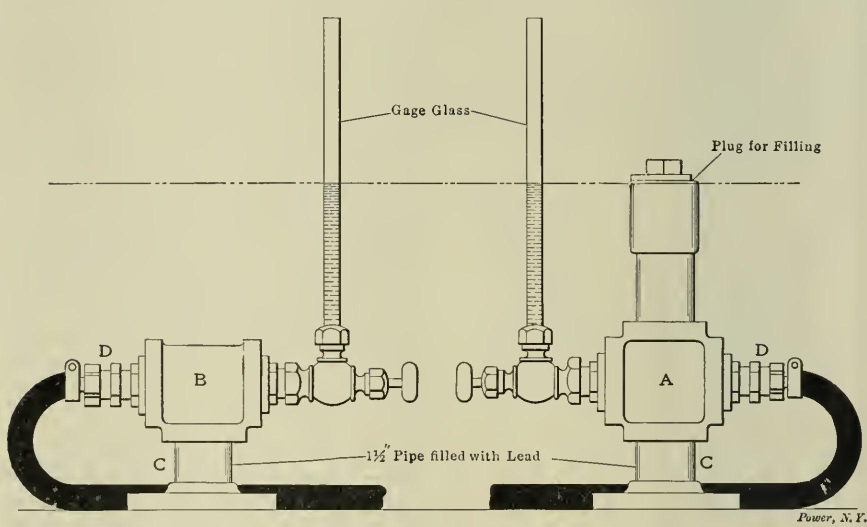
Many of these small details which the operating engineer sees do not come to the notice of the designer, as he does not have the opportunity to see the weak points in his plans; however, it is usually these very things which cause the annoyance and extra labor in operating and maintaining the plant.

Lewis C. Reynolds.

Willard, N. Y.

A Useful Leveling Instrument

The accompanying sketch shows how a leveling instrument I have used for some time is made. The two gage-glass standards are made of ordinary pipe and fittings, except that at *C C* the pipes are filled with lead and calked. A ¾-inch hose nipple is used at *D D* to connect to an ordinary 50-foot garden hose, although a small rubber gas tube would do as well.



A USEFUL LEVELING INSTRUMENT

In filling, place the standards side by side on the bench and allow the hose to trail out on the floor; then fill with water to the top of the coupling and screw the plug in tight. See that there are no air pockets in the hose, as the air might cause an inaccuracy in the level by bubbling up through the water.

One person must tend each gage, and at a signal each must mark the hight of the water level on the wall; then after closing the valves A transports his gage and holds the water level at the mark made by B while B makes a new mark; thus relays may be established for any practical distance.

This device will be found very convenient where it would be inconvenient to use a transit, even if one were at hand, because of darkness and intervening walls. It will also be found useful in grading long lines of steam pipe, etc.

Philip Parker.

Woburn, Mass.

Throwing Coal Away by the Ton

I was recently in an engine room that showed how coal could be thrown away by the ton. There were two 1000-horsepower vertical engines of the high-speed, cross-compound type running condensing. There was also another smaller engine of similar type to carry the lighting load nights. The real trouble was in this small engine and in one of the larger units. Their exhaust connections are arranged as in the accompanying sketch, and to make matters worse, the pistons are of the oval type with dished heads, so that the bottom one is like a cup in which condensation may collect.

The exhaust connections shown in the sketch may work all right if the engine is loaded all the time, and there is sufficient volume of steam to keep it swept clear of water. When the engine is not fully loaded the steam will cut across corners and allow all the condensation to run back into the cylinder, as it is a difficult matter any way to carry the water around the curve *A*, up the vertical portion and turn a right angle into the exhaust pipe.

EXHAUST CONNECTIONS OF LOW-PRESSURE CYLINDER

All the water from the top of the cylinder is also blown down to the bottom. When it accumulates in large quantities a portion of it will be blown out, but there will always be some left in the bottom of the cylinder, which will leak through the packing and make it almost impossible to keep the piston or valve rods tight, and frequently flange joints leak, too. There is not sufficient water to cause a wreck, but there is enough for the piston to give light blows and distress the weakest part, which, after a time, will give way.

It is wholly inexcusable to make an exhaust like this, as on a vertical engine the exhaust should go out straight from the bottom so as to thoroughly drain all condensation. I had a low-pressure cylinder like this at one time, and I put in a 2½-inch drain pipe, as shown by the dotted lines, and led this pipe down into the condenser.

At this engine room the trouble is [illegible] credited to the boilers giving wet steam, notwithstanding thousands of boilers of the same make are giving good service, and show no tendency to prime.

To remedy the trouble they have taken the trap off every drain pipe and opened them wide, some five or six 1- to 1½-inch pipes and 130-pound steam pressure. Then all of the cylinder cocks are run wide open. Just think how much coal can blow to waste under these conditions. Also the chance the boilers have to give dry steam with such a drain and the first run so hard that the breeching to the chimney is badly blistered.

They have decided to get some new boilers, also some new engines of some kind. Getting the new engines is all right, but there is nothing wrong with the boilers if they only had a chance.

W. E. CRANE.

Broadalbin, N. Y.

Transformer Connections

When reading Mr. Carroll's letter, I noticed that he does not quite understand that his two transformers being connected in open delta take current from the three phases, as he states they take current only from phases one and two. One transformer is connected between leads one and two, and the other transformer is connected between leads two and three, and the resultant of the phase displacement between the two transformers, which is taken care of by the leads one and three, is a third phase supplied to the transformers, so with the motor connected to the circuit all three leads supply the same amount of power.

The transformer which supplies current to the lamps, connected to one phase, should not cause any serious effect on the regulation of the system, as [illegible] the three-phase circuit which supplies the power side. If the lighting load is heavily [illegible] under unbalancing of the [illegible], it would be advisable to add another transformer and balance it with the other so each delta [illegible] lines, and then evenly divide the load on the secondary side. This will eliminate unbalancing. The regulation of circuit mentioned should not necessarily give any trouble.

JAMES E. KELLY.

Lincoln Place, Penn.

Pressure Required to Raise a Valve

In recent numbers there have been letters discussing this subject. I have made several tests on three 2x3-inch double-cylinder (crank between cylinders), single-acting oil pumps which worked against a common pressure of 200 pounds and entirely independent of each other, with pipe connections. The illustrations and table explain the results obtained. Taking pump No. 1, the bearing surface of valve *A* is 3/32 inch and the tank pressure 190 pounds. The cylinder pressure, or that necessary to raise the valve is 195 pounds. With the valve having a bearing, as shown at *B*, Fig. 1, the tank pressure was 180 pounds and the cylinder pressure 190 pounds. The tank pressure was raised by the same gage, through a simple arrangement of piping, before and after any test. There was no special arrangement of the [illegible] except that the springs were so [illegible]

Wear of Bearings on High Speed Engines

Many engineers say they do not like high-speed engines, because of their wearing so fast. I have a 150-horsepower high-speed engine and I find its performance remarkable in this respect.

The engine has been in service over five years and the tool marks are quite visible on every wearing journal. I have taken up on the two main bearings once since the engine was erected, and by disconnecting the eccentric rod at the bail joint and working the valve by hand, after steam is turned on, no shaft lunge can be noticed, and it will probably be another year before the bearing caps will have to be removed. The crank-pin brasses ran for thirteen months without adjustment, and all I took up then was the thickness of a piece of very thin paper. Not the slightest wear on the crosshead pin can be detected with a pair of calipers, although the engine has done a twelve-hour "stunt" every day since it was first started. The valve has a large wearing surface and seems to be as tight as at first. I use metallic packing on the piston rod.

I also have a 20x42-inch Corliss engine that has been in service over five years. I have never had to take down a single rod or bearing. I had one of the dashpots out once, and also centered the piston rod in the cylinder. We also do the ordinary adjusting all around every so often.

OAKS KYGER.

Danville, Ill.

Pump Valves

The writer was recently called to a plant to locate the trouble with a boiler-feed pump. The engineer said he had just taken out the brass valves and replaced them with hard-rubber valves.

I found that he had placed the rubber valve on a seat which did not have any bearing next to the stud, the stud being cast solid on the seat and required a valve with a hollow stem which works over the stud.

It was evident the water would be forced up through the hole in the valve, around the stud and then forced back again by the pressure from the boiler, the water churning back and forth through the valves. I had him get a new set of valve seats, having a screw stud and a bearing around the same.

I have found that a good rubber valve is the best for a boiler-feed pump, no matter how hot the water is, but I think it a good idea always to place the old brass disk on top of the rubber, as it distributes the pressure all over the valve and keeps it from cutting down or sinking through the seat.

Some engineers argue that they must have springs on top of the valve on a boiler-feed pump. I cannot see why this should be, because the pressure from the boiler always holds them down, and again the area of the top is a great deal more than the bottom, the spring only making it harder to lift.

H. T. FRYANT.

Jackson, Miss.

An Engine Accident

Not long ago I was running a 16 and 30 by 42-inch cross-compound Corliss engine. It had only been installed about three months when the high-pressure piston rod broke off in one of the three threads remaining outside of the jam nut of the crosshead, with the result that the cylinder head was pushed off, pulling the stud bolts out, breaking out the holes and cracking the walls for a distance of from 1 to 6 inches.

We had to get a new rod, piston and cylinder, and as the engine was guaranteed for a year the company naturally expected the builders to pay the damage. The agent was in town and had been in looking the plant over the day before and, as he said, had noticed that we were carrying 5 pounds receiver pressure with an average load of about 300 horsepower. The agent took the short piece of broken rod which showed about one-third of its area as a new break. The other two-thirds had been pounded smooth, showing that the crack had been opening and closing a great number of times, perhaps, since the rod was put in.

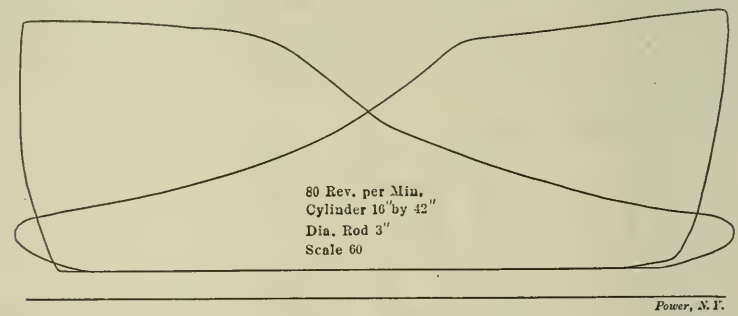
In a week he came back with data from experts showing that there was enough good metal in the rod to pull the load, provided the load were balanced. I was called to the office to explain why I did not run the engine as it should be run. I stated that the engine was balanced as well as it could be without taking diagrams every time the load changed; but the agent pointed out that I was only carrying 5 pounds receiver pressure, and that the gage was tested and found to be all right. My argument did not "go," for I could not talk as well as the agent.

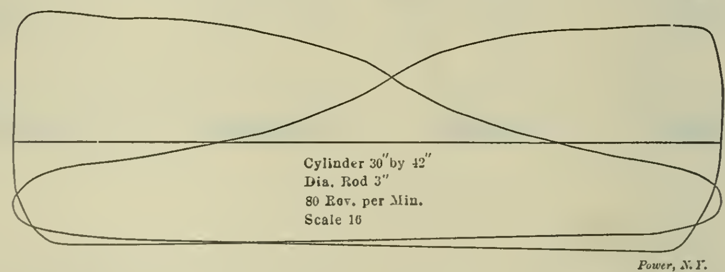
I told him that the specifications called for a square thread on the rod, not a V-shaped thread, neither did they call for a cracked rod.

The accompanying diagrams were taken under the same conditions as when the rod broke, and I should like some of the readers to point out the defects of each and figure the horsepower.

THOMAS SHEEHAN.

Pittsfield, Mass.





DIAGRAMS FROM A 16 AND 30 BY 42-INCH CROSS-COMPOUND CORLISS ENGINE

Use of Coal Oil on Commutators

I can recommend the use of coal oil on commutators for low-voltage machines. After shutting the machine down I take a little coal oil on a rag and wash the commutator with it. This removes the foreign matter and will generally keep it in good condition, providing the machine is free from grounds, short-circuits, etc.

For machines much above 110 volts I have found it unsatisfactory. I first tried it on a 550-volt rotary converter. It sparked so badly that I had to take it off the line and give it a good cleaning, using paraffin for my brushes. I have used coal oil on other machines of about that voltage with the same result.

I obtain good results with paraffin on the higher voltages. It not only lubricates the commutator, but stops all chattering. I heat the paraffin quite hot and dip the brushes into it.

A Cause of Engine Wreck

The following conversation took place between a license examiner and an engineer:

Examiner—What would be the result of lengthening the long rod and shortening the short rod on the governor of a Corliss engine?

Engineer—It would make the cutoff longer.

Examiner—But would it?

Engineer—Certainly it would.

Examiner—If the load and steam pressure remained the same, would it?

Engineer—The governor would assume a higher plane.

Examiner—That's it, the governor assumes a higher plane.

If the engineer had been allowed to continue he would have said "And to assume this higher plane the engine must run faster, and to run faster the cutoff must be longer." There is another question that comes in here and that is: Will it bring the governor to a point where, with no load, the cutoff is too long and the engine will run away?

There have been many flywheel wrecks from this cause. When the engine is erected these rods are left so that the governor at its highest point will not allow the valves to open to admit any steam and care should be taken that the governor is always in that condition.

Poppet valves are usually opened by one cam sliding around on the small side of another. To set the valves the governor is raised to its highest point, and in that position the governor is turned to bring the highest point of the cam opposite one of the valves. The valve should be set so that the cam will pass and just touch but not open it. The other valve is then set the same way. The governor is then lowered and brought up to one of the valves so that the cam will open it the amount of lead that is necessary. The engine should be on the same center.

Poppet valves are driven by gears. The gear should now be put on the stud and put in mesh with the gear on the engine shaft. If it will not mesh upon the first trial, turn it around until it does. The valves are now set to give the full range of cutoff, and the engine will not run away, as it cannot get steam to run above a certain speed. There are no belts to break and nothing can happen to the governor.

The same thing should be looked after in all engines. An engine that will admit steam after the governor is at its highest position is unsafe to run, for with a vacuum and no load a runaway is almost assured. To change the length of the rods on the governor without investigating this point is to invite trouble. This is one of the most important [illegible] about any kind of an engine, but in how many cases does it receive a thought?

With governor belts there is always danger and a safety stop is necessary. If gears and a positive drive could be substituted it would reduce the danger.

Some Condenser Troubles

A certain steam plant was equipped with a barometric condenser which discharged into a hotwell, overflow of which led to the river some distance away. Upon starting the engine a vacuum of from 26 to 27 inches was obtained, but in about ten minutes the vacuum would drop to 18 or 20 inches and remain there. No air leaks could be found and the supply of water was ample. An investigation of the hotwell showed an overflow pipe but little larger than the condenser-discharge pipe, and about 2½ feet below the top of the well, which was fitted with an air-tight cover. When the water rose above the overflow, the vapor from the condenser accumulated in the top of the well and raised the pressure in the well above that of the atmosphere. This reduced the effective weight of the column of water in the discharge pipe and decreased the velocity of the discharge, consequently causing a loss of vacuum. A larger overflow pipe was put in and the trouble disappeared. A vapor pipe in the well cover, to prevent the accumulation of vapor, would probably have answered as well.

A combined air and circulating pump in another plant discharged into a small sewer. As time went on many connections were made to the sewer, and the condenser began to give trouble. With the engine under a heavy load the pump would become suddenly flooded in several instances [illegible] the pump. As there was no automatic atmospheric valve the exhaust had to pass through the pump until a gate valve was opened by the engineer. A separate sewer for the condenser was built at considerable expense, but the writer believes that a vapor pipe on the condenser discharge with an automatic atmospheric valve in the exhaust pipe would have overcome the trouble which was doubtless due to an accumulation of vapor in the sewer.

In another steam plant a barometric condenser gave considerable trouble due to air leakage. A vacuum could be obtained and held when the engine was not running, but when running the vacuum would fall off and break with a heavy load. It was at first thought that the water supply was insufficient, or that the [illegible] leaking enough to cause the trouble.

[illegible] showed that the [illegible] of the [illegible] leaked considerably, causing them to [illegible] a mixture of air and water in the [illegible]. The air came over with the water to the [illegible] and then to the condenser, accumulating in the top of the condenser until it finally broke the siphon. A new [illegible] pump solved the trouble.

One plant apparently had no difficulty in the condenser line. The gage on the board showed 30 inches, and the engineer claimed that it was correct, as it had been tested. A test gage placed directly upon the exhaust pipe showed about 26 inches. The engineer said that when the plant was first started the gage showed 26 inches, but this had gradually increased until it reached 30 inches. He had supposed that the condenser was becoming more efficient with use. Upon loosening the union nut beneath the gage the needle dropped back to 26 inches, where it remained when the nut was tightened.

This engine operated part of the time exhausting to the atmosphere, and when so working the condensation was forced up into the gage pipe, nearly filling it. When running condensing the gage showed the vacuum, plus the weight of the water in the pipe. Loosening the nut on the union had allowed the water to flow back to the exhaust pipe.

Improper Boiler Blowoff Connection

Our boiler blowoff pipe was [illegible] inches in diameter and was screwed into the back head about 2 inches above the bottom of the shell, so that it was impossible to blow out the mud and sediment which in time accumulated in the boiler to a considerable extent. It was impossible to wash it out with a hose, so the only way to clean the boiler was with a [illegible], which was not satisfactory. A hole the same size as the blowoff pipe had been tapped in the bottom of the shell about [illegible] from the back end, but plugged. To put the blowoff pipe in the proper place could not be done until a reinforcing ring had been placed around the hole. A local [illegible] was asked [illegible] boiler-repair work was [illegible] of putting [illegible] reinforcing ring.

The boiler had no manhole in the back head, while one had to the front [illegible] smaller than the average, and it was difficult to get the rivet [illegible] inside the boiler. The [illegible] was made the shape of a [illegible] plate, [illegible], and had to go in [illegible] so it could be pushed back toward the back head. We [illegible] succeeded in getting it in place, allowing [illegible] to [illegible] the holding and hammering. Since [illegible] was pulled out through the [illegible] blowoff hole.

Safety Valves*

A Posthumous Contribution to the Recent A. S. M. E. Discussion; How Safety Valves Should Be Rated; An Argument against "High Lift"

BY A. B. CARHART

Certainly there is one way in which safety valves should *not* be rated, and that is by the *area* of the disk or of the inlet connection; for in every case the outlet-discharge capacity is proportional to the circumference of the valve seat and the circumference will, of course, increase in proportion to the diameter, while the inlet and disk areas will increase in proportion to the square of the radius. If the lift of the disk is the same for all the ordinary sizes of valve, the discharge areas and capacities of the valves are directly proportional to the diameters, and the inlet diameter becomes a direct measure of the relative size or capacity of the valve. There seems to be no good reason to depart from this method of denoting valve sizes, which has been the uniform custom in the past, and it will be found to be more accurate and satisfactory than any other method. The lift may properly be assumed to be uniform in all the sizes of valve such as we are considering, for this is the actual performance in practice. If there is any measurable difference in special cases, it will generally be found that the larger valves lift less vertically than the smaller ones. This is as it should be in proper designing, from the practical point of view of prompt and quiet action, durability of the valve and safety to the boiler. The smaller valves have less weight of moving parts, less momentum, less load, springs of more tractable proportions and may safely lift higher.

Valves should not be rated in discharge area alone. The discharge rating of a valve would be different for every pressure and would be dependent upon the care in maintaining the uniformity of commercial springs; and it would be in any case a theoretical amount arrived at by a formula which might be amended by any designer or salesman to suit the exigencies of every contract price or specification of capacity. This would introduce in the first place a hopeless confusion in odd sizes, and leave the engineer wholly at the mercy of the representations or the misrepresentations of selling arguments. The standard sizes, familiar in practice to all engineers, now denote the size of the inlet-pipe connection which must be provided in the boiler; if different designs of valve have different apparent or claimed efficiencies, allowance can be made for this in the judgment of the engineer. We do not rate iron pipe in discharge capacity or area, but by commercial-diameter sizes; and this universal custom has never been overturned at anyone's suggestion merely because the inside diameter of hydraulic or extra-heavy or brass pipe differs from that of ordinary pipe, or because bends and elbows may reduce the flow; engineers exercise their judgment in specification. The actual lifts or discharge areas of valves should be determined and reported upon after impartial tests conducted by competent and disinterested engineers, under conditions of scientific accuracy and fair precautions, where each valve is intelligently regulated to work under its intended normal limits, and not from any reports of tests conducted by any one manufacturer without the knowledge of the other makers whose valves were thus treated, and where the one measurement noted was in many cases purposely limited.

My judgment is that the valves should be so designed and proportioned to the boiler capacity that the valve disk should not be required to lift too far from its seat. The effects of hammering the seat and unduly distorting the loaded helical spring are to cause leaky valves, which require frequent regrinding, and the sticking of the valves in opening and closing. All such trouble or danger can be avoided by limiting the rise of the disk in valves for stationary boilers so as to give an effective free opening through the valve seat equal to 0.05 inch vertical measurement as the maximum; and I believe there is no argument, except unreasoning demand for cheapness of boiler equipment, that would increase this limit; in most cases the considerations of stability and safety would suggest to conservative engineers reducing the amount of lift instead of increasing it. The increased discharge capacity of the larger valves is measured by the enlarging circumference of the valve seat, the discharge area increasing in direct proportion to the diameter size rating without increasing the lift.

At 200 pounds pressure the total spring load upon a 4-inch disk is over 2500 pounds, and as the valve lifts the farther compression may increase this 1000 pounds more; and this force acting upon a large disk, through any considerable distance, develops a tremendous energy, which is redoubled as the time or suddenness of movement is lessened, and rapidly multiplies in proportion to the square of the distance for every increment of higher lift. The destructive effect of such augmented force in actual experience is beyond anything that the mere figures of a formula for acceleration and energy would convey to the mind. The loads and reaction and the unwieldy proportions of such large springs will, of course, be reduced to about three-fourths as much in the flat-seated valve. I do not refer now to the mere pounding of the seat, causing leaks and chatterings, and requiring frequent repair and regrinding, but the destructive and dangerous effects upon the boiler. The circumstances of opening up the seams in testing boilers when models were tried out, the condemning of boilers on account of leaks developing soon after being fitted with new valves of the so-called improved design, are well known, not to one manufacturer, but to everyone who has undertaken any original work in this field, and not this year only, but a dozen and twenty years ago, within the knowledge of those who were leaders in the business at the time. For, after all, this is a practical question, about which the best manufacturers know more from the records of past experience than all the discussions of a year could suggest for possible trial. Tests of lifts and capacities of safety valves are reported in textbooks, such as Peabody and Miller's "Steam Boilers," printed a dozen years ago.

For locomotive valves, where the steaming capacity of the boiler is relatively large, and the steam is freely discharged into the open air in all directions, and the valves are subjected to thorough monthly inspection and repair, sometimes by requirement of law and always by skilled and experienced repairmen, the lift of the disk has been commonly equal to about 0.075 or 0.08 inch of effective vertical measurement, but it should not be more. In valves of the 45-degree bevel-seated type, the effective opening is only about 0.7 of the actual vertical lift, less also any overlap of the regulating lip or ring which controls or throttles the steam after it passes the valve seat, so the actual spring compression should be about 1½ times the measurements given. Freedom and directness of flow of the escaping steam are essential points to con-

*Discussion submitted since the A. S. M. E. February meeting, which was devoted to "Safety Valves" and was reported in our issues of March 9 and 16, 1909.

sider, and measurements of dimensions and time of discharge are subordinate to and to be interpreted in the light of actual performance in long-continued service.

In this matter of proper opening for a valve, "it is a condition which confronts us and not a theory." The present practice of some manufacturers is deliberately what it is, because, in their judgment, it is the wise and the proper one. Customers have not in recent years inquired so much about the lift and dimensions of safety valves, but manufacturers themselves have studied and considered them from all sides.

A high lift is not in itself a desirable thing nor a direct measure of the discharge. It would be ideal if, when the critical pressure were reached, some by-pass valve or outside linkage would operate the lever and lift the disk, freely to permit the steam to escape directly to the open air over a rounded edge. But the too common practice is exactly contrary to this, and the steam which theoretically has been released at the seat of the valve finds itself imprisoned in an outer chamber where it must be delayed and harnessed, in a sort of low-pressure cylinder, until by its impact in a tortuous passage and its expansion against the enormous spring load, it forces the disk up in the "pop" lift. Not an ounce nor breath of all the steam (supposedly necessary to be released at a critical moment of danger, and freed only to relieve the boiler) can escape to atmospheric pressure until it has thus given up its measure of work to lift the disk, and the larger the disk area and corresponding spring load, the greater will this work be; and the higher the lift desired, the longer and more completely will the steam be confined and throttled to extract the utmost of work from the escaping flow. The expansion chamber is sometimes cunningly constructed with a regulating ring (patented by Richardson in 1866 and 1869) so devised that the edge overlaps the edge of the lip of the disk to prevent all free passage to the air whatever until the disk has lifted at least the amount of the overlap, so the first few hundredths of an inch of lift are practically ineffective and the remainder of the lift gives the equivalent of only 0.7 of the actual vertical movement. Richardson himself described the essential feature of his invention, in thus limiting the outlet flow: "Consisting in forming the valve with a surface outside of the ground joint for the escaping steam to act against; the said surface being surrounded by a projecting or overlapping lip, rim or flanch, leaving a narrow space for the escape of the steam when the valve is opened, but which, although of greater diameter than the valve seat, by reason of the said lap, presents a less area of opening for the escape of steam than is produced at the valve seat."

Although traditionally accepted by the various boards and approved under the admiralty rules, I cannot help looking upon this as a wrong engineering principle and design, deliberately to throttle or constrict the outlet during the first part of the lift, and strangle the escape discharge, for the sole purpose of getting extra work out of the steam, instead of discharging it freely and immediately. The steam may appear to get out over the valve seat with the large lift, but it is not yet safely out into free air to give the boiler relief. If the steam can be made to get away freely in proper quantity, without any delay, restraint or expansion chamber, why should it be thus hindered simply to produce a spectacular lift of the disk?

The lifting of the valve disk against the increasing pressure of the shortening spring should be performed by an auxiliary stream, separate from the main discharge. If we could discharge sufficient steam with even less lift, any valve would be the more efficient and desirable. With large lift the strain and torsional deformation of the spring are unnecessarily great, with resultant cocking and side thrust on the guide-wing bearings, which have been known to show a reduction in diameter of 1/4 inch in a few weeks of service; the strain upon the boiler itself is dangerous when such a valve opens and closes, and water is drawn out of the boiler with the steam when the opening is too great and sudden. The throttled-lip action can be likened to the mule that stops to kick over the whiffletree: it is spectacular, but there is not a pound of useful pull on the traces and no progress made until it is over. We do not buy mules by measuring the height they can kick, but by the load they will actually haul in a steady pull, and sudden jumps and jerks that break the harness but do not really start the loaded wagon are not useful work. In Africa the savages buy old muskets by their kick or recoil, that gun is considered the most powerful which has the worst kick; but we know that all the kick of a gun is subtracted from its effective work of discharge upon the bullet, and we do not buy guns on that basis.

For stationary boilers, which are used generally at the lower pressures, 4 inches diameter of the valve seat is the limit which should be attempted, and valves larger than 5 inches in diameter cannot be recommended. A 5-inch valve is the largest size permitted by law so far used in Massachusetts, and the board in this State was not influenced by any [illegible] from manufacturers on this point. [illegible]

[illegible] larger than 5 inches is a fair indication that such practice is reasonable and within good judgment.

My opinion, based upon experience and the records of the performance of many thousands of valves in use, of the several styles of different manufacturers, is that pop safety valves for locomotives should not be larger than [illegible] inches diameter at the seat. At 200 pounds pressure the total load upon the valve disk in the bevel-seated type of valve is [illegible] pounds, increased perhaps [illegible] pounds more to maintain the lift when the valve opens, or more than [illegible] pounds as the maximum. For the flat-seated annular valve the initial load is [illegible] pounds, increased to about [illegible] pounds when the valve lifts, but the possible maximum is under all conditions less than the initial or maximum load upon the bevel-seated valve; and the effective discharge area in the [illegible]-inch size amounts to a little more than 1 square inch at only [illegible] inch lift of the disk, or something over [illegible] pounds of steam per second, according to a common formula. [illegible]

[illegible]

ness, as endless experiments in mechanics are designed to demonstrate. Much better practice is that recommended and more commonly followed for locomotives, using three valves of comparatively smaller size, set to open 2 pounds or 4 pounds apart, one or more of the valves being called into operation in succession as the steaming conditions may require; the successive sudden shocks not being dangerous or destructive. This prevents any serious rise in boiler pressure before relief is afforded.

We know that in actual service two 3½-inch valves or three 3-inch valves have been ample to take care of the largest locomotive boilers under the most severe requirements of heavy steaming and freight service on mountain railroads, and that under such circumstances the third one of a series of three 3-inch valves has never been known to blow; while records made of locomotives under special observation on this point prove that on many locomotives not more than one of the 3-inch valves has been known to blow and the pressure has never increased sufficiently to reach the second one set at 2 pounds or 4 pounds above the first. The effective discharge area of a 3-inch flat-seated valve with a lift of 0.075 inch is a little more than 0.8 of a square inch, actually discharging 2.5 pounds of steam per second, so that the combined capacity of the three 3-inch valves would be 7.5 pounds of steam per second. This confirms my opinion that Mr. Whyte is correct in saying that safety valves need not have a discharge capacity equal to the steam-generating capacity of the locomotive boiler under forced draft. I believe that experience has been sufficient to demonstrate that a total valve capacity theoretically equal to 2 square inches of discharge area for ordinary locomotives, and 3 square inches for the largest ones, has been safe and efficient, and has never been called upon for more than two-thirds of even this provision. To provide greater capacity than required means either a multiplication of valves unnecessarily or a provision of larger valve capacity in each unit, not only needlessly, but recklessly regardless of other conditions of certainty of operation and freedom from repairs in the more vital daily operation of a locomotive. What purpose will it serve for a designer to point with pride to a locomotive and boast that its valve capacity is a certain large and heretofore unrequired amount, if those valves are of short life, cause dangerous strains and costly deterioration in the boiler and constantly leak so that ordinary working pressure cannot be maintained in the daily runs? The last state into which we are led by theoretical discussion may easily be much worse than anything that conceivably could happen to us, but has never yet happened, when empirical rules of the past have been sensibly and reasonably applied.

Our own honored past president, F. R. Hutton, wrote not long ago upon the subject of steam boilers: "There are supposed to be, in some circumstances, sudden evolutions of steam in such quantities that no relief is possible through safety valves. In regard to such cases it can easily be shown that by reason of the high specific heat of water, as compared with iron, it is very difficult for any large quantity of steam to be made even from overheated plates, so that disasters perhaps rightly attributed to low water are the result not of excessive internal pressure but of strain from contraction when such overheated plates are suddenly cooled by contact with water."

I believe that the most sensible solution of this whole question will be found in equipping a locomotive with three valves each of 3-inch or 3.5-inch diameter size, as may be indicated in proportion to the capacity of the boiler. The first one of such valves would be a muffled valve set at 200 pounds, to permit only 2 pounds drop in steam pressure when it opens, to be a working valve to take care of all ordinary running conditions, leaving the locomotive with proper pressure to continue its work after the blowing of the valve. The second would be a reserve valve of the same type, set at 202 pounds or 204 pounds, to take care of unusual conditions under which the steam pressure might possibly continue to rise in spite of the first valve, and set to permit a drop of 5 pounds or 6 pounds and yet not let the pressure go much below the normal 200 pounds. The third valve of the series would be an emergency valve, of the same general type as the others, but of different proportion of disk and an extremely resilient spring, with an adjustment set to insure an exaggerated lift and large discharge, which should cause the boiler pressure to drop 15 pounds or 20 pounds, thus practically putting the locomotive out of service temporarily until this drop in pressure could be regained; and this would be its true function, for the blowing of such a valve on rare occasions would indicate an extreme condition which would need immediate remedying and would compel attention not only from the engineer and fireman, but from the conductor of the train as well. Such a valve would not be practical as an economical or satisfactory working valve for the ordinary purposes in running a locomotive such as is desirable in the first and second valves of the series recommended, to be true safety valves of economical range, designed simply to limit the working pressure to 200 pounds and to blow and relieve the boilers under ordinary conditions, but not to stall the train, and not intended as the only or ultimate protection against boiler explosion, which function the third valve would undertake. To distinguish these valves in service, some sort of difference in design or marking might be established by the manufacturer; or the working valves might be muffled and the emergency valves be of the ordinary open type or fitted with a lever.

Large discharge capacity and high lift are not necessarily synonymous, but a valve of small capacity can have its discharge increased by making the disk lift higher. Any manufacturer can make any disk lift higher, and every manufacturer can make a valve of high lift if desired, for there is no secret or invention involved; but this is not the same as saying that every manufacturer can and will supply what may be possible in this direction. Some manufacturers have been through the experience of experimenting with freak valves, going to extremes in size dimensions and lift, and have discovered the rational objections to their use; and if called upon to furnish valves of such specifications would advise customers why their use could not be recommended. It is conceivable that some manufacturers might, for their own reputation, refuse to put out under their trade mark or guarantee valves to meet peculiar specifications which they could not approve and which they knew would cause dissatisfaction to the user and damage to the maker.

The ordinary practice in making valves for locomotives has been to design and regulate the valves so that they would cause the steam pressure to drop 5 pounds before closing, and the regulating ring or device would be set at the time of testing to accomplish this. The greatest difficulty valve makers meet today is not in the simple problem of mechanical design to build safety valves with large discharges or lifts, but in educating and persuading operating engineers actually to utilize the valves to their intended normal capacity instead of resetting the regulating adjustment so as to throttle the valve beyond reasonable limits, to prevent what they regard as waste of steam when the valve does open in performance of its proper function. It is not reasonable to expect a valve designed and regulated to lose 5 pounds in boiler pressure to perform equally well when the regulating device is readjusted so that the pressure is allowed to drop only 1 or 2 pounds, as is the actual condition on many railroads today. Engineers should not complain of lack of valve capacity as much as of their own blindness in throttling the valves they already have. That locomotive valves designed for 5 pounds loss do actually work so well and give such satisfaction without chattering or singing, when regulated to lose only 1 or 2 pounds pressure, without change of spring or dimensions, is remarkable. But locomotive valves would operate much more satisfactorily and give much more effective relief in volume with only 2 pounds drop of steam pressure if they were originally designed and regulated to accomplish this, instead of the 5 pounds drop nominally specified and desired; and therefore the proposed emergency valve, to lose 15 pounds or 20 pounds with extremely large volume of discharge, should have proportions of valve disk and springs different from the closely regulated working valves intended to lose only 2 pounds. Anything of this sort can be provided by any manufacturer who understands the principles of design, but complaint should not be made because the manufacturer has designed a thing which serves its purpose admirably when properly used according to instructions, but may develop unsatisfactory actions when working conditions are deliberately and unreasonably altered.

However, the number and diameter sizes of safety valves have always been specified by the locomotive builders without consulting the valve makers in any way; and their practice has become arbitrary, confident that they were well within safe limits. The locomotive builders also limit the over-all hight and diameter of the valves, so that valve makers have had little choice or responsibility in the whole matter. Apparently the safety valve has always been regarded as a minor detail of the equipment, whether for the boiler plant or locomotive, and hardly worth much consideration; they must go on as an afterthought, wherever they can be crowded in, in the limited space in the steam dome of the locomotive as already laid out, and to clear all overhead obstructions, or in the cramped room that may be left by chance above stationary boilers when set in place.

If a valve of given size does not discharge sufficient steam, in the judgment of engineers, to relieve the boiler of a certain design and rating, a larger valve should be applied, or two or more valves should be used instead of one. But if low initial cost is to be attained by using only one valve or valves of proportions which involve much attention or regrinding or renewal to keep them in proper serviceable condition, or require the boilers to be shut down for frequent attention, the advantages of low first cost are more than counterbalanced and the valves become a source of danger and annoyance instead of a feature of security and protection.

The term "simmering" valve might more accurately convey to some the idea of one which opens at a variable pressure, sometimes a little higher or lower, and is not held positively to its seat, so that it may allow a constant small leak or wisp of steam to escape. Such valves are an unalloyed nuisance and disappointment: the steam clouds the vision ahead, the constant small leak robs the steam pressure at critical times and cuts the seat, no matter of what material, and the slow condensation deposits lime salts from bad water over the threads and inner parts of the valve so that the testing and adjustment make the repairman's life a burden. A slight "warning" like the blowing of a moderate [illegible] of sound than of louder noise, is a desirable feature and will generally be noticed in valves properly set; except where the adjustment has been changed to reduce the pressure drop and make the valve lose too little. The throttling of the adjustment is therefore generally the cause of howling or singing sometimes complained of, and can be instantly cured by putting the adjustment back to allow the 4 or 5 pounds drop in boiler pressure intended by the valve maker; the same cure could be effected by making the valve with slightly different disk proportions, if this close adjustment had been thought proper or specified.

The inlet or throat diameter of all valves is many times greater than the effective discharge area, so that point is not important to discuss. The valves should in all cases be connected directly to the boiler, without intervening bends or piping; otherwise, relief of the boiler is not immediate and uniform, but an irregular destructive hammer to the boiler will result. The essential characteristics of any proper muffling device is to afford ample volume for the increasing expansion of the escaping steam, with rapidly enlarging outlet passages, thus effectually muffling the noise without any appreciable back pressure, such as would be caused by series of baffle plates or deflectors.

Dry Niagara

By James L. [illegible]

The third week of February brought a most unusual experience to the power interests at Niagara Falls, while the scenic interests gained from the customary [illegible]

[illegible]

ness prevailed, but careful comparison of photographs taken in 1903, 1905 and this year indicates that there was little difference in the conditions of the American channel in 1903 and 1909. This year the ice was heavier; there was seemingly more of it. Snowfalls assisted to cover up the rocky bed of the stream, leaving more of a plain-like whiteness, bleak in its appearance and impressions.

Crossings were made from Prospect park to Luna island a short distance back from the brink of the American fall, and others crossed the channel above Goat-island bridge. Still other bold adventurers made their way from the head of Goat island over the ice to Port Day, where the Niagara Falls Hydraulic Power and Manufacturing Company receives its water supply. These were most unusual trips, and their possibility should indicate the remarkable conditions that existed in the Niagara river in front of the intakes of all the power companies on both sides of the river, for the effects were felt by all.

Under normal conditions the inlet canal of the Niagara Falls Power Company carried 12 feet of water, but during the "low period" this was reduced from 4½ to 5 feet, it is understood. The full load of current was not kept up, and some of the plants on the power company's land were shut down for a brief period. The water in the surface canal of the Niagara Falls Hydraulic Power and Manufacturing Company was lowered about 8 feet in the forebay. This result made clear the advisability of placing the mouthpiece of penstocks well down toward the bottom if they are not to draw air at such times. The new forebay over station No. 3 was designed by Chief Engineer John L. Harper with this possibility in view, and its penstocks were well supplied with water. The Cliff paper mill and the Pettibone paper mill, both on the canal basin, had a day or two of idleness.

All of the power companies on the Canadian side experienced more or less difficulty, and yet it is reported that one day during the second week in February the water on that side was lower than during the period of greatest trouble on the New York side. After the American channel was closed as an outlet for the water of the upper river, the flow of the stream was diverted to the Canadian channel, but this did not give the Canadian companies all the water wanted. Dynamite was used on both sides, and after the river started to resume business route channels were opened to assure a full flow of water.

During the night of Tuesday, February 16, the wind changed and early on Wednesday morning it was evident that Lake Erie had resumed its effort to provide a suitable overflow to redeem the reputation of the Niagara cataracts. Throughout Wednesday, Thursday and Friday the recuperative effort continued, but normal conditions had not been attained as the week closed.

The severity of the experience has been very instructive to engineers, and it may be of benefit to the Niagara as well as other power installations. Above all, however, credit must be given for the manner in which the great power companies met the conditions that practically settled down on them in a night. It will be recognized as a stupendous task to continue the development of power in such quantities as at Niagara, when so much of the available water as that represented by the normal flow of the American channel is diverted to other routes.

"DRY NIAGARA," IN FEBRUARY, 1909

For busbars and back connections in switchboards, aluminum is frequently advantageous, the saving in weight allowing of lighter supports and framework. For the front of switchboards aluminum is also suitable for bolts, lampholders, instrument cases, etc. There are several methods of jointing aluminum conductors. For small-diameter wires, as used for making into cable, the usual butt-welded joint is made either in the flame of a blowlamp or by means of the electric welders as used for copper. For bare stranded cables the two ends are welded together by pouring molten aluminum into a cigar-shaped mold previously clamped round the joint, but where high tensile strength is required a mechanical joint may be used, so designed as to give a wedging action when pulling tight in order to insure good electrical contact.

Some Useful Lessons of Limewater

What Would Happen if Nitrogen Were Removed from the Air; How to Prepare Pure Oxygen; Things to Remember; Making Iron Wire Burn

BY CHARLES S. PALMER

We have seen that there are two principal things in the air, as far as burning is concerned. One, oxygen, which helps ordinary burning—and which makes up about one fifth by volume of the air—and the other, nitrogen, which does not help common burning, although it makes up nearly all of the other four fifths of the air and, as far as combustion is concerned, is only "so many chips in the porridge."

The two-sided question has been proposed: What would happen if the nitrogen were to be taken out of the air, leaving only the oxygen, or what would happen if the nitrogen were to be taken out of the air and its place supplied by oxygen? In the first case, where the nitrogen is simply taken out, there would be no difference, as far as common burning is concerned, but there would be a great difference in the atmospheric pressure. One would see burning go on about the same as it does at present, because although the air pressure would be only about one-fifth of what it is now, all of that pressure would be in terms of oxygen, which would then make it practically all of the air, so that a flame would get the same quantity of oxygen that it does now. But a man would be under much less air pressure than he is now and would be, physically, in the same condition that he would experience if he were to ascend many thousands of feet above the sea level. He would suffer from bleeding at the nose, at the same time that his lungs would be taking in the same quantity of oxygen as at present. There would be no difference, practically, in the oxygen, but the loss of the four-fifths pressure now supplied by the nitrogen would make a great physical difference.

You want to think this all over, and you will see that each gas exerts its own pressure independently of any other gas; and if the nitrogen were taken away without any other gas taking its place, the difference would be simply a difference of pressure of the air as a whole, and so that air would practically be made up of oxygen, the supporting of burning by the only thing in the air that helps burning, oxygen, would be changed very little if at all. We cannot easily construct such conditions, because it would require a set of large and powerful apparatus to sustain the greatly diminished air pressure; but we can easily imitate the conditions of the other side of the question, namely, the case where the nitrogen is removed and its place taken by oxygen; and you will find that you will have an air which is practically made up of oxygen at the same total pressure as that supplied by both the oxygen and the nitrogen which make up common air. This experiment we will proceed to prepare, by making a few jars of practically pure oxygen, and as we will collect it in a jar which is closed under the pressure balance of the air acting on water, we will have the conditions of the second part of the question.

FIG. 1

FIG. 2

The Preliminary Work

As we get ready for this experiment, we will study some of the new conditions of your wash-dish pneumatic trough. You will take your fruit jar and fill it with water; also have the wash dish about half full of water, as shown in Fig. 1. Take a piece of common cardboard about 4 inches square and, holding it over the mouth of the jar, slide it on so that no bubbles of air get below the cardboard into the jar. It will take one or two attempts to do this, but you will soon learn the trick. One good way is to have water over the full jar as you are sliding the cardboard cover over the mouth of the jar. As soon as you have secured this "seal," hold the cover tightly on the mouth of the jar, and with the other hand grasping the jar at the side or end turn it upside down—all the time holding the cardboard cover on tightly so that no air bubbles can get into the jar—and place the jar, mouth downward, in the wash dish, as shown in Fig. 2. This will take several trials, but you will soon learn to do it successfully. What is wanted is to fill the jar with water, cover it with the pasteboard and invert it in the wash dish, mouth downward, without letting any bubbles of air get into the inverted jar. Of course, if one or two little bubbles of air get in the jar while turning it, it will make no serious difference; but do not let more than a little air get into the jar, because you are going to fill this jar with oxygen, and if there is very much air left in the jar it will dilute the oxygen just so much.

Just to practice "displacing" the water in the jar by a gas, take a tube of glass or rubber and blow through it, placing the farther end of the tube in the water in the wash dish and under the mouth of the jar. You will note that as the air from your lungs rises into the jar, which is at first full of water, the jar catches the air blown in and at the same time releases the same volume of water, and now you will begin to respect this old but ingenious device of the pneumatic trough. You will see the elegance and simplicity of this scheme for isolating a separate part of any desired gas by the simple trick of leading a gas below the mouth of a full and inverted jar.

In the case of the water pneumatic trough, of course, there is some absorption of the gas in question by the water, and that itself will suggest to you that it would be a refinement and an improvement if we could get some liquid like mercury which absorbs gases very little. It is too expensive to use such expensive and [illegible] liquids as mercury for some simple experiments such as we are trying in our homemade water home-made apparatus, although it is a satisfaction to know that there are other and more exact methods and to know what they are. But we will stick to water, and we will find that it will give us results [illegible] to be desired.

So now we will blow bubbles of air from the lungs into the full and inverted jar until the jar is full of air and some of the bubbles "underflow" from the mouth of the jar, which is kept locked by the water seal, from the air outside. In this way you will soon get hold of some of the possibilities of this pneumatic trough in its power to receive, to hold and to isolate or separate a quantity of any desired gas, as the air from the lungs or the oxygen which you will now get ready to make. Be sure to try this filling and inverting of the full jar in the wash dish, and the blowing of air into it, until you become perfectly familiar with the principles and purposes of this simple but useful apparatus; for we shall find that much of the foundation of chemistry has to do with gases, and it is a trick not to be despised to know how to take a portion of a slippery thing like air, or any gas, and handle it as though it were a solid which can be taken hold of and locked up temporarily. But this pneumatic trough is only the receptacle or storehouse of the gas, pure oxygen, which we want to get; and the next thing to attempt is the planning of a simple piece of apparatus for preparing some of this oxygen.

Preparing the Oxygen

The first thing to do now is to take one of the 4-ounce flasks which came with your outfit and fit it with a perforated cork, with a glass-tube outlet, or leader, a rubber conducting tube and a glass delivery tube, as shown in Fig. 3. Get a good cork which fits the flask snugly, roll it under your foot on a clean floor until the cork is soft and springy, and try it again in the neck of the 4-ounce flask. Next, bore a hole through the cork, lengthwise, a little smaller than the glass tube which came with your outfit. You can cut this hole in the cork with the small blade of your jackknife, which leaves the hole rough; then carefully trim out the hole with the round or "rat-tail" file. With a little care you can trim this hole through the cork so that it will exactly take in the glass tube, the edges of which should be rounded in a hot flame, or it may be filed off. Be sure and do this, for if you do not get a smooth and tight fit for the glass tube through the cork your apparatus will leak, and you won't think that chemistry is worth your while, a disappointment which can be avoided by exercising a little care.

The piece of glass tubing, or leader, which passes through the cork must reach only just through the cork, extending not very far into the inside of the body of the flask, and this tube should be bent at right angles, with the two arms each 2 or 3 inches long from the bend. In case you have to bend the glass tube yourself, don't try to bend it in a round gas flame, but in a wide, *flat* gas flame, as shown in Fig. 4; then the tube will bend with a good even curve, without buckling. The old-fashioned "fish-tail" burner will be just the thing for your purpose. Also, as you heat the glass tubing preparatory to bending, turn the tube around in the flame, giving it time to get well heated before trying to bend it. As soon as it is hot enough, a gentle pressure will bend it at the heated portion so that you can easily get the two arms turned at right angles to each other as shown in the cut. Before cooling, let the heated part become covered with soot in the flame, to anneal it by slow cooling. The tube can be cleaned when cool.

The delivery tube also has to be bent, not at right angles, but at an angle of about 120 degrees ("finger bend"), as shown in Fig. 3. The short arm needs to be only some 2 or 3 inches long, leaving most of the tube as a "poking" tube, to be thrust down into the water. You will, of course, connect the leader tube and the delivery tube with a bit of rubber tubing.

You have just tried the trick of filling the inverted jar in the pneumatic trough with air from the lungs, and before you make oxygen drive some air from the flask over into the jar, by heating the dry, clean, empty flask over the flame of an alcohol or gas lamp. As you heat the empty flask, considerable air will pass through the leader tube, the rubber connector and the delivery tube, down under the water and up into the jar in the pneumatic trough; and in this way you can see how the oxygen, which you will soon make in the flask, will pass over to the water-filled jar in the pneumatic trough. But you cannot get very much air over in this way, only enough to show that heated air expands, and that this air can be put into the jar in the pneumatic trough by displacing the water from the water-filled jar; for just the same volume of water will escape from the jar for each bubble of air driven over from the dry and heated flask.

Some Things to Remember

Remember this: *You must always remove the delivery tube from the water before you take the heat away from the flask, or before you take the flask away from the lamp.* The reason is that the closed and heated flask is really a very sensitive air thermometer, and as soon as the heated air in the inside of the dry flask has been cooled the water in the trough will rush up back through the delivery tube into the hot flask and crack and break it. Remember, then, not to allow any water to be sucked back into your dry flask, by cooling it, unless you have first taken the delivery tube out of the water before you cool off the dry and partly empty flask.

All this will set you to thinking about some of the laws of heat which you know perfectly well, but which you may never have had put up to you before in just this way. You will see that heat expands all substances, and gases more than liquids or solids. If you get a considerable expansion of the air in the oxygen-making flask when it is empty, naturally you will get this same expansion when the flask contains some of the "oxygen mixture" which you will put into it in this lesson or the next. You can see that all this preliminary explanation is to show you how to throw away the first air that will come over, before the real oxygen comes; for the air is much more sensitive to heat than is the "oxygen mixture," and you do not need to save

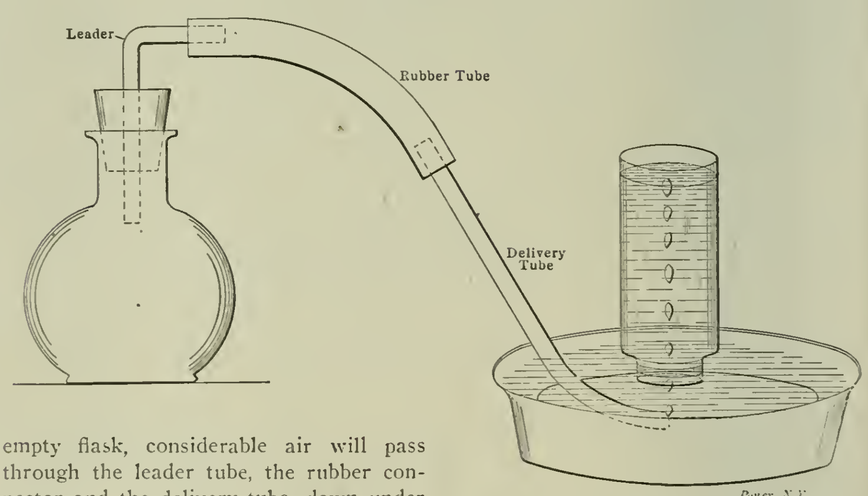

FIG. 3

the first bubbles which come over when you make oxygen, because that is only common air from expansion and will only dilute your oxygen just so much.

Now, if you will look over the outfit which you procured, as recommended in the first lesson, you will note the potassium chlorate and the black oxide of manganese. The white salt, potassium chlorate, is the stuff which is going to give you pure oxygen; and yet it is best to mix it with some of the black oxide of manganese, because if you heat the white potassium chlorate alone the oxygen will come off rather too rapidly for perfect safety; while if mixed with some of the black oxide of manganese, the oxygen will come off quickly enough, and much more evenly and quietly. The reason for all this is not entirely understood, and the explanation therefor would take us too far away from the point; but the fact is that a mixture of one part of black oxide of manganese with three or four parts of potassium chlorate will give up oxygen in a clean and satisfactory manner. By the way, the black oxide of manganese will itself give off some oxygen, if heated to a red heat, but you will not get that probably in this experiment, and as that side of it does not immediately concern us, because you will not heat your flask nearly as hot as to a bright red heat.

There is another matter to which you want to give a moment's attention, and that is the advisability of testing the mixture of the potassium chlorate and black oxide of manganese—with all due apologies to the excellent and reliable agents from whom you may have bought your supplies. The point is this: There are many black things in the world, and even if there is no desire to adulterate your goods, "accidents will happen in the best of families." So just take a "knifepointful" or two of the white potassium chlorate and another knifepointful of the black oxide of manganese, both well powdered and well mixed, and heat them hot in a common iron spoon, watching carefully to see what happens. If there

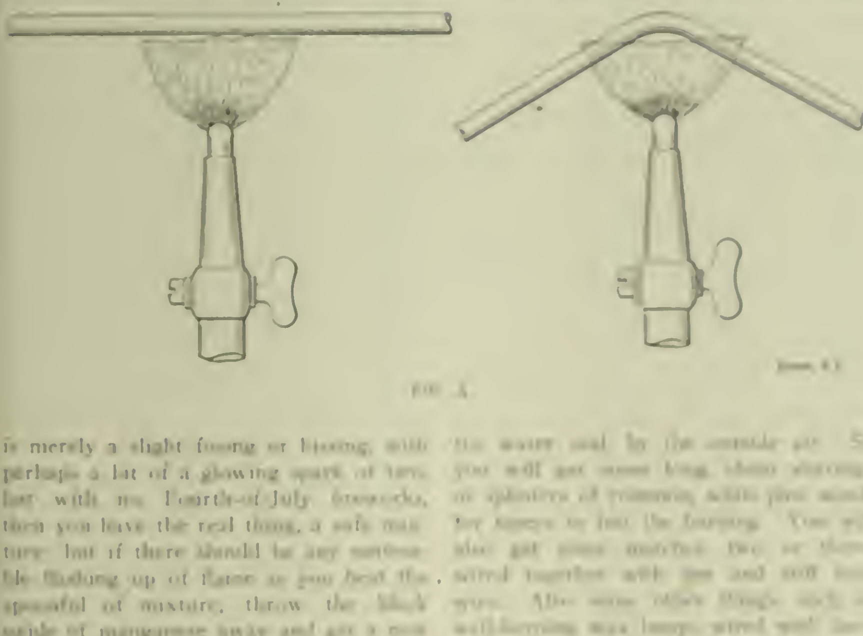

FIG. 3.

is merely a slight fusing or hissing, with perhaps a bit of a glowing spark or two, but with no Fourth-of-July fireworks, then you have the real thing, a safe mixture; but if there should be any noticeable flashing up of flame as you heat the spoonful of mixture, throw the black oxide of manganese away and get a new supply—your dealer will cheerfully make good; although there is not one chance in a thousand that you will find anything wrong with the black oxide. The reason for all this caution is that such things as carbon, soot, coal dust and the like are common, and once or twice I have found that no time was wasted in taking pains to be sure that one has a safe mixture.

Before you put the mixture in the flask, be sure that the flask is clean and dry. Wash it out with good soapsuds, with a few bits of scrubbing paper, as described in the first lesson. Then rinse it out well, waving it violently in a wide swing, mouth away from you, to throw the few clinging drops out by "centrifugal force." Then set the nearly dry bottle up in some safe and warm place, and when the flask is dry and hot, if you put the glass tube into the flask and suck the air out three or four times, you can be sure that your flask is clean and dry, but you will soon learn to taste the characteristic "dry test" of the last air sucked through the well-cleaned flask. All this trouble is worth while, because you will soon learn that it is just as easy to make things go right the first time as later; and it pays in experimenting to take pains.

MAKING THIS WORK BURN IN OXYGEN

Another matter: You are going to make some pure oxygen, and it will illustrate what would happen if the nitrogen of the air were removed and its place were taken by oxygen. You can see that if one-fifth of the air, at 30 inches pressure of the barometer, helps common burning, this new kind of air, which is also at 30 inches pressure of the barometer, will do something in the way of burning which will be worth watching; and you know that the oxygen to be collected in the jar is at 30 inches of barometric pressure (instead of one-fifth of this) because it is balanced through the water seal by the outside air. So you will get some long, clean shavings or splinters of common white pine wood, for tapers to test the burning. You will also get some matches. Two or three, wired together with fine and stiff iron wire. Also some other things, such as well-burning wax tapers, wired with [illegible] 8 or 10 inches long. Also [illegible] [illegible] of piano wire [illegible] [illegible] and prepare it as follows: Heat the end red hot for a moment, and plunge it into some powdered sulphur, or flowers of sulphur. Then, when the [illegible] a little [illegible]. You see, you are going to light [illegible] that will light the sulphur [illegible] will light the fine wire [illegible] the match [illegible] and the fine steel [illegible] will burn in the oxygen so well [illegible] you will be surprised to see how [illegible] [illegible] will burn [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]

[illegible] But it will be a good thing to try [illegible] and don't be disappointed if it doesn't work so long.

Remember what we said about [illegible] and that Mother Nature is [illegible] [illegible] the same [illegible] [illegible] [illegible]. If you can think of any other things that will burn, [illegible] [illegible] [illegible] [illegible] or two of the oxygen; but if you do this carefully, you will get results that you will remember as long as you live, results that will put new ideas into your head and new dollars into your pocket.

There is one other thing to do, and that is to read all this [illegible] right over again and again, until you see just what you want to do and how you are going to do it. In this really good experiment of making oxygen, an experiment that will put you in shape to begin reading the marvelous history of chemistry. As you learn the names of Scheele (pronounced "Shaile"), Priestley and Lavoisier (pronounced "Lav-wah-see-ay"), you will find that you have jumped right up and [illegible] that good sense under your hat into some of the [illegible] that ever [illegible] scientific discovery. You will [illegible] that you are doing all this as the [illegible] of [illegible] [illegible], right down in your boiler room.

[illegible]

very noticeable vibrations, where is the trouble likely to be?

If the vibrations are generally distributed over the entire machine and increase in intensity with the speed of the armature, the noise is likely to be caused by a poorly balanced pulley or armature.

976. *How should a pulley or armature be tested and remedied for an unbalanced condition?*

Remove the pulley and armature from the machine and test them separately. The armature can best be tested by placing it so that its shaft is supported at the ends upon two knife edges *a* and *c*, Fig. 284, placed flat and parallel to each other. Then, if the armature is poorly balanced, the heavy side will cause rotation except when this side happens to be downward. By setting the armature at rest on the knife edges with different points around its periphery placed upward the weighty side may be easily ascertained. The trouble may be remedied either by firmly fastening some lead on the lighter side, or by filing or boring holes in the heavy side.

A shaft should then be provided temporarily for the pulley in order that it, too, may be tested; if necessary, it may be balanced in the same manner as described for the armature.

977. *State how noise produced by the pulley, belt or shaft collar striking against the bearings of the machine can be easily detected.*

By pushing the shaft or belt away from the one or other of the bearings while the motor is running and noting if the noise ceases.

978. *How may noise produced as mentioned in 977 be stopped?*

The trouble may usually be overcome by changing slightly the direction of travel of the belt. However, if this change does not improve matters, shifting the pulley on the shaft or turning off the shoulder of the bearing, as the case may be, will probably effect the desired result.

979. *What kind of noise is made by the pounding of the jointed portion of a belt against the pulley?*

The loud thump which occurs but once during each revolution of the armature.

980. *Does not the armature when striking against the pole faces make a similar noise?*

Yes, but it is less of a thump and more of a scraping character.

981. *How should a trouble of the nature mentioned in 980 be investigated?*

Usually, an examination of the armature surface will determine if it has been striking the pole faces. Great care should be taken to make this examination thorough, for the danger of damage to the armature when it comes in contact with the pole faces is very great. Another, and perhaps a better, test consists in removing the belt or power connection from the armature shaft, and while slowly turning the armature by hand, observing whether or not it sticks at any point.

982. *How should a trouble of the nature mentioned in 980 be remedied?*

If the trouble is caused by one side of the armature winding projecting abnormally, it may be remedied by binding down the bulging part with a wrapping of iron wire which should extend around the armature body but be well insulated from it at all points. If the armature is out of center, it may be possible to adjust the bearings so there is a uniform clearance between the armature surface and each of the pole faces. Sometimes the trouble lies in one or more of the pole faces projecting abnormally; in this case it will be necessary to file out the projecting portions.

983. *What is indicated by a hissing sound produced at the brushes?*

Either a dry or sticky commutator, or rough contact surfaces on the carbon brushes. By listening near the commutator, it is easy to ascertain if there is trouble from these sources or if the defect lies in the brushes instead of the commutator.

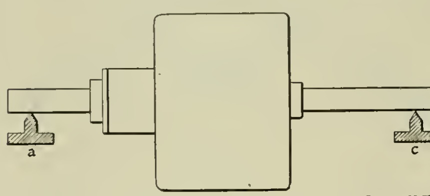

FIG. 284. METHOD OF TESTING AN ARMATURE FOR AN UNBALANCED CONDITION

984. *If the brushes are making the noise, how may the noisy ones be detected?*

By raising one brush at a time while the machine is in operation, and noting if the noise ceases. This test, however, can be applied only to motors having more than one brush on a stud, as otherwise the motor circuit would be opened by the raising of a brush and an arc would be formed that might endanger the experimenter and burn the commutator.

985. *How can brushes usually be made to operate noiselessly?*

Sandpapering their contact surfaces or applying oil to them at this part will generally reduce the noise. Sometimes it is merely necessary to raise or lower the noisy brush a trifle in its brush holder to stop the hissing sound.

986. *How should a noisy commutator be silenced?*

Recourse may be had to filing or sandpapering if the commutator is rough, or to the application of a minute amount of oil or vaseline if it is dry. In the case of a new machine having a noisy commutator, it is advisable to run it awhile unloaded until both the brushes and the commutator become adjusted to each other and smooth.

Estimating the Horsepower of a Gas Engine

By Cecil P. Poole

Knowing the kind of gas to be used, the bore and stroke of the engine and the number of revolutions per minute, it is a simple matter to estimate the probable horsepower at maximum load by assuming a mean effective pressure appropriate to the gas quality and applying the old steam-engine formula, $P\ L\ A\ N \div 33{,}000$. But a less tedious method is to base the estimate on the piston displacement, the quality of the mixture and an assumed heat economy for the engine. This latter assumption is not likely to be as far wrong as the assumption of mean effective pressure in the first method. Natural-gas engines will readily yield a brake horsepower on 10,700 B.t.u., producer-gas engines on 11,500 B.t.u. and illuminating-gas engines on 12,000 B.t.u. per hour. Natural-gas mixtures will average about 50 B.t.u. per cubic foot at the temperature existing when the inlet valve closes; producer-gas mixtures will average about 46 B.t.u., and illuminating-gas mixtures about 60 B.t.u. per cubic foot. Since $178\frac{1}{3}$ B.t.u. per minute ($10{,}700$ per hour $\div$ 60) will yield one brake horsepower with natural gas and each cubic foot of mixture contains 50 B.t.u., a natural-gas engine should yield $50 \div 178\frac{1}{3} = 0.28$ brake horsepower per cubic foot of effective piston displacement per minute (by "effective" displacement is meant the displacement during power strokes only). Similar reasoning will produce the numbers 0.24 for producer gas and 0.3 for illuminating gas.

The effective displacement per minute by a single-acting piston is equal to the displacement per stroke multiplied by one-half the number of revolutions per minute, working on the four-stroke cycle. For a double-acting engine the effective displacement per minute in each cylinder is equal to the displacement per stroke $\times$ revolutions per minute. These statements apply to hit-and-miss engines as well as the throttling type because at maximum load the governor does not cut out any explosions.

Computing piston displacement in cubic feet, however, is tedious, and as the displacement is proportional to the stroke multiplied by the square of the diameter in inches, it is simpler to change the constants 0.28, 0.24 and 0.3 to others which will cover the translation of piston displacement in cubic feet per minute to $d^2 \times s \times r.p.m.$ This gives the constants in Table 1. The proper constant multiplied by the square of the piston diameter, the stroke (both in inches) and the number of revolutions per minute will give a fair estimate of the maximum probable brake horsepower per cylinder.

TABLE 1

Kind of Gas.	Single-Acting	Double-Acting.
Natural	0.000065	0.00013
Producer.........	0.000056	0.000112
Illuminating.....	0.000070	0.00014

In double-acting engines the piston and tail rods considerably reduce the exposed piston area. The space neutralized by the rods ranges from 6 per cent. of the gross piston area in relatively small engines to about 10 per cent. in large engines. The accompanying Table 2 gives values of the product of the constants in Table 1 and the square of the piston diameter for single-acting engines of 5 to 30 inches bore. For double-acting engines the product has been modified by an allowance of 6 per cent. for the piston rods in all sizes. The higher efficiency of larger sizes tends to compensate for the deficiency in piston-rod allowance. This may seem to be a highly academic refinement of a method designed to give only approximate results, but it gives a nearer approach to accuracy than would be obtained if the piston-rod space were ignored, and is therefore considered justifiable. If the reader prefers to disregard it, the constants for single-acting engines, multiplied by 2, will serve for double-acting engines, of course.

EXAMPLES

1—A natural-gas engine having three single-acting cylinders each 25 inches bore and 30 inches stroke developed on test 530 brake horsepower at 150 revolutions per minute. The estimated power would be

0.0406 × 30 × 150 × 3 = 548

brake horsepower, or a trifle under the actual power.

2—A natural gas engine with three single-acting cylinders 13½×16 inches developed 130 brake horsepower at 225 revolutions per minute. The estimated power would be

0.0118 × 16 × 225 × 3 = 127.4

brake horsepower. This engine was rated at 125 horsepower, but tested to 130.

3—A two-cylinder double-acting (tandem) natural-gas engine with cylinders [illegible] inches, rated at [illegible] brake horsepower at 200 revolutions per minute, had to be driven at [illegible] revolutions to obtain the rated output. The estimated power at 200 revolutions per minute would be

[illegible] × [illegible] × 200 × 2 = [illegible]

horsepower; at [illegible] revolutions per minute [illegible] would figure out [illegible] horsepower.

4—A tandem single-acting producer-gas engine, [illegible] inches, developed [illegible] brake horsepower at [illegible] revolutions per minute, [illegible] rated at [illegible] horsepower [illegible] revolutions per minute. The estimated brake horsepower would be

0.0[illegible] × [illegible] × [illegible] × 2 = 315.

5—A twin tandem producer-gas engine with cylinders [illegible] inches is rated at [illegible] brake horsepower (maximum) at [illegible] revolutions per minute. The estimated output would be

0.0[illegible] × [illegible] × [illegible] × 2 = [illegible]

brake horsepower.

6—A single-cylinder single-acting illuminating-gas engine of [illegible] inches bore and [illegible] inches stroke gave [illegible] brake horsepower at [illegible] revolutions per minute. The estimated output is

[illegible] × [illegible] × 0.00[illegible] = [illegible]

brake horsepower.

7—A similar engine of [illegible] inches bore and [illegible] inches stroke gave [illegible] brake horsepower at [illegible] revolutions per minute. The estimated output would be

0.00[illegible] × [illegible] × [illegible] = [illegible]

brake horsepower. This engine was rated at [illegible] revolutions per minute, but developed full power at [illegible] revolutions because of unusually rich gas ([illegible] B.t.u. at [illegible] degrees Fahrenheit). At the rated speed the estimated output would be [illegible] brake horsepower.

Those familiar with the principles of gas-engine operation will recognize that the close agreement between some of the test results here cited and the results estimated are due to the fact that in those cases the engines used happened to be working under a combination of thermal conditions which gave constants very near to those on which the method is based. Thus, the engine cited in example No. 1 actually used over 11,000 B.t.u. per brake horsepower-hour, but the mixture was enough richer than the assumed value of [illegible] B.t.u. per cubic foot to produce almost exactly the constant [illegible] of Table 1. Again, the engine in example No. 2 is rated at [illegible] B.t.u. per brake horsepower-hour, but its piston rods cover about [illegible] per cent. of the piston area and the heat value of the mixture required to give the rated output at the rated speed [illegible] [illegible] B.t.u. The close agreement between the tested and the estimated output was purely accidental and will not [illegible] when the ratio [illegible] the [illegible] of the [illegible]. It is not to be expected that the method will give close results in all cases, but it serves well in determining the "order of magnitude" of probable output, [illegible] in the terms of the particular [illegible], whether high [illegible] or low [illegible] be the [illegible].

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for February, 1909, was (weekly and monthly) 151,000.

March 2	42,000
March 9	37,000
March 16	37,000
March 23	37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Exhaust Steam

Ask ten engineers which is the more economical, a condensing or a noncondensing engine, and nine of them will tell you: "A condensing engine, of course;" and patronize or pity you for having to ask.

And yet in many cases, most cases we had almost said, the condensing engine is the more expensive to use, and money would be saved by replacing the condenser with a back-pressure valve. This is true wherever there is use for the heat rejected. It costs less than four per cent. more in heat units to make a pound of steam at 150 pounds than to make it at atmospheric pressure. If there is use for heat at or about 212 degrees it is much cheaper to make the steam at the higher pressure and expand it in an engine down to that temperature. Of the 1191.2 heat units required to make a pound of steam at 150 pounds, an engine using 30 pounds of steam per hour per horsepower will take out only about 85, and the rest, with the exception of the trifling amount lost by radiation, passes out with the exhaust. If any smaller number of heat units were voided with the steam they would accumulate in the cylinder and melt it down; if the exhaust took out more than the steam brought in (besides radiation and that converted into work), it would make a refrigerator out of the cylinder. Each pound of exhaust from such an engine, therefore, contains some 1100 heat units which are available for heating and manufacturing processes requiring heat around 212 degrees. It would cost just about as much to make low-pressure steam especially for this purpose as it did to make the high-pressure steam, and the power has been had practically for nothing.

There is no more efficient power-generating proposition than a steam engine used as a reducing valve between a high- and a low-pressure system.

This truth escaped general attention for a long while on account of the attempt to use exhaust steam just as dry high-pressure steam is used. It was characterized as "cold" and "sluggish" simply because the water was not taken out of it and sufficient cross-sectional area given to the conducting pipes to conduct the required weight at the large volume due to the low pressure. With the separators now available exhaust steam can be easily purged of all moisture in excess of the percentage allowable in "commercially dry" steam.

Of course the amount of exhaust made must be in accord with the demand. It would not do to run a thousand-horsepower engine noncondensing for the sake of using up one-tenth of its exhaust and letting the rest go to waste. In the New England textile mills, where exhaust steam is used, even in the summer time, for manufacturing processes, engines are often run one-half condensing, the exhaust chest being divided so that one end can be exhausted to the condenser and the other to the back-pressure system. It is a common practice to take steam for such purposes from the receiver of a compound engine, and we know of one instance where the course of the steam through a compound engine was reversed, the larger cylinder being made the high-pressure; so much steam being taken out of the receiver that there was only enough, even in its expanded condition, to run the smaller cylinder. Successive heatings from the different stages of a steam turbine would bring the temperature of the feed nearly to that of the steam, fulfilling the compression condition of Carnot's cycle.

But whether the demand for exhaust steam warrants the running of the main engines noncondensing or not there is usually occasion for the use of all the exhaust which the auxiliaries can make in heating feed water. Where this is the case it is wasteful and extravagant to run the auxiliaries from the main engine, electrically or otherwise, for the main engine, notwithstanding the smaller number of pounds of steam it uses per horsepower-hour, cannot compare in efficiency with the most extravagant steam pump credited with all of its exhaust. When the exhaust is used for heating feed water the water of condensation which it contains makes no difference, but can be mingled with the water being heated, as can also the rest of the exhaust condensed by such mingling. This not only saves the water which by its previous use has been freed from scaling materials, but the heat which would otherwise be carried away by that water.

Centralized Auxiliary Control

In the design of power plants of importance the modern tendency is toward the use of a system of auxiliary control from the switchboard. In addition to the remote control of oil switches in the main circuits, which has long been practised, it is now quite feasible to start and stop motors for all purposes from a central point. The old idea that a controlling switch must be located within a few feet of its motor has been modified by the production of remote-control motor starters, the master switches of which are grouped at a central point. It is only a question of a little more wire and a little more elaborate controller, the extra cost of which in most cases will be a small price to pay for the greater convenience of operating the various motors for pump service, valve operation, coal and ash handling, fan driving, air compression and the like, many of which may be located in places inconvenient of access.

Additional switches on the switchboard

for the control of lighting circuits in the engine and boiler rooms, coal pockets, oil-storage room, pipe tunnels and of the motor circuits for the traveling crane constitute an added improvement which does not interfere in the least with the provisions of parallel switches or controlling apparatus located near the equipment they control, and in the light of the necessity for continuity of service this duplication of control in many instances would be well worth while.

Condenser Speed and Vacuum

In operating a compound condensing engine the condenser should receive the same intelligent attention that is given to the engine. Condensers are installed usually for the purpose of making the engine a more efficient means of converting the heat in the steam into useful work, and logically to fulfil their mission they should not only be efficient machines, but should also be efficiently operated. Pipe joints between the condenser and the engine cylinder should be absolutely airtight and the condenser should be run at the lowest possible speed which will maintain the desired vacuum.

While it is generally true that the higher the vacuum the better, it is not always so. If the engine is lightly loaded it is sometimes better to reduce the vacuum by reducing the speed of the condenser, if independently operated, or, if directly connected to the engine, by reducing the injection, allowing a little longer cutoff in the cylinder and a higher temperature of the exhaust to give up heat to the feed water.

But under most conditions the degree of vacuum should be regulated by the hight of the governor, that vacuum being carried which will cause the governor to revolve in the highest possible plane. Under certain conditions of load and steam pressure the governor will be found to revolve in a higher plane with a vacuum of twenty-six inches than with a greater vacuum. It will be found that the receiver pressure, also, will have much to do with the hight of the governor, and by judicial experiment with both vacuum and receiver pressure, the relation of one to the other and of both to the governor hight, the best vacuum and the proper receiver pressure for each condition of load may be found.

Changing the receiver pressure will alter the distribution of the load between the cylinders. By reducing the receiver pressure more work is thrown on the high-pressure cylinder, while an increase in the vacuum will increase the work of the low-pressure cylinder, and it is probable that with a long cutoff in the low-pressure cylinder the highest possible position of the governor will be maintained with the highest possible vacuum in the condenser.

Gas Equipment for a British Battleship?

According to a brief press cablegram published recently in some of the New York dailies, the British government has made all the necessary arrangements for the construction of a fighting ship of the "Dreadnought" class to be equipped throughout with gas power. Efforts to get at whatever facts may have given rise to the dispatch have thus far produced no results, nor have any supplementary cablegrams appeared to corroborate the first one or amplify the "information" which it purported to present. It is possible that a new series of experiments with larger equipment than that tested recently on the "Rattler" may form the basis of the cabled report. Certainly it does not seem probable that a government as conservative as that of Great Britain would incur the great risk of flat failure involved in an attempt to construct a [illegible]-horsepower producer-gas battleship, with no precedent beyond the 500-horsepower unit tried out in the "Rattler," or the [illegible]-horsepower unit now in process of trial.

When it is considered that the maximum gas-engine output per cylinder thus far secured on land, under the most favorable conditions yet known, is less than 1500 horsepower, schemes as to the equipment of a battleship or other vessel with units which would need to develop at least that much power per cylinder, and probably more, take on the aspect of what the street gamin characterizes as "pipe" dreams. There is no doubt whatever that gas power in large units will be applied to marine work some day; there is, however, doubt amounting to incredulity on our part that it will happen this year. There exists right now a most promising opportunity for someone to produce a satisfactory marine engine of 1000 horsepower for service on the Great Lakes of this country, but no builder has as yet accumulated the necessary nerve to make the attempt, although a perfectly responsible financial concern has signified its readiness to buy and pay for such an engine the moment it is built.

The Art of Economical Steam Production

Among the many factors which enter into the successful or unsuccessful operation of the power plant is not only the man in the chief engineer's place, but also the man in front of the boiler. The plant may be of the latest design, with every sort of [illegible] produced by the best of manufacturing concerns, and [illegible] may be installed, and yet the good results of all the refinements of modern practice may be nullified by a fireman who does not understand economical steam-making.

Economical steam production is an art to which altogether too little attention is given. If an intelligent fireman is wanted, he is paid, as a rule, [illegible] with the [illegible] to which his ability as a [illegible] makes him entitled. Firemen, like poets, are born—not made—and when one is discovered who is intelligent and active, interested in his work and willing to do his best all of the time—one who knows how to get the most out of the coal under the conditions existing in the plant where he is employed, and does it every day—he should be encouraged, the results of his work should be recognized in a substantial way. Such a man is not to be parted with lightly. His work appeals to the owner in a practical way, with the eloquence and logic of dollars and cents saved. The plan that his work makes for him should be recognized and every possible effort put forth to make him feel satisfied with his position, not with words alone, but with a part of what he saves and an improvement of the conditions under which he works.

Firing, at the best, is work for strong men, but strength and intelligence are not incompatible, and in the operation of steam boilers their association in the same man is an absolute necessity if good results are expected from the fuel burned.

It is pleasant to note that from many different parts of the country it is learned that advanced ground is being taken by power-plant designers and owners, and that boiler rooms and the men who work in the plants are receiving more attention than formerly. Sanitary and comfortable, if not always pleasing, conditions obtain. [illegible] the employees are [illegible] that they are regarded as of some importance in the operation of their plants [illegible].

It has been estimated that the total consumption of [illegible] in plants [illegible] tons [illegible] by the railway systems and [illegible] the [illegible] that the consumption of [illegible] power [illegible] of using the coal [illegible] the proper [illegible] gas [illegible] could be [illegible] per [illegible] the value of the [illegible] to the [illegible] should be [illegible].—The [illegible].

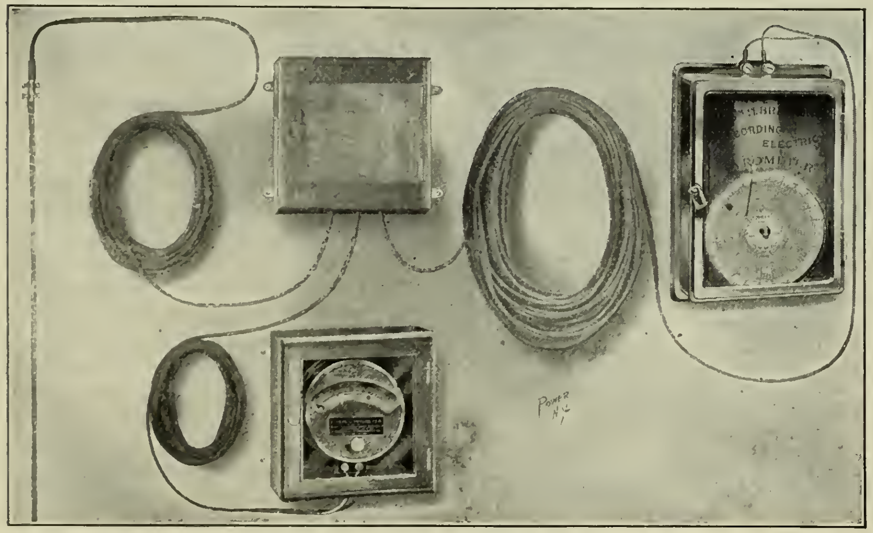
Combination Indicating and Recording Units

The illustration herewith presented shows the complete combination indicating and recording units of the Bristol electric pyrometer, manufactured by the Bristol Company, Waterbury, Conn., as wired up in actual operation.

The recording instruments with the necessary switches and checking system can be mounted in protected cases, either separately or as shown in the illustration. Each combination unit can be made to suit the particular application for which the pyrometer outfit is to be used. By this arrangement the recording instrument can be installed in the superintendent's office, or any convenient place. Their purpose is for all commercial ranges of high temperature, and they are especially recommended for annealing and case-hardening furnaces, water-gas machines, blast furnaces, galvanizing plants, gas producers and open-hearth furnaces.

The indicating instrument of this combination unit is for the use of the operator while at his post of duty. The instrument is in a case so it can be located at the most convenient point for the attendant. The open scale makes it easy for the fireman or operator to read the furnace temperature at a glance.

The recording instrument of the unit is for the benefit of the superintendent or manager in his office. This instrument may be located at a distance, connection being made to the fire end by flexible leads. It makes continuous records automatically of the same temperature shown by the indicating instrument. The record charts are intended to give the superintendent full information and serve as a check on the men.



COMBINATION INDICATING AND RECORDING UNITS

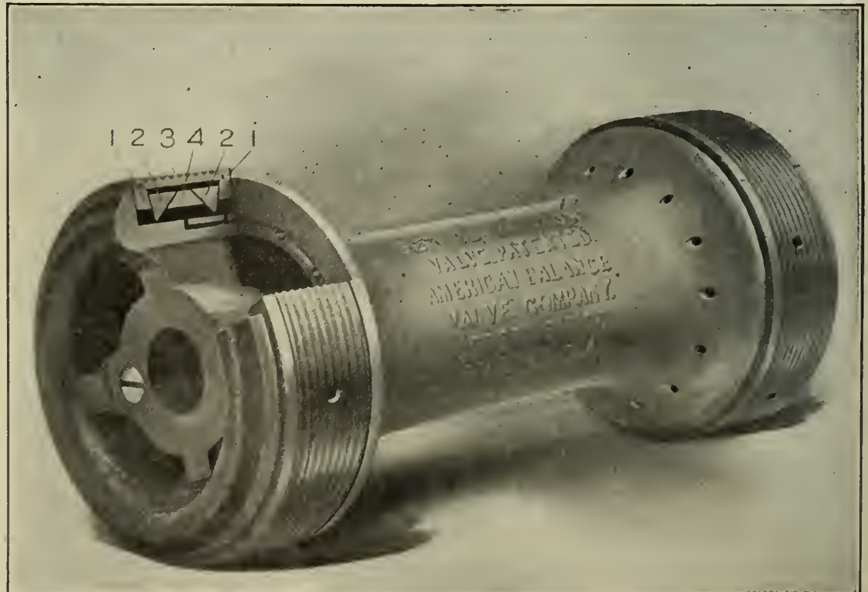
"American" Semi-plug Piston Valve

This valve is called "semi-plug" because while it is without steam it is a snap-ring valve; the packing rings being expansible fit themselves to the valve chamber, but when the throttle is opened the steam is admitted to the chest and enters the space below the rings. The action of this pressure is to lock the snap rings in a fixed diameter, making practically a plug of it during the time the pressure is on. The valve has been designed on the principle of leverage by wedges, the pressure acting upon the wedges. In the valve the wedges take the form of cones, or circular wedges, as shown in the illustration.

The outside walls of the snap rings *1* are straight and fit against the straight wall of the follower and spool. The inner walls of these snap rings are beveled, forming a cone. Next to the snap rings are wall rings *2*, the sides of which are beveled to fit the cones of the snap rings. These wall rings are uncut, nonexpansible steel rings. Between them, in the center, is placed a double-coned expansible wedge ring *4*, which, with the wide ring *3*, interlocked into each snap ring, forms the complete packing.

The wide ring performs two important functions; it carries the snap rings across ports while drifting, and also keeps the snap rings parallel with each other.

The wedge ring is put in under tension and its tendency is to crowd the two solid wall rings laterally against the cone sides of the snap rings *1*. This prevents lateral wear of all rings. The degree of



SECTION OF "AMERICAN" SEMIPORTED PLUG PISTON VALVE angle on the cones is much greater on the double-tapered wedge ring than on the snap rings. These angles are so calculated that, while the pressure is underneath all the rings, the leverage of the double-tapered wedge ring, crowding the solid wall rings against the cones of the snap rings, is just sufficient to prevent the snap rings from farther expansion, but not sufficient to reduce the snap rings in diameter.

When steam is admitted to the steam chest it passes through the small holes around the spool, and finds an outlet, first, under the first snap ring, and second, under the central wedge ring, thus causing the rings to fit the valve chamber, and the wedge ring to lock up the rings.

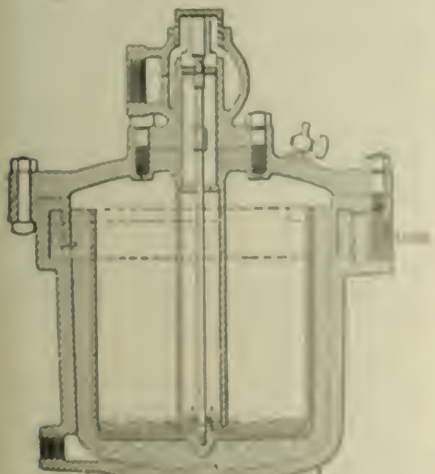
The packing consists of the combination of rings, which are free to move up and down on the spool, that the rings may fit the cage perfectly correctly, regardless of any variation in the position of the spool, which is carried on the valve rod.

This valve is manufactured by the American Balance Valve Company, Jersey Shore, Penn.

Stickle Bucket Trap

The Stickle bucket trap is shown in cross-section in the accompanying illustration. It is designed to be connected to separators used on large steam mains, where boilers prime and there is a large amount of magnesia brought over in the steam. The separating ring around the top is designed to stop the greater part of sediment while the trap is filling. As soon as it opens, it is wide open. The rapid discharge through the ring is intended to clear it from sediment, and it is discharged through the valve when it is wide open. The buckets are very heavy. It is claimed that it never sticks, as the equalizing coupling lets the valve go straight to the seat.

This trap is manufactured by the Open Coil Heater and Purifier Company, Indianapolis, Ind.



STICKLE BUCKET TRAP

Erie City Feed Water Heater

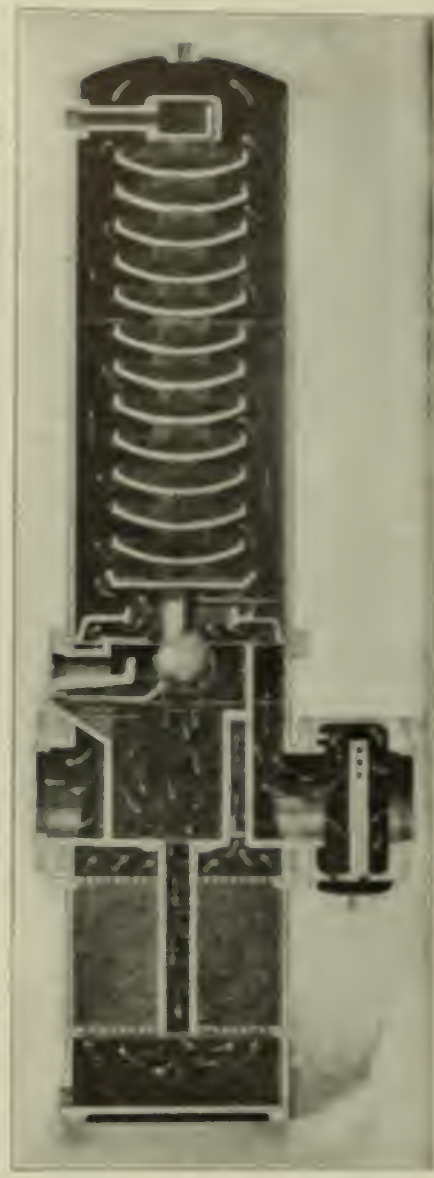

FIG. 3. SECTIONAL VIEW OF ERIE CITY HEATER

specially designed. The illustrations show the construction without going into minute details, but attention is especially called to the [illegible] chamber shown in Fig. 2. The feed water is taken from this chamber, which is directly opposite to and in direct connection with the [illegible] [illegible] [illegible] [illegible] Fig. 3 is a sectional view of the heater, [illegible] The heater is manufactured by the Erie City Iron Works, Erie, Penn.

Book Reviews

The Modern Power Gas Producer. By Horace Allen. Published by D. Van Nostrand Company, New York, 1908. Cloth; 332 pages, 5x7 inches; 136 illustrations; numerous tables. Price, $2.50.

This is not a college textbook. It is a résumé of modern European practice in the construction and application of gas producers for power purposes, to which is added an explanation of the principles involved. The material is valuable and the author's style of exposition is clear and interesting; it is greatly to be regretted that engravings of extraordinarily poor execution have been used to illustrate such worthy text. The diagrams and sectional drawings are so badly reproduced and so excessively reduced in size as to be useless in most instances. The arrangement of the material is not altogether praiseworthy. Much of the technical information which should be given in the chapters devoted to principles is scattered through those which present descriptions of commercial equipment. But the information and data contained in the book are highly useful when once sorted out.

Social Engineering. By William H. Tolman. McGraw Publishing Company, New York. Cloth; 394 pages, 6x9 inches; illustrated. Price, $2.

If it is the function of the engineer to adapt and apply the materials and forces of nature to the use of man, the specification is broad enough to include the "Social Engineer," as Dr. Tolman calls himself. Industrial betterment is something more than a philanthropy. "The betterment of the labor element is a cold business proposition," as Dr. Tolman says in his preface, "and is undertaken commonly to get the best results out of labor."

The damages which a manufacturer pays for loss of life and limb are a part of the operating cost of his business, and included in the selling price of his product, so that it is the consumer who pays them in the last analysis, and it is the consumer who will profit by the betterment of conditions which will not only avoid such loss of life and limb, but increase the efficiency of the producer.

The first chapter of the book treats of the promotion of efficiency through various educational and other methods. Succeeding chapters treat of The Social Secretary; Hygiene; Safety and Security; Mutuality; Thrift; Profit Sharing; Housing; Education; Recreation; Communal or Social Betterment; Does it Pay?

The work will well repay perusal by everybody who is interested in social progress, and especially by those who are engaged in industrial pursuits, either in the office or in the shop.

General Lectures on Electrical Engineering. By Charles P. Steinmetz. Published by Robson & Adee, Schenectady, N. Y., 1908. Cloth; 280 pages, 6x9 inches; 48 illustrations. Price, $2.

The contents of this book comprise seventeen lectures and two appendices, the latter being reprints of papers read before engineering societies. The lectures are extremely simple in treatment, practically no mathematics being employed. The author's manuscript was "edited" by J. LeRoy Hayden, and there are many spots where more careful work by Mr. Hayden would have increased the clarity and smoothness of diction very greatly. The lectures are "popular" in character and their scope embraces the whole field of electric light and power engineering; consequently, many of them are conspicuously inadequate, even for the avowed purpose of the book. There are several obscure statements in the book, and one or two which seem to be erroneous, if the reviewer reads aright the author's meaning. On page 104, for example, varying the number of poles on an induction motor is said to be analogous to varying the number of expansions in a steam turbine, and on page 105 the author says that the mean [effective?] pressure in a gas-engine cylinder "is low"! The reviewer confesses inability to trace the analogy or to imagine what kind of a modern gas engine develops a "low" mean pressure.

The Economy Factor in Steam Plants. By George W. Hawkins. Hill Publishing Company, New York. Cloth; 133 pages, 6x9 inches; illustrated. Price, $3.

This book is intended for the designer of steam-power plants or the student of the subject of steam-plant design. The author has had access, as a member of the engineering staff of C. C. Moore & Co., to a mass of data upon the several efficiencies of the various factors which go to make up such a plant, has analyzed the effect of varying conditions upon such apparatus and devised formula charts or "graphs" and tables which will assist the designer in determining the constituents of the most efficient plant for a given set of conditions, or the probable efficiency of a proposed plant. The author deals with engineering efficiencies simply and does not consider the over-all efficiency, including standing charges based upon investment, furnishing rather the means for enabling the engineer to estimate the expense of maintenance which may then be corelated with cost. The work is divided into four parts. Part I treats of Individual Apparatus, and considers in separate chapters Boilers; Engines; Electrical Generators; Condensing Apparatus; Feed Pumps; Oil Pumps; Oil Burners; Radiation Leakage; Feed Water Heaters; and Fuel Economizers. It was the original intention to make the analysis applicable only to oil-burning plants, but inasmuch as the same method might obviously be made to apply to any fuel whatsoever it was decided to add such conversion charts as would afford a ready means of applying the results to coal and wood or other fuels.

Part II deals with the Factor of Evaporation. All of the quantities which go to make up this factor are readily obtainable except the temperature of the feed water and this chapter contains "graphs" showing the temperature to be obtained from open and closed heaters for various temperatures of air-pump discharge and percentages of exhaust steam available, and the effect of fuel economizers; and tables showing the percentages of steam used by auxiliaries. Parts III and IV treat of Complete Plant Economy, the first under full and the latter under variable load.

The charts or "graphs" are a prominent feature of the book and present in a condensed yet comprehensive form the information which the author has gathered from exceptional opportunity, and the deductions therefrom.

Practical engineers are prone to hoard the results of their experience as capital in the competitive struggle for advancement. Mr. Hawkins has in this work made available to the engineering profession information which to determine experimentally would entail thousands of dollars worth of experiment or years of varied experience.

Books Received

"Modern Cement Sidewalk Construction." By Charles Palliser. Industrial Publication Company, New York. Cloth; 64 pages, 5x7½ inches; illustrated; indexed. Price, 50 cents.

Anniversary of American Institute of Electrical Engineers

The members of the American Institute of Electrical Engineers and their wives, in all three hundred persons, celebrated the twenty-fifth anniversary of the organization of the institute Thursday evening, March 12, with a dinner at the Hotel Astor, New York City.

Louis A. Ferguson, of Chicago, president of the institute, was toastmaster. The speakers were President Jesse M. Smith, of the A. S. M. E., Past Presidents Elihu Thompson and Frank J. Sprague, of the A. I. E. E., and President Alexander C. Humphreys, of the Stevens Institute of Technology, who delivered an address on "Electrical Engineering as a Profession."

Those occupying the rostrum in addition to the speakers were Theodore Beran, John Bogart, C. C. Chesney, C. A. Doremus, William C. L. Eglin, W. W. Freeman, B. Gherardi, Robert Mather, E. E. Olcott, Ralph W. Pope and G. G. Ward.

In his opening speech President Ferguson called attention to the fact that although the youngest the American Institute of Electrical Engineers now was the largest of the four great engineering societies of America.

President Smith, of the Mechanical Engineers, told what wonders the electricians had accomplished. Professor Thomson was greeted with great applause. He joked about the temerity of the men who took upon themselves the title of "electrical engineers" twenty-five years ago, but praised the optimism which prompted them in that self-assertion.

The institute has had twenty-one presidents since its founding in 1884. Of these, three, Norvin Green, the first president; Franklin L. Pope, the second, and William A. Anthony, are dead. Of the living past presidents, T. Commerford Martin, Elihu Thomson, Frank J. Sprague, Francis B. Crocker, Charles F. Scott, Bion J. Arnold, John W. Lieb, Jr., Schuyler S. Wheeler and Henry Gordon Stott were present at the anniversary.

Preceding the speech of Mr. Sprague, Toastmaster Ferguson called on the seven charter members present to stand and as he read off each name the diners applauded vigorously. The seven were Charles L. Clarke, George A. Hamilton, C. O. Mailloux, T. Commerford Martin, Jesse M. Smith, Prof. Elihu Thomson and Elmer A. Sperry.

Plans of Combined Associations of Brooklyn

The delegates of the Combined Associations of Engineers of the Borough of Brooklyn will hold a banquet in the near future to celebrate the first anniversary of the association. This organization, it seems, is the source of the inspiration for the new engineers' and firemen's license law adopted by the Greater New York Charter Revision Committee. The annual summer outing will be held on July 18, at [illegible] Park, N. J., and the annual ball at the [illegible] Engineers' society, on the eve of Washington's birthday, February 21, 1910. Since its inception this organization has divided one thousand dollars among the several associations forming its membership.

Engineers' Blue Room Club Outing

One hundred and sixty members of the Engineers' Blue Room Club of Boston, Mass., paid a most profitable and instructive visit to the Wood Worsted Mill, the latest addition to the American Woolen Company's plant in Lawrence, Mass., Saturday, March 7.

The party started at 10.30 a.m., in two special cars attached to the regular train, and was met upon its arrival in Lawrence by the mayor of the city and officers of the American mills, which, under the guidance of special committees, were thoroughly inspected.

The power plant, of course, was the principal point of interest, and George H. [illegible], the consulting engineer of this great corporation, explained the many latest and interesting devices.

An extended inspection of other parts of the mill followed, after members and guests found themselves in the restaurant of the mill, where the committee had provided a most appetizing lunch. This being done away with, all were called to order by the president of the Blue Room Club, [illegible] H. Parker, who voiced the sentiments of the members in extending thanks for the invitation to the members, and named Past President George H. [illegible], toastmaster.

Mayor "Billy" White extended the welcome of the city to the members and guests and dwelt at length on the advantages of Lawrence as the greatest textile center of the world, [illegible].

Other addresses were made by Mr. [illegible], the agent of the mill; Mr. [illegible], of the Washington mill; George H. [illegible] and Mr. [illegible], who [illegible] Past Presidents [illegible] and [illegible] as well as Mr. [illegible], secretary of the club, and Harry H. [illegible], chairman of the arrangements committee.

A group picture of all present was then taken. Handshaking and good wishes were then in order, and after three hearty cheers for the hosts and "the city," George M. [illegible], the party left for Boston, having enjoyed the most interesting and instructive visit ever made by this club. The committee who so ably conducted the affair consisted of Harry H. [illegible], Harry H. [illegible] and Richard E. [illegible].

Brooklyn Engineers' Club Social and Smoker

The Brooklyn Engineers' Club held its third annual social session and smoker at the Imperial, [illegible] street, Brooklyn, on Saturday evening, March 14. There were more than three hundred persons present and a most enjoyable evening was spent. A vaudeville entertainment was given by the "[illegible]," there being frequent intermissions between the numbers for the serving of refreshments. The efficient committee in charge of this successful event comprised C. L. [illegible], H. F. [illegible] and Frank W. [illegible].

Civil Service Examinations

The United States Civil Service Commission announces an examination on April 21 and 22, 1909, to secure eligibles to the position of [illegible] in the [illegible] service, at an entrance salary of [illegible] a month. The subjects and weights are as follows: [illegible] mathematics (arithmetic, geometry and algebra), 20; drawing to scale from sketches, 30; [illegible] and lettering, 30; training and experience (rated on application), 20. Applicants must [illegible] be required.

Personal

[illegible] B. [illegible], [illegible] engineer, Boston, Mass., has been elected a member of the corporation of the Massachusetts Institute of Technology.

Prof. Charles M. Spofford, of the Brooklyn Polytechnic Institute, has been chosen to succeed Prof. George F. Swain as Hayward professor of civil engineering at Massachusetts Institute of Technology, beginning next school year. Professor Swain will go to Harvard.

George E. [illegible], for the past two years [illegible] engineer with the Middle States Inspection Bureau, an organization maintained by thirty-six insurance companies, has joined the staff of the George H. [illegible] Company. Mr. [illegible] is a graduate of [illegible] College, Cornell University.

L. F. [illegible], professor of mechanical engineering at the University of [illegible], has been [illegible] in connection with the work of the United States Geological Survey, will have charge of the [illegible] at [illegible]. [illegible] Professor [illegible] will return to his duties next September.

Business Items

The Kennedy Valve Manufacturing Company announces that William Martin, who is well and favorably known in engineering circles, has joined the forces of that company as manager of the New York City sales department, with offices at 57 Beekman street.

The Parker Boiler Company, Philadelphia, Penn., installed last fall a 258-horsepower boiler for the Convent of the Good Shepherd, Wheeling, W. Va., and has just received an order to duplicate the installation; also, an order for three 300-horsepower boilers for the Gardner Harvey Paper Company, Battle Creek, Mich., and two 234-horsepower boilers for the Mount de Chantal Academy, Wheeling, W. Va.

A Eugene Michel, who has for the past three years been Manager of the George H. Gibson Company, has opened new offices at 1572 Hudson Terminal buildings, New York. Mr. Michel will in future confine his efforts as an advertising engineer to the promotion of steam specialties and apparatus, power transmission appliances and machine tools, and will limit his clientele to the number of firms to whose work he can give personal attention. Mr. Michel is a graduate engineer, associate member of the A.S.M.E., and with eleven years' advertising and engineering training, which includes practical experience in machine design, testing, etc., is well prepared to conduct the advertising of mechanical products.

The space-saving qualities of the angle-compound engine, recently introduced by the American Engine Company, Bound Brook, N. J., is illustrated by the fact that one of these engines of a capacity of 500 horsepower was recently selected to drive a centrifugal circulating pump in connection with the condenser outfit of the Interborough Rapid Transit Company, at the Fifty-ninth street and North river power house, New York City. The American Engine Company also reports a sale of an angle-compound engine to the United States Government for the Coast Artillery School at Fort Monroe, to be installed along with two American-Ball duplex compound engines.

The importance of forest preservation is appreciated by no one more than by those who are vitally interested in hydroelectric development throughout the country. Many individuals are exerting themselves in this cause, and the Appalachian National Forest Association continues to enlarge its membership. An example of a manufacturing company interested in this preservation is the Crocker-Wheeler Company, of Ampere, N. J., builder of electric-power machinery used in hydroelectric development, which has recently become a sustainin member of this association, whose object is the "perpetuation, through wise use, of the remaining forests of our country, national and State."

New Equipment

City of Camden, Ark., will construct water-works.

The Midland Electric Co., Lexington, Ky., will erect a new power house.

The Granger (Texas) Oil Mill Company will install an ice plant and water-works system.

City of Panama City, Fla., contemplates erection of electric-light plant and water works.

It is reported that the Sapulpa (Okla.) Interurban Railway Company will construct power house.

H. E. Johnson, Carson, Iowa, has purchased electric-light plant and will make improvements to same.

It is reported that the Clark Memorial College, Newton, Miss., contemplates installing an electric-light plant.

The city of Mart, Texas, has voted $50,000 bonds for construction of water-works. R. W. Bass, mayor.

The Farley & Loetscher Mfg. Company, Dubuque, Iowa, has completed plans for a new power house.

The Union (Iowa) Electric Light Company, recently granted franchise, contemplates constructing electric plant.

The citizens of Marion, Kans., voted to issue $60,000 bonds for construction of electric-light plant and water works.

The citizens of Camden, Ala., have under consideration the question of establishing a municipal electric-lighting plant.

The Providence Hospital, Washington, D. C., is in the market for a 100 kilowatt direct-connected unit, also passenger elevator.

The plant of the Rockford Electric Light Company, Marysville, Mo., recently destroyed by fire, will be rebuilt at once, it is said.

Plans are being prepared for a three-story cold storage building for Conron Bros. Co., Brook avenue and 153d street, New York.

W. H. Bourke and others, of Spokane, Wash., have been granted franchise to construct and operate an electric-light plant in Lewiston, Idaho.

The Italy Water Company, Italy, Texas, contemplates the erection of a standpipe or steel tank and tower and would like to hear from builders.

The Musketaquid Worsted Mills, Lowell, Mass., has awarded contract for erection of an addition. A new power plant and water wheel will be installed.

The Craig Water Power Company, Roanoke, Va., has been organized with $200,000 capital. Two plants will be erected. A. L. Sibert, president.

The Northern Illinois State Normal School, De Kalb, Ill., contemplates installing new engine, generator and switchboard. Jas. A. Clark, engineer.

Muralt & Co., New York, have been awarded contract for remodeling and enlarging water-power plant at Tower Mills, L. I. New turbines will be installed.

Bennings Power House of Potomac Electric Co.

Essential Operating Features of an Important Central Station in the District of Columbia, which Embodies a Number of New Ideas

BY F. L. JOHNSON

Situated on the eastern branch of the Potomac river, about three miles from the Capitol, is the Bennings power house of the Potomac Electric Power Company, which furnishes current for nearly all the electric lights used in the District of Columbia and power to more than 200 miles of electric railway.

MOUTH OF INTAKE TUNNEL

ELECTRIC TRAVELING COAL HOIST

250-HORSEPOWER ELECTRIC LOCOMOTIVE AND COAL CAR

This power house was built to take over the work of three overloaded reciprocating-engine plants of heterogeneous character located in widely separated districts in the city. Current is generated at 6600 volts and stepped up to [illegible] volts for distribution to 14 substations, where it is stepped down to 2300 volts for general lighting distribution mains and converted into direct current of 575 volts for traction work. Compactness of arrangement and facility of operation seem to have been uppermost in the mind of the engineer who designed the plant.

Hollow concrete blocks, [illegible] inches, were used in building the walls and the two main partitions which divide the building into three sections, the largest of which is the boiler room; through the middle of this section rise three chimneys of reinforced concrete, 12 feet in diameter and 200 feet high. Steel I-beam columns of generous proportions support the roof girders, the boilers, the coal bunkers, the traveling crane (which covers the entire turbine room), the reinforced-concrete floors and the lighter partitions which divide the building into rooms, galleries and alcoves.

BENNINGS POWER HOUSE

One hundred and eight feet of the length of the building, which is [illegible] feet, is occupied by the boiler room, which now contains sixteen of the twenty-four [illegible] Babcock & Wilcox boilers for which it was designed. The boilers are arranged in four rows, with the fronts of those in the outer rows [illegible] those in the inner rows.

Steam is taken from each boiler through a [illegible] and a 7-inch [illegible] angle stop valve to a long-radius bend which extends over the top of the boiler [illegible] from the top of the steam main. The diameter of the main [illegible] from 7 to 12 inches [illegible] between the [illegible] of boilers. [illegible] of 14 inches in diameter. [illegible] the plan of the [illegible] ary plentifully used and [illegible] are [illegible] by bends of long radius.

Coal and Ash Handling

Roney stokers are installed, to which coal is fed in closed chutes with [illegible] bottoms designed to keep the

TRANSFORMERS IN TRANSFORMER STATION

[illegible]

[illegible]

veyer for distribution to the overhead storage bins as desired. These bins are of rather small capacity, holding only about four days' supply. For the storage of a large quantity of reserve coal to tide over any failure on the part of the transportation company to deliver the required amount on time a dumping pit is provided about 1000 feet north of the building. Into this all coal delivered in excess of the regular demand is dumped, to be picked up later by an electrically driven traveling coal hoist and distributed in long piles on both sides of the track.

MAIN FLOOR IN TRANSFORMER STATION

Under the boiler-room floor, which is 14 feet above the main floor of the building, are ash hoppers to catch all ash and clinker. These hoppers are equipped with easily operated valves by means of which their contents may be emptied into small dump cars which, when filled, are pushed over and dumped into a hopper which delivers to the same elevator that handles the coal. By the change of one dumping block on the side of the elevator frame the ashes are made to spill into a large hopper of reinforced concrete, located above the boiler-room door, from which they may be run into cars on the outside of the building through a chute which also serves to control the flow of ashes from the hopper to the car. An empty coal car is left at night over the crusher hopper and under the ash chute, which comes through the wall about 12 feet above the track. In the morning the ashes which have been collected the day before and elevated to the hopper are allowed to run into the empty coal car, which is pushed by the electric locomotive onto the side track of the steam railroad, to be hauled away.

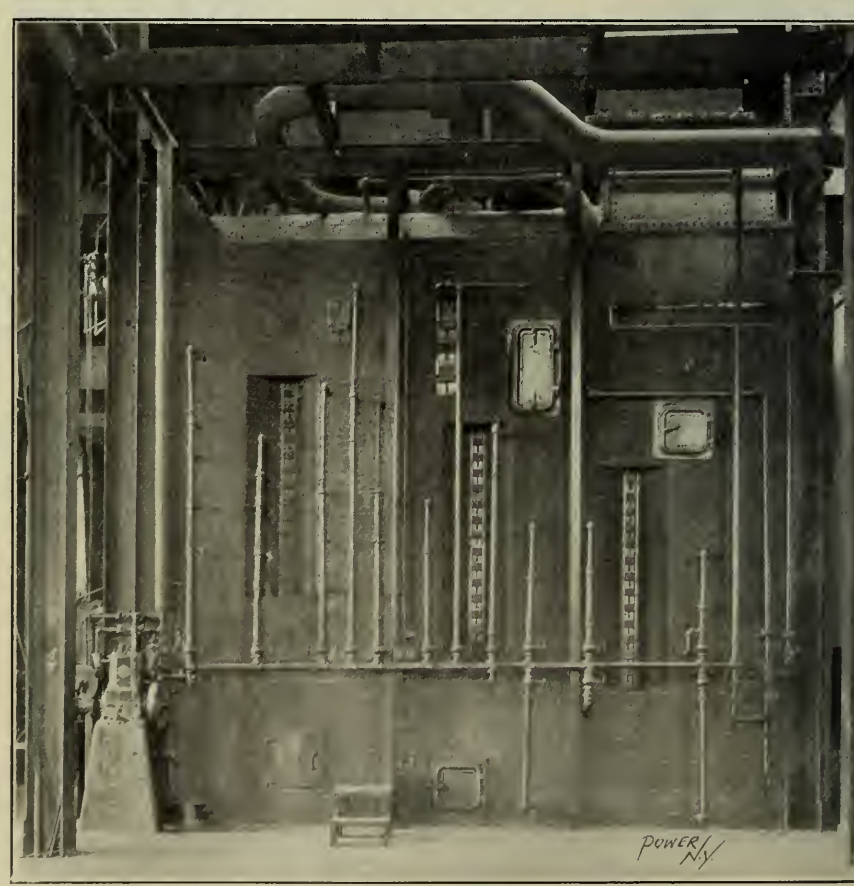
Water is used freely to wet the ashes in the hoppers under the boilers and render the handling of them free from the annoyance due to dust which usually attends most ash-handling operations.

All of the boilers are fitted with "Vulcan" flue blowers by which all of the tubes of all the boilers in the plant may be thoroughly cleaned in less than one hour. Each flue is provided with a damper controlled by a Locke damper regulator, and also with a recording pyrometer. The variations in temperature indicated by the wavy line on the chart show clearly the action of the damper regulator, the low-temperature line on the chart from 1:30 to 5:05 a.m. indicating that the damper had checked the draft while still keeping steam pressure within its usual limits, as shown also by the chart from the pressure gage.

Feed Water

Feed water is delivered to the boilers through extra-heavy brass pipe from any or all of three 16x10x16-inch outside-packed plunger pumps which take water from two Webster open heaters located on the boiler-room floor, one on each side of No. 1 chimney. Exhaust steam from the power ends of the circulating and dry-vacuum pumps, after passing through separators to remove the cylinder oil, is led to the heaters, where it mingles with and heats the condensation from the turbines, which is delivered from the condensers by electrically driven two-stage centrifugal hotwell pumps.

What makeup water is needed is automatically supplied to the heaters by water from two makeup tanks, each of 3000 gallons capacity, located in the boiler room and kept full all the time by the so-called house pumps, which are controlled by a



VULCAN FLUE CLEANERS ATTACHED TO BOILER

Ford pump governor. There is a float in each tank which, as the water rises, closes a valve in the delivery pipe of the pump and as the pressure in this pipe increases it checks the steam supply to the pump, reducing its speed to that necessary to keep the tanks just full.

As practically all of the steam made in the boilers is condensed and returned, the problem of feed-water supply resolves itself into the question of a small amount of makeup water, which is furnished by wells near the plant from which plenty of suitable boiler water is drawn.

Varying demands on the boilers from the peak to the lightest load render it necessary to carry banked fires on some of the boilers for twelve or more hours each day. This of necessity cuts into the economy of operating to some extent and an experimental installation of oil burners

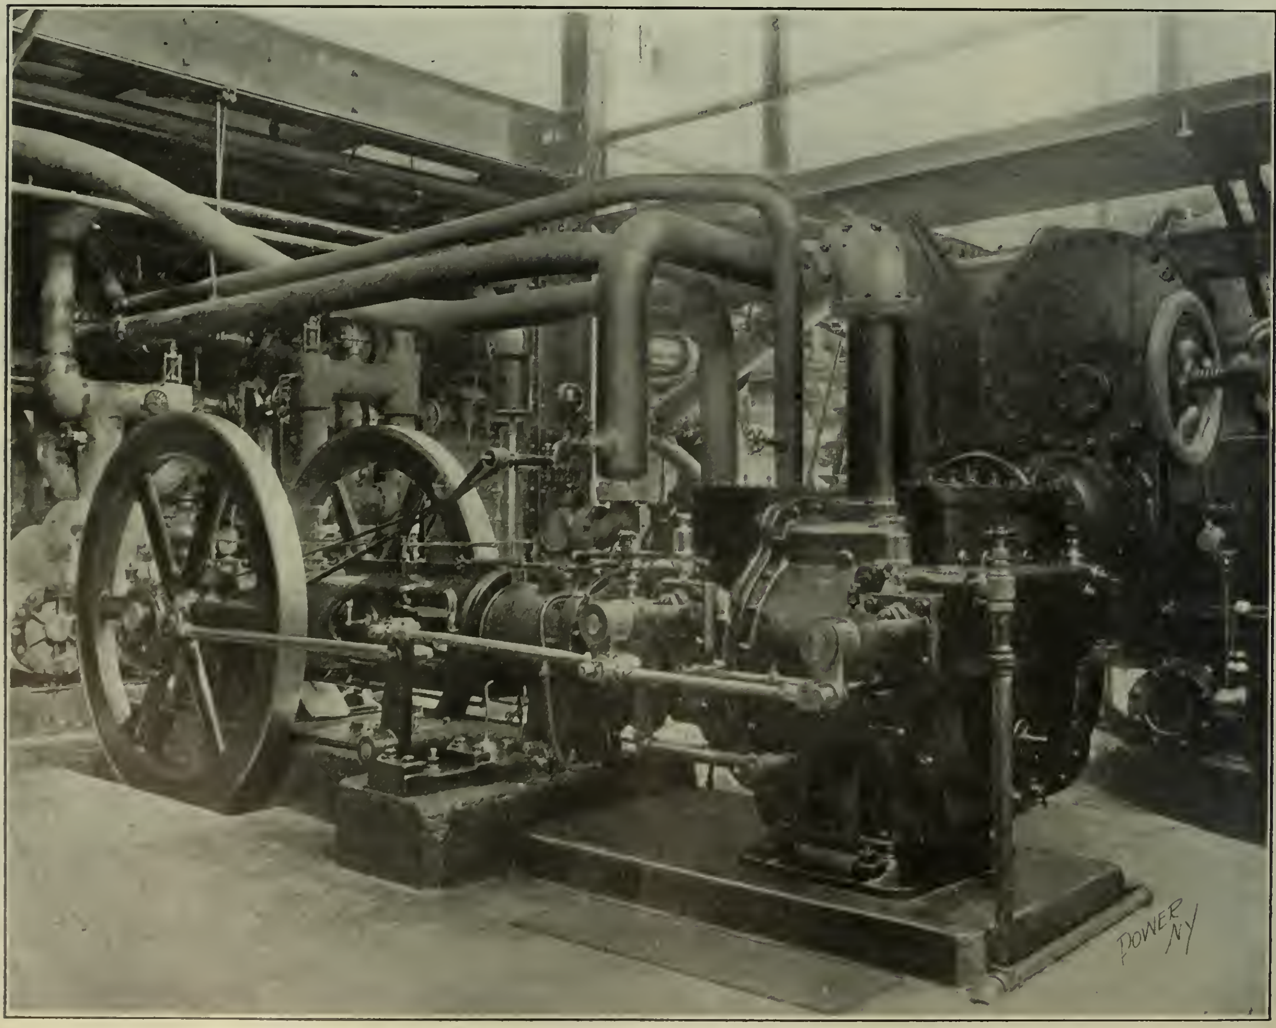
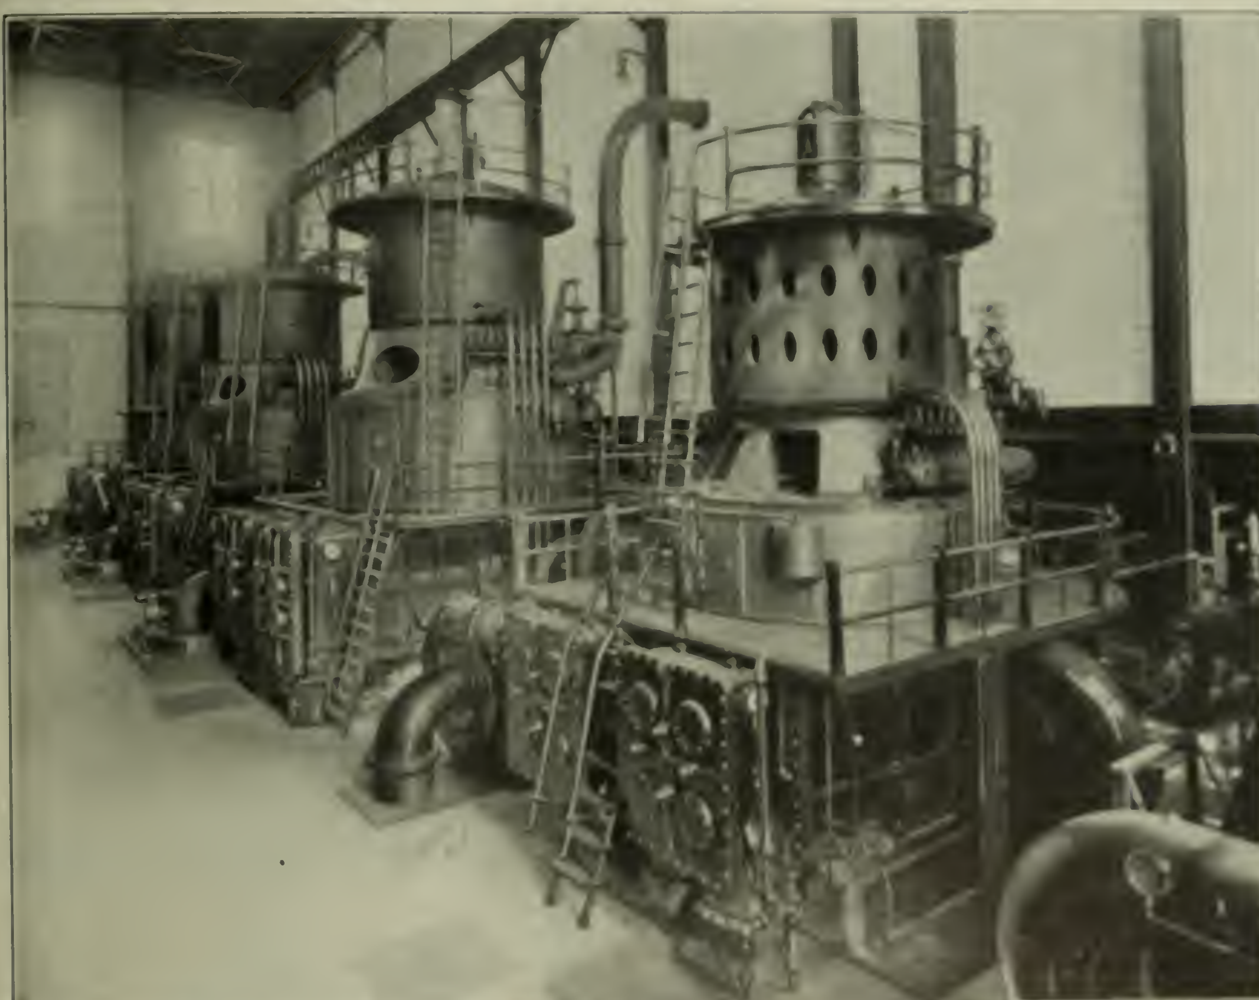
OIL SWITCHES UNDER MAIN SWITCHBOARD IN POWER HOUSE



LAIDLAW-DUNN-GORDON SINGLE STAGE DRY-VACUUM PUMP is being made under two of the boilers to ascertain if, for a short run, it is not more economical to use the more expensive oil fuel than to incur the loss that inevitably occurs from the slow and incomplete combustion that goes on with banked fires. It is also proposed to install one set of oil burners above the grates in one boiler and burn the oil above a coal fire in order to make an attempt to burn the oil in addition to all the coal that can possibly be burned on the grates and thus produce a higher furnace temperature than is possible with coal alone. If it should be found possible with coal and oil together



VIEW OF TURBINE ROOM FROM ENTRANCE TO POWER HOUSE

to get 50 per cent. more evaporation from a boiler than with coal alone, the necessity for banked fires will disappear and no more boilers will be needed when carrying the peak than with the average load.

At this plant the load from 1 to 5 a.m. is about [illegible] kilowatts. From 5 a.m. until 9 a.m. it gradually increases to [illegible] kilowatts, after which it drops to 9000, where it remains until about 4 p.m., when it again increases until a peak of [illegible] kilowatts is reached at sundown. After about two hours the load drops to [illegible] kilowatts, where it continues until midnight, when it again drops off, reaching the lowest point at about 1 o'clock in the morning.

STEAM PUMPS.

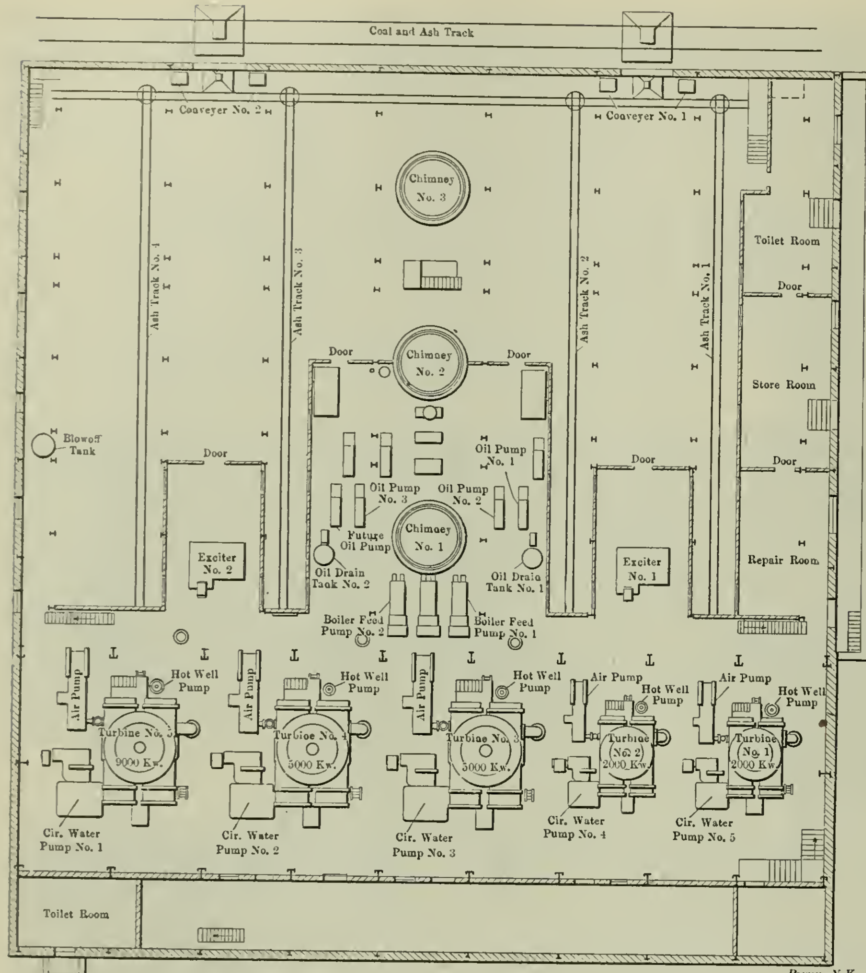
On the main floor of the power house, which is 14 feet below the boiler-room floor, around No. 1 chimney and between it and No. 2 chimney, are grouped all of the steam pumps of the plant. There are three [illegible] outside-packed plunger pumps for boiler feeding, two [illegible] plunger oil pumps, maintaining a pressure of [illegible] pounds per square inch for the step bearings of the larger turbines; three [illegible] plunger-pattern pumps, maintaining an oil pressure of [illegible] pounds per square inch for the steps of the smaller turbines; two [illegible] piston pumps, maintaining an oil pressure of [illegible] pounds, for operating the hydraulic-valve gear and guide bearings, and two small oil-tank pumps which automatically take care of all of the oil that flows to the drip tanks from the step bearings, the guide bearings and the hydraulic-valve gear, and deliver it to the [illegible] oil filters located on either side of the room. There is also one fire pump, which is used occasionally for furnishing water for sprinkling, washing down boilers, or for any purpose for which water under pressure may be needed.

Near No. 1 chimney is located a [illegible] Engineering Company's water meter, to which all of the motor-driven [illegible] pumps are piped. From the discharge tank of the meter a low-duty tank pump, automatically controlled, takes all water passing through the meter and delivers it to the Webster feed-water heaters. Watt-hour-meter and water-meter readings are taken for any length of time desired, and one reading divided by the other gives the pounds of water per kilowatt-hour, the [illegible] of the [illegible] rate [illegible] a very simple matter.

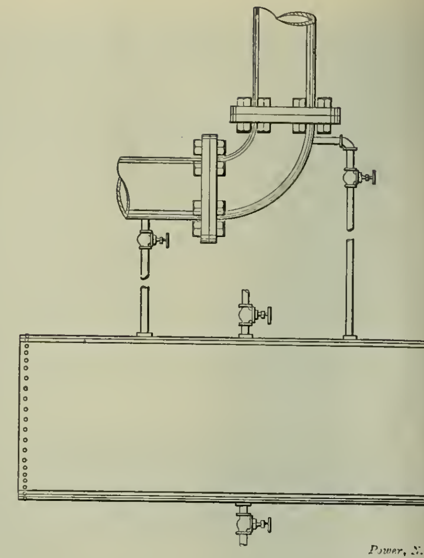
Between No. 2 chimney and the north wall, over the boiler-room basement, is located a building for compressed air, in which two Westinghouse air-brake pumps keep the pressure up to [illegible] pounds per square inch.

At each side of the pump room on the main floor, and also under the boilers, are two sumps, in each of which is a motor-driven [illegible] pump of [illegible] capacity.

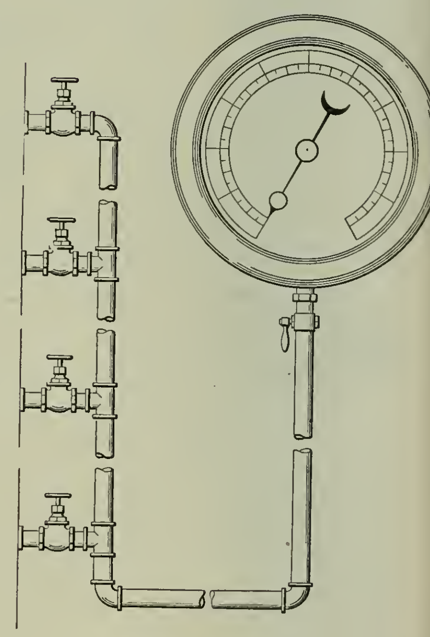
Calculations were made to decide [illegible] the [illegible] should be



GROUND-FLOOR PLAN BELOW LEVEL OF BOILER ROOM



DRY-VACUUM PUMP DRAINING SCHEME



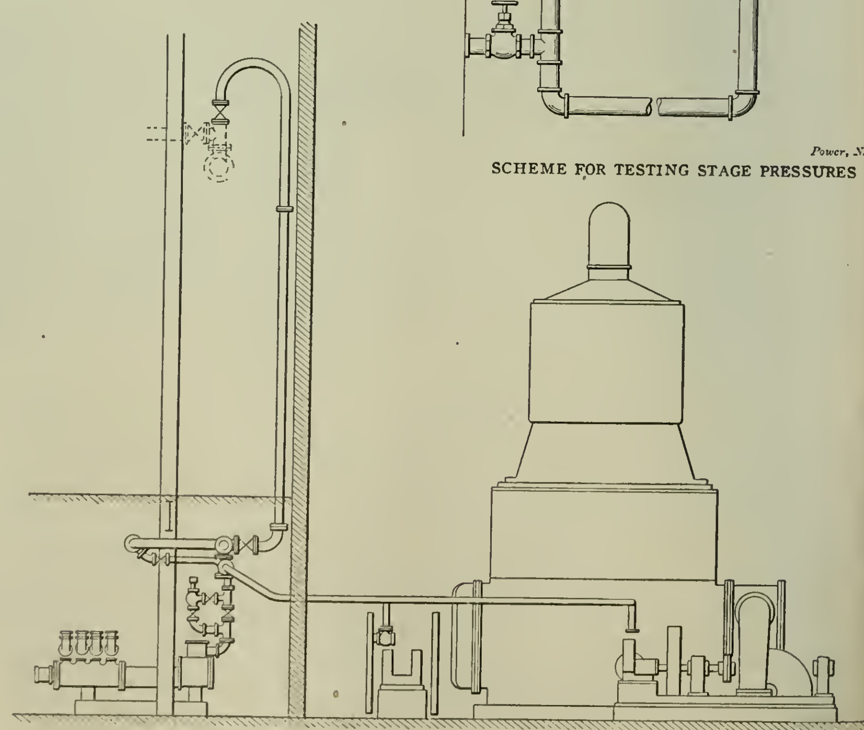
SCHEME FOR TESTING STAGE PRESSURES

steam-driven, it being desired to heat the feed water as hot as possible and yet use no more steam in the auxiliaries than would be condensed in the feed-water heaters. That the balance was very closely calculated is shown by the fact that the average temperature of the feed water for one year was 186 degrees.

The Steam Turbines

On the main floor of the turbine rooms are five vertical Curtis turbines mounted on Worthington condenser bases. One turbine generator is of 9000 kilowatts capacity, two are of 5000 kilowatts each and two of 2000 kilowatts each. As the 2000-kilowatt units are too small to carry the entire load at any time of the day or night it is intended in the very near future to replace these two units with one of 14,000 kilowatts capacity

Steam for the turbines is taken from the side of the main pipe line through pipes with long bends, while steam for the auxiliaries is taken from the top of the same main by risers with return bends of 2-foot 3-inch radius, the long ends of which descend below the boiler-room floor, thence through long ells and bends to the machines where the steam is to be used.



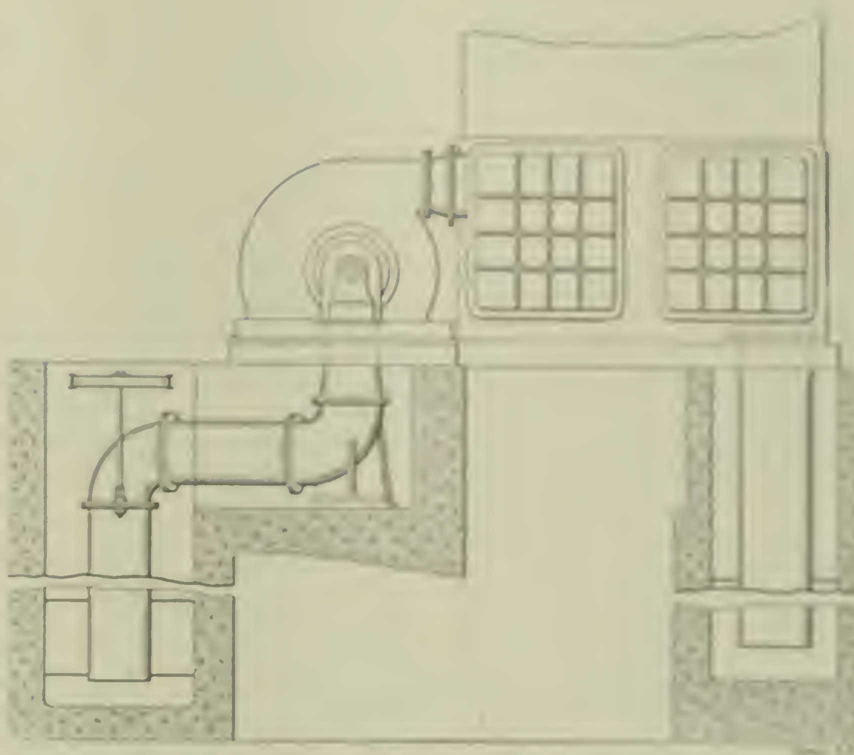
ELEVATION OF AUXILIARY PIPING

In order to obtain condensing water economically a channel about 200 feet long was dredged out from the mouth of the intake tunnel to the river. From this channel the water is taken to the turbine room under the floor in a concrete duct 13 feet wide and 5½ feet deep. Throughout the length of the turbine room the overflow pipe, also of concrete, lies on top of the intake, side pits being provided for the suction pipes of the pumps so that they do not pass through the overflow. As both the intake and overflow are below the river level, the discharge pipes from the condensers are sealed at all times and the work done by the circulating pumps is simply that of overcoming the friction necessary to move the water through the condensers and connections. Each condenser is served by a centrifugal circulating pump, direct-connected to a Fleming engine, a steam-driven Laidlaw-Dunn-Gordon single-stage dry vacuum pump and a motor-driven two-stage centrifugal hotwell pump.

When the plant was first started considerable annoyance resulted from water which collected in the suction pipe of the dry vacuum pumps, necessitating a shut-down once in about four hours to drain the water from the pipe. The chief engineer hit upon the scheme of tapping the suction pipe at two points, one at the bottom and the other above this, and leading both pipes to a closed tank below the level of the suction pipe. When water came along with the air it ran through the lower drain pipe and collected in the tank. At the end of two or three hours the valves in the pipes leading to the tank were closed and the tank opened to the atmosphere, when the water ran out. When the tank was empty it was closed to the air and opened to the suction as before. Since this plan has been in operation no trouble has been caused by water in the dry-vacuum pump cylinders.

There is also an ingenious arrangement by which with a single connected gage the pressure or vacuum in any stage of the turbine can be tested. From the gage on the wall a single pipe leads upward past all four stages of the turbine casing. From each stage a pipe with a valve leads to the gage pipe. By opening one valve with the others closed the degree of pressure or vacuum in that stage is read and may be compared with that of the other stages or with former readings.

Chief Engineer [illegible]



ELEVATION OF CONDENSING-WATER SYSTEM, SHOWING INTAKE AND OVERFLOW

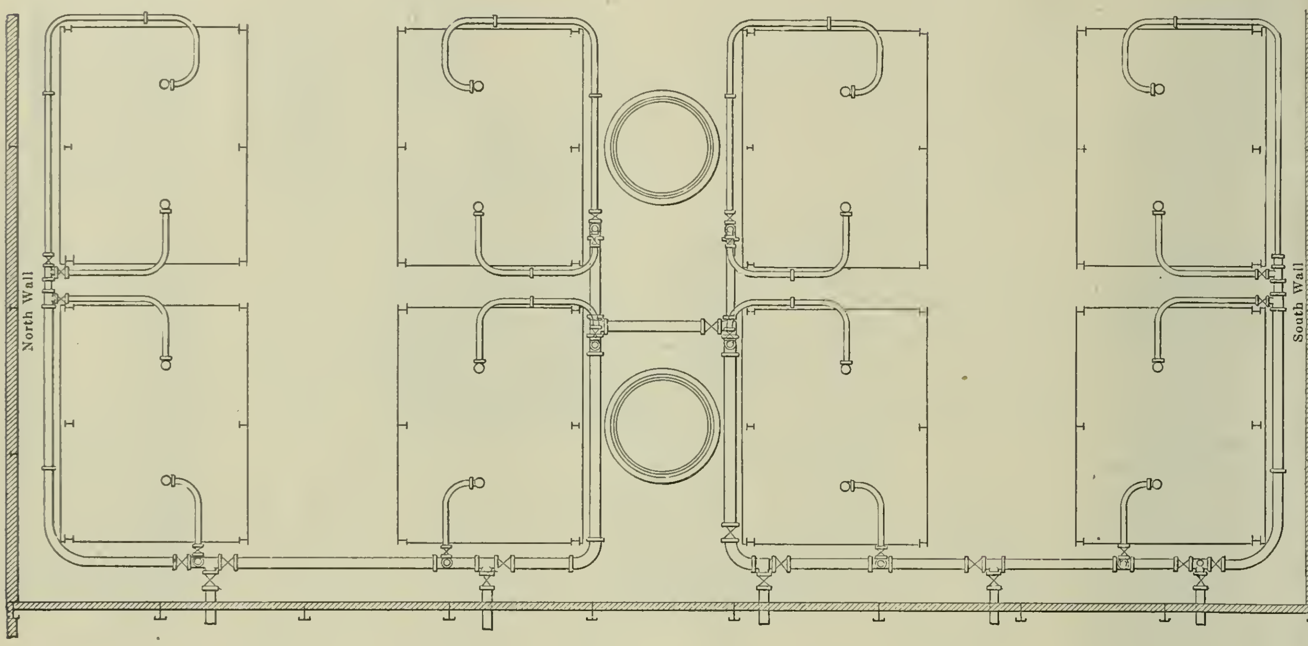
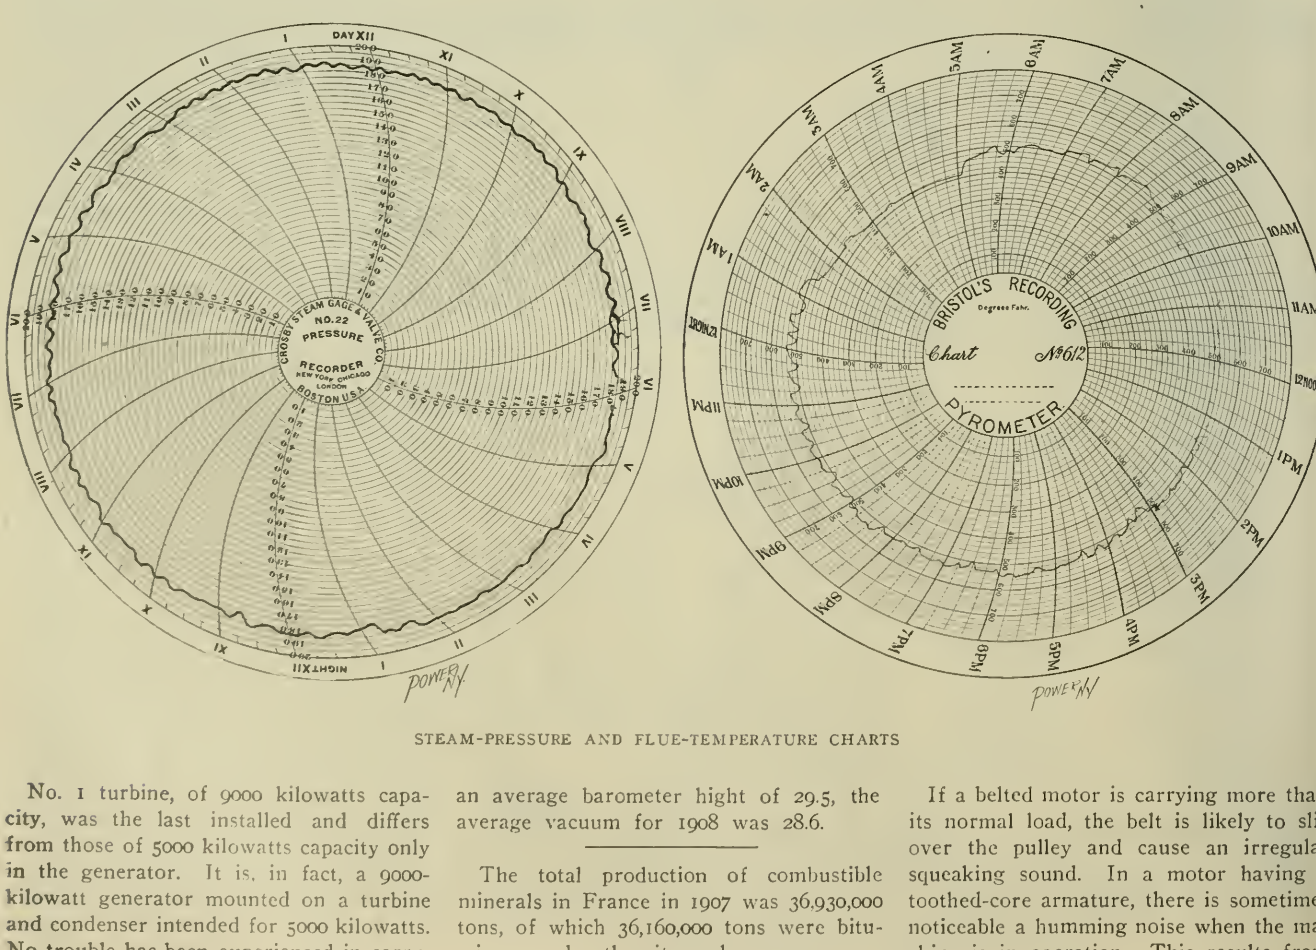
thought that their durability will be increased.

Steam is furnished to the turbines at 180 pounds pressure with 138 degrees superheat at the throttle.



PLAN OF MAIN STEAM PIPE OVER BOILERS



STEAM-PRESSURE AND FLUE-TEMPERATURE CHARTS

No. 1 turbine, of 9000 kilowatts capacity, was the last installed and differs from those of 5000 kilowatts capacity only in the generator. It is, in fact, a 9000-kilowatt generator mounted on a turbine and condenser intended for 5000 kilowatts. No trouble has been experienced in carrying a full load of 9000 kilowatts and maintaining a vacuum of 29 inches with a condenser having only 20,000 square feet of cooling surface, which is an overload on the condenser of 80 per cent. With an average barometer hight of 29.5, the average vacuum for 1908 was 28.6.

The total production of combustible minerals in France in 1907 was 36,930,000 tons, of which 36,160,000 tons were bituminous and anthracite coals.

Catechism of Electricity

987. *What causes other than mechanical ones are responsible for noise in a motor?*

If a belted motor is carrying more than its normal load, the belt is likely to slip over the pulley and cause an irregular squeaking sound. In a motor having a toothed-core armature, there is sometimes noticeable a humming noise when the machine is in operation. This results from the passage of the teeth of the core past the field-magnet poles.

988. *Cannot objectionable noise caused by overload on a motor be reduced without decreasing the load?*

Tightening the belt or applying powdered rosin to that part of its surface which comes in contact with the pulleys may be found to answer the purpose. If, however, these remedies fail, a pulley of larger diameter or a belt having a wider dimension must be employed.

989. *Can the humming noise due to a toothed armature core be remedied?*

It can be remedied, but only in the reconstruction of the machine, either by reducing the number of ampere-turns in the field winding or by altering the shape of the pole pieces or that of the teeth in the armature core so that the teeth do not all pass the edges of the pole pieces at the same time.

Motor Speed Too Low

990. *What are the usual causes that tend to slow down the speed of a direct-current motor?*

Overload; friction between the armature and the pole pieces; friction between the armature shaft and the bearings; a short-circuited coil or ground in the armature; low voltage in the supply circuit.

991. *What indications accompany an overloaded motor running slow?*

There is usually bad sparking at the commutator, the armature is very warm and in the case of a belted machine the belt is very tight on the tension side and may slip excessively.

992. *Is there any remedy for the case mentioned in 991 except reducing the load?*

No.

993. *What symptoms indicate that friction between the armature and the pole faces is keeping down the speed?*

A roughened armature surface, a tendency of the armature to stick when turned slowly around by hand, or a scraping noise when the armature is rotated.

994. *How should friction trouble of this kind be remedied?*

By binding down the protruding portion of the armature winding, or by properly centering the armature in its bearings or by filing out the pole faces where the friction occurs.

995. *If there is sufficient friction between the armature shaft and the bearings to cause drop in speed, will they not become very warm?*

They will, and the armature will be difficult to turn by hand.

996. *What remedy should be applied in such a case?*

The bearings, if out of alignment, should be readjusted. If the shaft surfaces are rough they should be smoothed, cleaned and oiled.

997. *How may a short-circuited coil or a ground in the armature be found?*

A short-circuited coil in the armature will cause the motor to draw excessive current. A ground occurring at two points in the armature will produce the same effect as a short-circuit, but a ground at only one point will not be noticeable. Continuity tests with a magneto bell, made by connecting the terminals of the magneto to the armature core and to the wire of the coil and turning the generator crank, will show up a ground if there is one. If the magneto bell rings, there is a ground; if it does not ring, there is probably not any ground.

998. *How should a short-circuited coil be remedied?*

If the trouble is due to a piece of solder or other metal getting between the commutator bars or their connections with the armature winding, the remedy consists simply in removing the solder or the metal. If the short-circuit is in the coil itself, the coil will have to be replaced by a new one.

999. *What should be done to remove a ground in an armature coil?*

If the ground is at a point where it can be reached, it can usually be remedied by inserting a strip of insulating material between the coil and the core. Otherwise, the coil must be rewound.

1000. *What produces a ground in a motor?*

Sometimes a ground is caused by a spark of static electricity, generated by friction between the belt and pulley, puncturing the insulation of a coil.

1001. *Is there any way to prevent trouble from the static electricity produced by the belt?*

If the frame of the motor be grounded, the static charge will be led directly to ground before it does any harm. As it is not generally desirable to ground the motor frame, a moistened thread, a heavy pencil mark on a piece of unglazed porcelain, or any other high resistance connecting the frame to ground that will carry off a static charge, which is of very high potential and very small magnitude, but will not allow the passage of an appreciable current, will answer the purpose.

Motor Speed Too High

1002. *What are the usual causes that tend to make a direct-current motor run too fast?*

Weak field magnets, too light a load, or too high voltage in the supply circuit.

1003. *Does a weak field magnet always cause a motor to run fast?*

A weak field magnet causes a shunt-wound motor to run fast if it is lightly loaded. If the motor is very heavily loaded, however, a weak field magnet will usually cause it to run slow. In case the field circuit is accidentally broken while the motor is running lightly loaded, it may even reverse its direction of rotation and run backward.

1004. *Is the speed of a motor likely to become dangerously high owing to the load being light?*

It is in the case of a series-wound motor, but not so in a shunt-wound motor. A series-wound motor is therefore generally geared or direct-connected to the load instead of being belted to it because if the belt should break the motor would increase in speed until the armature destroyed itself.

1005. *What special care should be exercised in running series-wound motors to prevent the load being removed?*

If the load is not direct-connected to the motor an automatic governor should be used in connection with the motor to reduce the current if the speed becomes too high.

1006. *What way is there of learning whether a high voltage in the supply circuit is causing the motor to speed up?*

Measuring the voltage across the supply wires with a voltmeter.

1007. *Where should trouble be looked for if a direct-current motor fails to start?*

An open circuit in the motor or in its connections to the supply wires; no current in the supply wires; improper connections; excessive friction between the moving parts; too heavy a load.

1008. *In what parts of a motor or in its wiring to the supply wires is an open circuit most likely to occur?*

One of the wires connecting the field winding or circuit may have slipped out of its connection, in which case the path [illegible] will not permit it. The brushes may not be in contact with the commutator. In the wiring to the supply circuit one or both of the fuses may be melted, the circuit breaker may be tripped or the main switch open.

1009. *What should be done in case an open circuit is suspected?*

Turn off the current, if need be, and examine the wiring and motor at the points mentioned in the previous answer. If they appear to be in good condition test the field circuit, armature, and connections to the supply wires by [illegible] a magneto bell as already described. If the trouble is not located, [illegible] the voltage in the supply wires.

Expensive versus Inexpensive Back Pressure

Several Interesting Examples That Were Taken from Actual Practice which Afford Reliable Information upon a Very Important Subject

BY W. H. WAKEMAN

This title may be considered a misnomer by readers who firmly believe that back pressure on the piston of an engine is always expensive, but this is not true, either in theory or practice, as it depends upon what use is made of the exhaust steam; for if all of it is utilized and live steam saved by the process, it matters not whether the back pressure is 1 or 10 pounds. There are cases, however, where back pressure is expensive and Fig. 1 illustrates one of them.

In this mill the exhaust pipe is 8 inches in diameter, and after the steam has passed through a suitable feed-water heater it is discharged into a vertical pipe fitted with a back-pressure valve as shown. Just below this valve there is an 8-inch tee that was installed for the purpose of securing exhaust steam for use in three vats. An 8-inch nipple was screwed into this tee, followed by an 8x6-inch reducing coupling. This carries a 6-inch nipple, followed by a 6x3-inch reducing coupling, after which 3-inch pipe was used and provided with three 1¼-inch outlets, one for each vat.

As the cylinder of this engine is 20 inches in diameter, and a heavy load is the rule rather than the exception, the exhaust pipe is none too large where it is 8 inches in diameter, with a cross-section of 50 square inches, but when the diameter is reduced to 3 inches with a cross-section of only 7 square inches, making a difference of 86 per cent., a very radical change has been made which is not warranted by the conditions of service. But even this great reduction of capacity is not prohibitive, provided good judgment is used in operating the device, for if a light weight is put on the back-pressure valve lever, limiting the pressure to 2 or 3 pounds a certain portion of the steam would go into the vats, and the remainder would be discharged into the air through the main pipe. This light pressure under stated conditions, however, would not supply the vats with sufficient steam to fulfil the requirements; consequently, the superintendent (who knew nothing about successful steam engineering) ordered the engineer to fasten the back-pressure valve lever down by means of a strong wire attached to a hook screwed into the floor, as shown. This created a heavy back pressure which caused more steam to be discharged from the cylinder, raising the back pressure still higher, until the engine speed was reduced enough to cause the safety-stop motion to operate and shut steam off from the cylinder. As feed water was passing rapidly through the heater and the vats were condensing steam at a high rate, a partial vacuum was formed in the exhaust pipe. Atmospheric pressure acting on the surface of material in the vats forced a thick, pulpy mass up into the pipes and heater.

Before starting the engine again, the engineer opened the back-pressure valve, but even then the piston moved slowly as if carrying an extra load, until there was a commotion in the heater, followed by a series of thumps on the roof, after which the flywheel speed was rapidly increased until the governor controlled the cutoff and the machines were running at normal speed. Investigation showed that a large quantity of partially manufactured material had been thrown out on the roof, and laborers were sent to reclaim it.

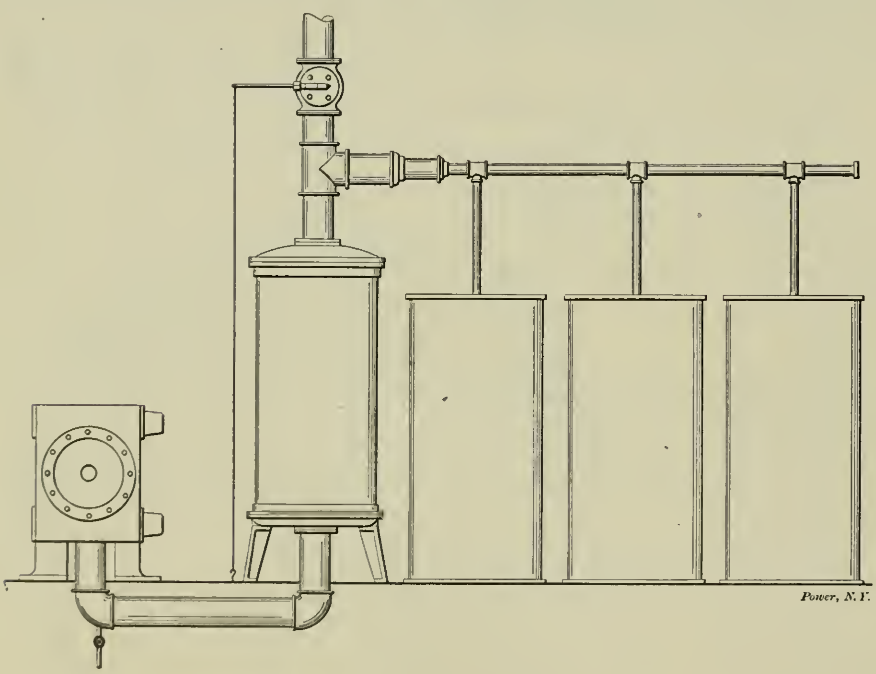


FIG. 1

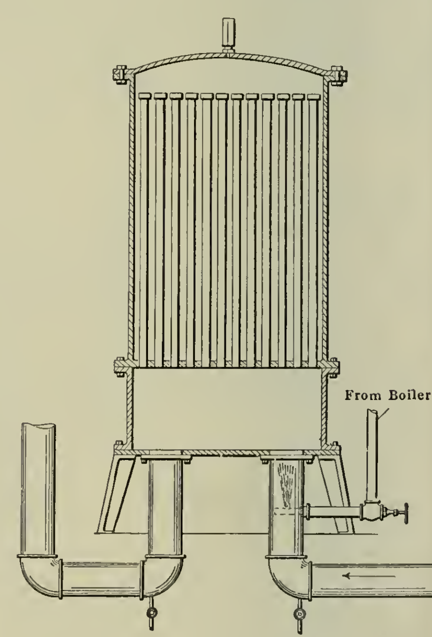

FIG. 2

Back pressure in this case was very expensive, although there was no necessity for it, as it was nearly all due to an inefficient system of piping. If live steam was to be used in these vats, the pipes would probably not be made smaller than 1¼-inch; and they were not increased for exhaust steam. If the outlet from this 8-inch tee had been continued full size as far as the third vat shown in the cut, and then reduced to 6 inches to convey steam to other parts of the mill, it would have proved much more satisfactory. The outlet to each vat ought to be 2½ inches in diameter, supplying four times as much steam as the arrangement shown, because a large quantity at low pressure would do the work well.

The adoption of this plan would make it possible to use all of the exhaust steam, provided it is needed in the vats, and if only a part of it is wanted here and elsewhere in the mill, the remainder would go to the atmosphere through the back-pressure valve, causing it to open at 2 pounds pressure.

A properly designed system of exhaust-steam piping costs more than pipes installed without system by a man who does the work in an ignorant manner, because he does not understand the requirements and makes no intelligent effort to find out what is wanted; but the results in practice will be much more profitable and satisfactory, because an abundance of steam will be available (provided a sufficient quantity is exhausted from the engine), there will be no useless back pressure and the engine will not be overloaded on this account, as it always was in the case mentioned.

Outlet Pipes Too Small

Fig. 2 illustrates a portion of the 8-inch exhaust-steam piping which conveys steam from another engine, with a cylinder 20 inches in diameter, through a feed-water heater of peculiar design and thence to the atmosphere, or to be partially used in heating the mill, as desired. Just beyond the heater and below the back-pressure valve, a 6-inch outlet is provided for conveying exhaust steam into a dry kiln, where much of it is condensed.

Another 6-inch pipe supplies heat for the mill, and out of this pipe numerous branches take steam for heating different rooms. This appears to be a good plan and it is, when the details are arranged to correspond, but it is not perfect in this case, because the pipes which branch from these 6-inch outlets are too small to convey all of the steam easily; therefore, it is necessary to carry a comparatively high back pressure in order to force steam to all parts of the mill, but owing to the lack of a steam gage on the exhaust pipe when the plant was examined, it was not possible to determine the exact pressure. It certainly was high because some of it escaped through a leak in a flange joint and came out with a sharp hiss that cannot be secured from steam at low pressure. A steam gage ought to be connected to the exhaust pipe of every engine (below the back-pressure valve), so the back pressure may be plainly indicated at all times. As this is not an expensive instrument, it is sure to prove a paying investment. It should be a low-pressure gage in order that the pointer may move a considerable distance for each pound, permitting its indications to be read easily.

The term "high pressure" as applied in this article to exhaust steam means 2 pounds or more above the atmosphere, and "low pressure" signifies less than 2 pounds. My reasons for this distinction are that a convenient line of separation is thus provided; also, because with a properly designed system of exhaust-steam piping less than 2 pounds is always sufficient to keep the pipes full of steam; consequently, anything in excess of this is properly termed "high pressure."

My attention was called to this plant by the cloud of exhaust steam issuing from the pipe above the engine-room roof on a cool day, as exhaust steam always seems to be of greater density and consequently more wasteful under such conditions than when a higher temperature of the air causes less rapid condensation.

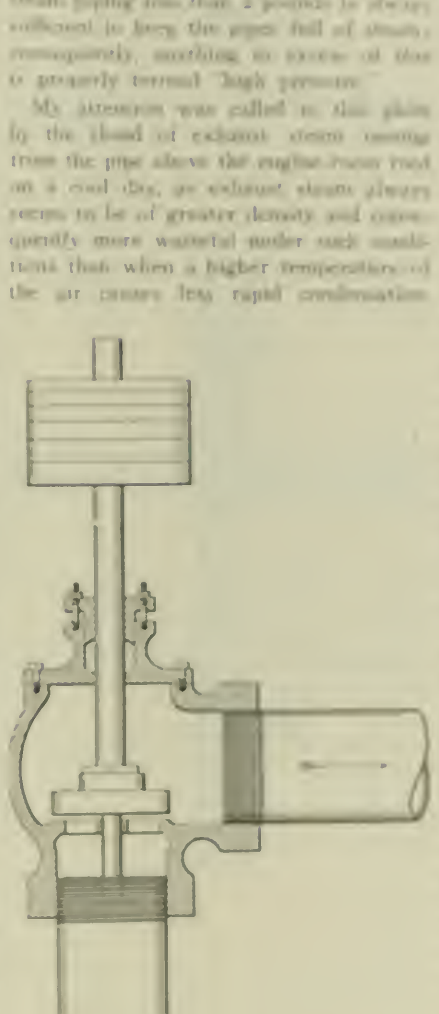

FIG. 3

Investigation showed that the back-pressure valve was not fastened open, as a casual observer might suppose, but was weighted down in the usual way. However, it opened at every stroke of the engine and allowed part of the exhaust steam to escape, while the remainder was used for heating purposes as stated. The valve was located above the roof where it was exposed to the elements at all times, and in order to change the weights or give it any other attention required, it was necessary to climb a ladder and walk several rods on a sloping roof, which was not desirable in cold and stormy weather.

Difference Between Dead-weight and Lever Valves

Fig. 3 illustrates the back-pressure valve formerly used on this exhaust pipe, although it was located under the roof. It is of the dead-weight type; therefore, the weight necessary to keep it shut under a given pressure is found by multiplying the area of the valve by the pressure. The area of this 8-inch valve is 50 square inches, and if the pressure is 5 pounds, it requires

$$50 \times 5 = 250$$

pounds to hold the valve down, including the weight of the valve. A certain engineer, when filling out an application for a license, stated that his safety valves were 4 inches in diameter and of the dead-weight type. If this statement was correct it would have required 1256 pounds of cast iron on the stem to carry 100 pounds on the boilers. The weight of the valve in this case would prevent it from opening until the pressure was slightly above 100 pounds, but this is necessary in order to secure the required boiler pressure without wasting steam through the safety valve. These valves were in reality of the lever type, thus differing materially from the dead-weight type, a difference which ought to be more thoroughly understood.

A few days after observing the cloud of exhaust steam, I secured indicator diagrams from the engine named while the back-pressure valve was closed, except when the pressure of exhaust steam raised it. Some of these are illustrated in Fig. 4 and they show nearly 5 pounds back pressure. Other diagrams taken the same hour with the valve open show practically no back pressure; therefore, the 5 pounds shown in Fig. 4 should be charged to the heating system. The power required to secure a portion of the exhaust steam for a useful purpose is found by multiplying the horsepower constant by the back pressure. The former is 4.127 for this engine; therefore, it requires

$$4.127 \times 5 = 20.6$$

horsepower to force steam through the small pipes. With the present system of piping in the mill the cheapest way to secure the required heat is to use the exhaust steam, although the conditions are unfavorable, and this was proved by allowing the engine to exhaust freely to the atmosphere, using live steam for heating purposes. Under these conditions it was necessary to maintain pressure enough on the boilers to keep the engine up to required speed, so the experiment was simple. It showed, as much more fuel was used than before.

Another point to be considered in this connection is that each horsepower is used to secure only one-half of the exhaust steam, while the other half is [illegible]; consequently the actual cost per [illegible] pounds of steam used for heating is just double what it would be if all of the exhaust steam was utilized. Fortunately, it is possible to prove [illegible] heating system for this mill that would use all of the exhaust steam in cold weather with one-half of the back pressure now carried, thus reducing the cost per 1000 pounds of steam used to one-quarter of the expense under present conditions.

The heater shown in Fig. 2 consists of tubes expanded into the middle head, with caps on their upper ends. Steam is discharged into these tubes and as they are surrounded by the cool feed water it is condensed and the resulting water falls downward, thus giving place to more steam. It heats the water to 200 degrees Fahrenheit. The angle valve shown is for the purpose of admitting live steam to the system when the engine is shut down. The connecting pipe, which is 1¼ inches in diameter, carries a 1½-inch bushing, to the inner end of which is fastened a brass nipple, whose inner end is securely closed by a plug. A hole was bored in this nipple and turned upward when it was put in, thus sending live steam in the proper direction to prevent any portion of it from going toward the engine, and almost the full boiler pressure is expended in sending steam through the pipe. If there is a chance to use a bushing about three sizes larger than the live-steam pipe, a long thread may be cut on the pipe and a cast-iron ell screwed onto the end, as the hole in the exhaust pipe will be large enough to admit the ell. It is possible to make one as illustrated in Fig. 2 without a bushing.

When the engine is started, live steam flowing through this fixture draws air, water and steam from the cylinder, thus assisting in heating the pipes quickly, without increasing the back pressure.

Care should be taken to know that the outlet of such a device is turned in the right direction, as otherwise it will do more harm than good. It ought always to discharge into the heater, as shown, in order to heat the feed water in case it is necessary to run the steam pump when the engine is shut down; and the pump should exhaust into the heater for the same reason.

Economical Exhaust-steam Heating

Fig. 5 illustrates part of the piping for exhaust-steam heating in a shop the machinery of which is driven by another engine with a cylinder 20 inches in diameter. After the exhaust steam is discharged from the cylinder it passes through a horizontal feed-water heater under the floor. It is then turned upward by an ell and, coming through the floor in the vertical 8-inch pipe shown, enters a cross. As the valve above this cross is now closed, the steam is divided and, passing out through two 6-inch pipes, goes into various departments in the shop. There is a valve in each of these branches by means of which the steam is shut off in warm weather. The weight which hangs near the floor, as all such

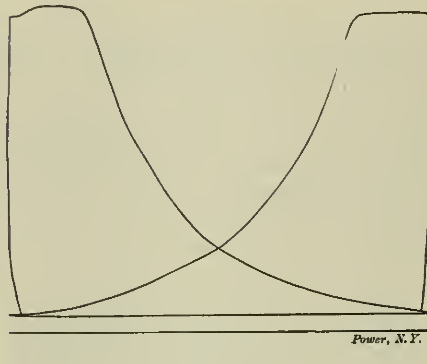

FIG. 4

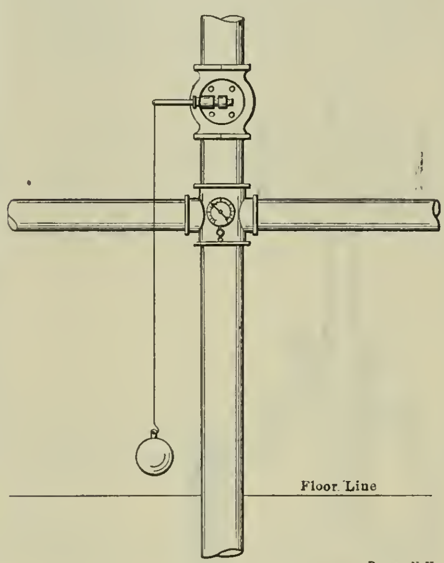

FIG. 5

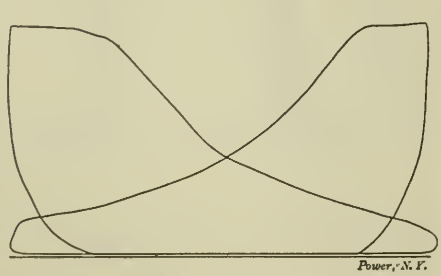

FIG. 6

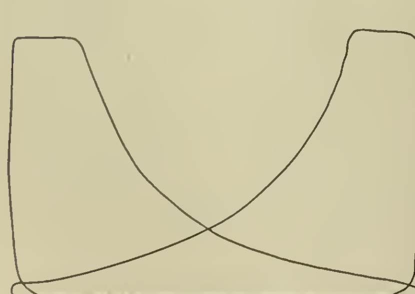

FIG. 7

weights should, is then removed and the valve is fastened open to allow free passage for the steam.

Fig. 6 shows a pair of indicator diagrams taken from this engine when the exhaust steam was used for heating purposes. They indicate not more than 1 pound back pressure. The horsepower constant of this engine is 5.994, therefore it requires

$$5.994 \times 1 = 5.994,$$

or say 6, horsepower to force all of this steam through the heating system. Even this power is not wasted, because all of the steam required to develop it is sent into the shop and utilized for heating the several departments. There can be no question about the economy of exhaust-steam heating in such a case, as there is no loss to charge against it.

Fig. 7 shows diagrams from a 16-inch engine, the horsepower constant of which is 2.12. The counter-pressure line is so near the atmospheric line that they barely form two separate lines. Measuring from center to center of these lines shows that the back pressure does not exceed 1 pound. This does not represent even a slight loss; neither would it if there was 5 pounds, because all of the exhaust steam is used for heating purposes. The heating system of this plant is unique, because all of the pipes are 6 inches in diameter, consequently there can be no contraction of area in the discharge lines.

The back-pressure valve and branch lines are illustrated in Fig. 8. A 6-inch pipe is large enough to allow all steam from a 16-inch cylinder to escape freely, but this soon branches into two 6-inch lines, giving the steam a still better chance to escape, especially when a portion of it is condensed in the heating process. This system was not efficient in practice because the steam expanded to a very low pressure and was all condensed before it filled the pipes. If there had been a greater load on the engine due to more machinery, or even a greater back pressure, the shop would have been heated much better, but the entire waste from this engine is used without cost.

Fig. 9 is a single diagram from another 16-inch engine. The horsepower constant is 2.923. About one-quarter of the steam from this engine is used for heating purposes and the remainder goes through the back-pressure valve. The heating pipes are small for the service required and a trap prevents the free escape of steam at the outlet, which in this case would be an advantage, and nothing would be wasted by such an arrangement.

Effects of Incompetency

The diagram shows about 2 pounds back pressure, therefore

$$2.923 \times 2 = 5.84$$

horsepower is required to force the steam through the system, proving very wasteful in practice. Coils of pipe were installed in one room for the use of live steam, but no trap was used in this case, and the men who occupied this room always opened the drip valve as wide as possible, thus wasting more steam. The combination found in this mill showed the effects of incompetency in designing and operating a heating system.

Fig. 10 is a diagram from the same engine after an incompetent engineer had been in charge of it for several months. Employees in the mill were cold because there was not sufficient radiating service to heat the rooms properly; consequently, they put more weight on the back-pressure valve lever, until the engine could not maintain its rated speed. Investigation showed that about one-third of the average pressure above the atmosphere was required to carry the useless load, even when the mean effective pressure was 100 per cent. higher than in Fig. 9.

The back pressure in Fig. 10 is 19 pounds, therefore it requires

$$2.923 \times 19 = 55.5$$

horsepower to dispose of the exhaust steam, which is much more than it ought to be. If this was the only loss due to bad conditions, it would be enough to warrant investigation and improvement, but the reduction of engine speed reduced the output of the mill, although the expense of operation was the same as before, and this is more serious than the cost of fuel to produce lost power. The back pressure was reduced to normal when the extra weights were removed.

The term "average pressure" is used advisedly in this case and it should not be mistaken for the "mean effective pressure," because they are not the same, although the difference is not always recognized; therefore, special attention is called to this point. The "average pressure" as used in this connection is represented by the average hight of the steam and expansion lines above the atmospheric line, while the "mean effective pressure" is the remainder after subtracting the average hight of the counter-pressure line from the foregoing result.

Where the counter-pressure line is nearly straight, as shown in Figs. 4, 6 and 7, the back pressure can be determined by measuring at the center, with the proper scale, the distance between the two lines; but when it is irregular, as in Fig. 10, the back pressure should be determined by the same method that is adopted for finding the mean effective pressure.

Fig. 11 illustrates a pair of diagrams from a 16-inch engine in a paper mill, with a No. 60 spring in the indicator. The horsepower constant is 2.023 and the back pressure is 8 pounds; therefore, it requires

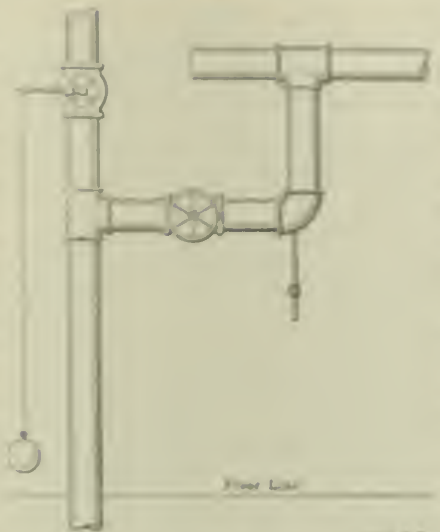

FIG. 8

FIG. 9

FIG. 10

FIG. 11

FIG. 12

$$2.023 \times 8 = 16.184$$

horsepower to dispose of the exhaust steam. Every pound of this steam is used in making paper, so no loss results from this back pressure.

Fig. 12 was taken from an engine used with a cylinder 14 inches in diameter, the horsepower constant of which is 1.4. At this time it was exhausting against 9 pounds back pressure; therefore, it takes

$$1.4 \times 9 = 12.6$$

horsepower to force steam out of the cylinder after its work is done. The mean effective pressure of these diagrams is 6 pounds, so the engine was developing

$$1.4 \times 6 = 8.4$$

horsepower in driving machinery. This demonstrates that the load due to back pressure above the atmosphere is 50 per cent. greater than the power required to operate the machinery. It does not necessarily follow, however, that this engine is run under wasteful conditions, and when these conditions are understood it is apparent that nothing is wasted in this connection.

During all the time that this back pressure is in evidence the exhaust steam goes into a heating system, where it is all condensed and the resulting hot water is returned to the boilers. During part of the time this is sufficient to do the required heating, but when the outside temperature is down to the freezing point, much live steam must be used to heat the buildings, and in zero weather more live steam than exhaust steam is used for that purpose; therefore, the steam required in the cylinder to overcome back pressure goes into the heating system instead of an equal quantity of live steam.

All the steam that is condensed in the cylinder of this engine is lost because the exhaust pipe is drained into the sewer. Steam is expanded to atmospheric pressure in this case, which is a condition that does not represent excessive cylinder condensation. When the point of cutoff in the cylinder of an engine is so short that the terminal pressure falls below the atmosphere and a loop is formed in the diagram, much steam is wasted in the cylinder, but no loop is formed here, except at one point, and that is not large enough to be seriously considered. The counter-pressure line crosses the expansion line in both diagrams, but these lines are wholly above the atmospheric line, being what is generally called [illegible]. If the back pressure were reduced the point of cutoff would be shortened, the terminal pressure would go below the atmosphere, causing more cylinder condensation, and the condensed water would go into the sewer, causing a direct loss of heat.

As a general rule the [illegible]

secure best results; but they close slowly here and no loss results from it. A more sharply defined point of cutoff would give a lower terminal pressure, the effect of which is explained in the preceding paragraph.

Pressure Wasted in Carrying a Useless Load

The single diagram shown in Fig. 13 was taken from an engine with a cylinder 12 inches in diameter, the horsepower constant of which is 1.6265. The back pressure is 5 pounds; therefore,

$$1.6265 \times 5 = 8$$

horsepower is required to overcome resistance to the passage of exhaust steam,

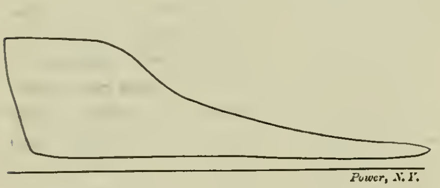

FIG. 13

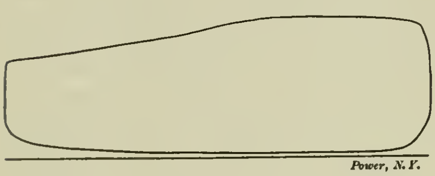

FIG. 14

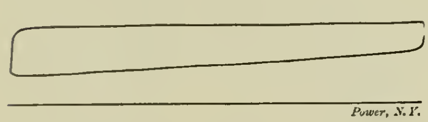

FIG. 15

and this is an unqualified loss because the steam is not utilized. This engine exhausts into a feed-water heater and the steam which is not condensed in heating water passes through a short pipe into the outer air; consequently, the back pressure is undoubtedly caused by contracted exhaust ports and passages in the engine.

The mean effective pressure is 26 pounds, therefore the average pressure above the atmosphere is

$$26 + 5 = 31$$

pounds. This demonstrates that about 17 per cent. of the average pressure as before determined is wasted in carrying a perfectly useless load. If this were eliminated, the point of cutoff would be shorter but the terminal pressure would not be low enough to form a loop in the diagram. Steam users should investigate this point when contemplating the purchase of an engine, as the defect illustrated in this diagram is a constant source of expense for which no benefit is secured. When more machinery is added to this plant, and there is no power to spare, this back pressure will become a greater detriment than at present, and a remedy is not easily secured in such cases, as a rule.

Fig. 14 is a diagram from another engine with a cylinder 12 inches in diameter. The speed is regulated by a throttling governor. A peculiar feature of this engine which is in contrast with the preceding case is the efficient way provided for allowing the exhaust steam to escape, for although the terminal pressure is nearly as high as the initial pressure, the line falls instantly at the completion of the stroke, and the average back pressure is only 4 pounds. The horsepower constant is 1.0988; therefore, it requires

$$1.0988 \times 4 = 4.4$$

horsepower to dispose of the exhaust steam. While this result is as good as could be expected with such a high terminal pressure, the power thus used is a total loss because the steam is discharged into the atmosphere after a portion of it is used to heat the feed water. The puffs of exhaust steam are sharply defined with clear spaces between them, which proves that the appearance of the exhaust steam from an engine is not an indication of its economy in the use of steam.

A peculiar feature of the diagram shown in Fig. 15 is that the load on the piston caused by resistance to the escape of exhaust steam is almost exactly equal to the load due to machinery in the shop, for this diagram was not taken from a direct-acting steam pump, as its appearance indicates, but from a throttling engine in a machine shop. It is not necessary to know the horsepower constant of this engine, nor the back pressure in pounds, in order to determine the comparative loads, for these are shown at a glance by the areas of the spaces which indicate these separate loads.

However, these are given as a matter of interest in this connection as follows: The cylinder of this engine is 10 inches in diameter. The horsepower constant is 0.6925 and the back pressure is 20 pounds; therefore, the load due to back pressure is

$$0.6925 \times 20 = 13.85$$

horsepower. The indicated horsepower is practically equal to this load. If the mean effective pressure is 20 pounds and the back pressure is the same, what causes the piston to move forward? This question will be asked by many readers, and in reply I would say that the mean effective pressure does not represent the force acting on each square inch of the piston area to move it forward. If it did, this engine would stand still; but the average pressure above the atmosphere is 40 pounds, and the back pressure is 20 pounds, consequently there is no mystery about the resulting motion.

Some Recent Developments in Marine Safety Valves*

The phenomenally rapid rate of evaporation attained by water-tube boilers fired with liquid fuel has made the safety-valve accumulation tests of such boilers an exceedingly onerous business. As is well known, the accumulation test consists of gagging every outlet from the boiler, except the safety valves, which must then be capable of carrying off all the steam generated when burning the maximum amount of fuel.

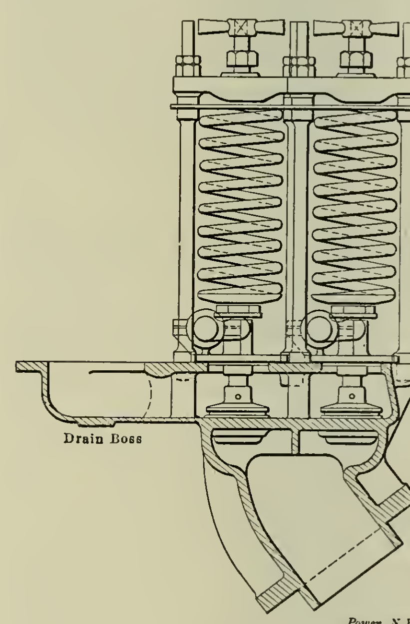

FIG. 1

The test generally lasts about 30 minutes after everything has settled down, and during this time the boiler pressure must not rise above a certain predetermined amount. Otherwise the safety valves are deemed to be inadequate for their duty, and either larger valves must be substituted, or certain other modifications made to the valve lips, the capacity of valve boxes, or the arrangement, size, and number of the waste-steam pipes.

An interesting series of experiments was recently carried out by Cammell Laird & Co., Limited, at its Birkenhead shipbuilding works, and we are enabled to give the results, which in many respects are remarkable, and indicate a striking advance in safety-valve design.

The boiler was a large unit, of the firm's well known "Express" type, capable of evaporating 61,000 pounds of water per hour when fired by liquid fuel.

The safety valve was quadruple, as

*J. Hamilton Gibson in *Engineering*.

shown in Fig. 1, and, as will be seen, was of the usual admiralty type, with exposed springs.

A preliminary test showed that the safety valves were incapable of carrying off the steam without undue accumulation, even when burning fuel corresponding to only half power. Calculations proved that the circumference and area of the valves were ample, but something evidently prevented them lifting to the required amount.

That something turned out to be the pressure in the valve box above the valves, which, though open to the atmosphere through the waste-steam pipe, rose to 60 to 70 pounds, and, acting on the top area of the valves, tended to keep them closed, thus forcing up the boiler pressure. There was the usual characteristic chatter of the valves on their seats, caused by the violent fluctuations of pressure in the box as the valve lips became exposed to the dynamic action of the escaping steam. By slightly easing the valves with the hand gear, and thus increasing their lift, the accumulation was kept within reasonable limits. This suggested the expedient of attaching to the easing gear a small piston, working in a fixed cylinder, and moved automatically by the steam pressure above the valves,

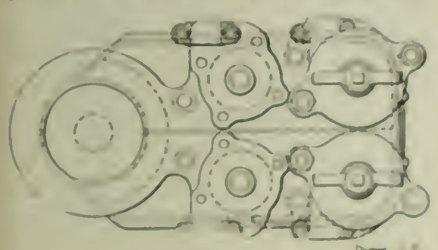

FIG. 2

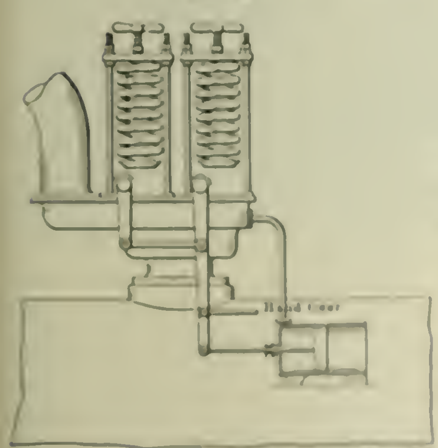

FIG. 3

as shown in Fig. 3. The device was successful, but was not considered a practical fitting, being extraneous to the safety valve itself. It was rightly concluded that any such device should be self-contained, and form part of the safety-valve fitting.

Accordingly, the modification shown in Fig. 4, suggested by Engineer-Commander Liversidge, was adopted, and proved entirely satisfactory. New covers were made containing on their inside a short cylinder, in which worked a closely fitting disk, the under side being exposed to the variable pressure in the valve box, and the upper side open to the atmosphere. The disk was rigidly attached to the valve, being, in fact, cast with it, and balanced the load on top of the valve, so that the valves were quite independent of any fluctuations of pressure above them, and lifted to the full amount permitted by the spring.

The time-honored lips at the rims of the valves and seats were cut away; this resulted not only in steadying the valves, but permitted them to close quietly without any appreciable drop. Incidentally, we may remark that this improvement is of equal importance to the increased lift attained, as the hammering of the valves on their seats is eliminated, and there is

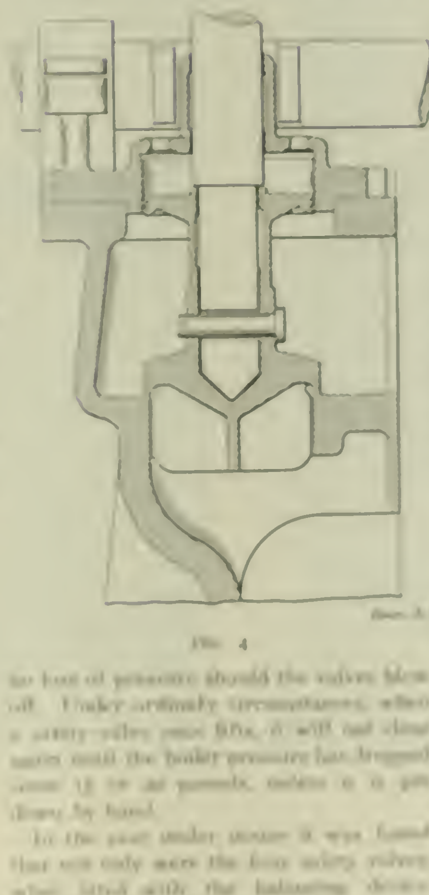

FIG. 4

no loss of pressure should the valves blow off. Under ordinary circumstances, when a safety valve once lifts, it will not close again until the boiler pressure has dropped some 15 to 20 pounds, unless it is put down by hand.

In the past under review it was found that not only were the four safety valves, when fitted with the balancing device, quite large enough to take away all the steam that could be generated without exceeding the limits of accumulation, but when one pair of the valves was gagged the remaining three were amply sufficient for the purpose. Fig. 5 shows the diagram from the results obtained on this boiler with only three valves and a single waste-steam pipe, whereas it was found at one time that four larger valves would be required, with a larger valve box having double waste pipes. Referring again to Fig. 4, it will be seen that if the diameter of the balancing disk is made larger than the valve, an augmented lift is allowed. This was clearly demonstrated during the series of tests, and offers a ready means of increasing the discharge, while still maintaining the valve at a steady, intermittent opening when the boiler is generating steam at, or above, full power.

On the whole, we think we are justified in the assumption that a considerable advance has been made in regard to marine boiler

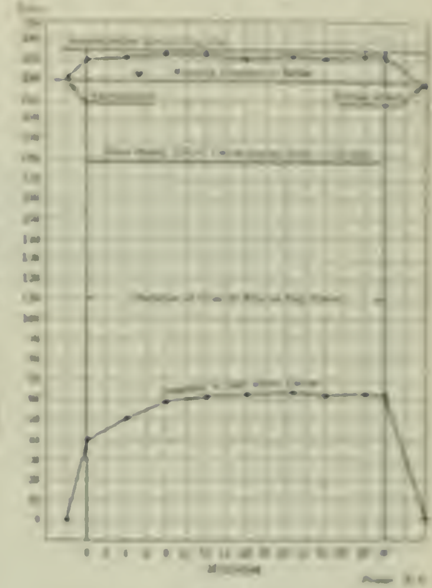

FIG. 5

safety valves, and that anything tending to reduce the size of these important fittings, which have been growing to abnormal proportions of late, is a step in the right direction.

Reading Ammeters and Voltmeters

To read an ammeter or voltmeter correctly the eye must be over the needle if the instrument is in a horizontal position, or directly in front of the needle if in the vertical position. The error in reading due to the wrong position of the eye is caused by the fact that the needle does not touch the scale. This error may be easily prevented by use of a mirror in the scale card. By looking at the needle and mirror so that the needle hides its own reflection, the correct reading will be obtained.

In order to avoid undue injury to instruments and incorrect readings the instruments must be handled carefully; they must be screened away from all magnets and conductors [illegible] when taking measurements an instrument must not be placed on a [illegible]; instruments should not be used on alternating-current circuits, and vice versa. The glass front of a meter should not be rubbed immediately before taking readings, because the pointer may be influenced by static electricity, causing [illegible] of the pointer [illegible] of the instrument.

Engineering in the Eighteenth Century

Interesting Facts about Steam Engineering Practice One Hundred and Fifty Years Ago, with Illustrations of the Quaint Engines Used

BY EDWARD P. BUFFET

The best cure for pessimism is to take a look back one or two centuries into the days of rack and thumbscrew. The best answer to the man who claims that this is not an enlightened age, mechanically, is to tell him something about the century before last. Just why steam engineering so long remained crude and undeveloped may be open to differences of opinion, though the prevailing view seems to be that it was because mankind were awaiting the appearance of POWER.

Records of eighteenth-century engineering are scarce, chiefly for the reason that there was then so little to record, but also because comparatively little of what then was done became embalmed in print. Specialized practical mechanical journals were, of course, unheard of. When an inventor was smitten with an uncontrollable attack of "itch for scribbling" he relieved himself either by writing a letter to the newspapers or else by seeking the patronage of some noble and "easy" lord for the wherewithal to confide his lucubrations to the public in pamphlet form.

For this reason it is a happy discovery when we unearth the files of any old periodical treating even occasionally upon engineering subjects. Probably not many readers of POWER have ever perused *The Universal Magazine of Knowledge and Pleasure,* a sixpenny monthly which was published in London, by J. Hinton, and lasted from 1747 to 1803, or longer. Many of its numbers contain descriptions, with copper-plate illustrations, of machinery used in its day, and these articles, although intended for popular reading, are presented technically enough to be instructive for the engineer. A set of the magazine constitutes, therefore, a most informing history of engineering progress in the eighteenth century. It is from skimming such a file that I propose here to serve up the cream.

The Newcomen Engine

In the very first volume of the magazine we find an elaborate description of "The Engine to raise Water by Fire"—in short, a Newcomen steam engine (Plate 1). Its writer may tell the tale in his own language:

"To the Authors of *The Universal Magazine,* Gentlemen:

"I have observed in the Circle of my Conversation that it appears very mysterious to those who are not learned in Hydraulics, how a Town or a House can be supplied with Water from a River, or Spring, that is in a Situation much below the Place into which it runs; when it is very certain that Water is of that heavy Nature as always to descend, when left to its own Course. Therefore I have sent you inclosed a Draught and Description of an Engine invented for this Purpose. And, though there are many other Sorts, I have rather selected this particular Engine because it is the most admirable, curious and compounded Machine amongst all those Inventions which have been owing to modern Philosophy, and affords the greatest Advantages to Mankind; as could be exemplified from the Water works near Chelsea, on the West of this great City, and again by those lately erected near Stratford in Essex, on the East of London, which are able to supply the adjacent Country, several Miles in circumference, with the necessary Provision of good and wholesome Water, at a moderate Charge, which before was wanting, both for household Service and in the Danger and Loss by Fires. To this I could add the Impossibility of working several Collieries without its Assistance, as the Proprietors of Elsick, Heaton, Biker &c. near Newcastle upon Tyne, can bear me witness. This Engine also is improveable for many other great and valuable Uses, as the Reader will be able to judge, when he has well considered what follows.

"About the year 1663 the Marquis of Worcester, having proposed, in print, the raising of great quantities of water by the *force of fire, or by turning water into steam,* mentioned an engine of that kind, at that very time in being, which could raise a continual stream, like a fountain, 40 feet high, by the means of two cocks, which alternately and successively were turned by a man to empty the hot, and to force and refil the vessel or cylinder with cold water, the fire being continually kept up; I must adjudge this invention to that noble Lord, tho' it must with justice be confessed that it has received many improvements since his time.

"This invention, great as it was, lay dormant, till Capt. Savery, treasurer to the sick and wounded office, having read the Marquis's book, took the hint, and pretended to find out the secret of nature by such a chance as upon experiment is found could not give him any such idea; and to secure the credit thereof to himself, he bought up, and burnt all the Marquis's books he could find. Thus Capt. Savery claimed the credit of this machine to himself, and obtained a patent for the sole erecting thereof, as I have been told."

Our writer informs us that the captain made a good many experiments to bring this machine to perfection and that he erected several with good success on gentlemen's estates, but "he could never bring it to bear for working of coal pits or mines, or to supply towns with water, where the water was to be raised high and in great quantities; because such a work required a steam too dangerously strong to be attempted in his way.

"These discouragements had certainly sunk this necessary machine into oblivion had not Mr. Newcomen, an ironmonger, and John Crowley, a glazier, at Dartmouth, about 35 years ago removed the objections, by improving it to its present state, or rather by inventing a new machine, which is the same you perceive herewith.

"This improvement differs much both in point of method, and in regard to the force of the engine first erected; but yet it is wrought by the same power, which is the expansion of water into steam, raised by fire.

"Now to describe *this engine: B* is a large boiler, whose water is converted into steam. *C C* is the cylinder. *D d* a pipe, about 4 inches diameter, joins them together; on the lower orifice of which, within the boiler, moves a broad plate *E,* by means of the steam-cock or regulator *10,* which keeps in or lets out the steam occasionally.

"The steam of the boiler ought always to be a little stronger than the air, that, when let into the barrel *C C,* it may be a little more than a balance to the pressure of the external air, which keeps down the piston at *d n.* The piston being by this means at liberty, the pump-rod will by its great weight, of at least 9 or 10 hundred of iron, descend at the opposite end to fetch a stroke; but, as the piston and weights at the other end do not exceed half that weight, the end of the lever at the pump will always preponderate, and descend when the piston is at liberty.

"When the piston, by pulling back the handle *10* is got up to the *C,* or a little higher, the plate of the regulator stops all communication of steam with the cylinder. Then the lever, commonly called the *F*, under the said handle, must be lifted up, so as by its teeth to turn the key of the injection-cock at *N*, and that will permit the water brought from the cistern *g*, by the pipe *g M N*, to enter the bottom of the barrel at *n*, which jet of cold water being driven all over the cylinder, condenseth the steam into water again by its coldness, and, as by this means its bulk is become 14,000 times less than it had when steam, it makes a *Vacuum* sufficient for the pressure of the atmosphere to act again unbalanced, and chance to be too full will run down the pipe *V* to the waste well at *Y*.

"*F f* is a pipe about 3 feet long, going a foot within the water in the boiler, to supply the water which is wasted in generating steam; *f* is a cup at the top of this pipe, and is supplied with tepid water from the cup *I* at the top of the cylinder. *G* represents two Gages of different lengths, to prevent the surface of the water from being too low or too high: which is known thus. If the stop-cock of the shorter pipe, being opened, gives only steam, and that of the longer, only than the air, may burst the boiler. The method of trying this strength is to lay a piece of lead fastened to the wire upon the valve; and if the steam shall raise up more than 15 pounds weight of lead to an inch square (which is the weight of air, nearly, on every inch square) it is known to be stronger than the air. For tho' the steam is of a variable strength, it is never 1/10 stronger or weaker than common air; it having been found by experience, that an engine will work well with one pound weight on every square inch of the valve *k*. [illegible] that the

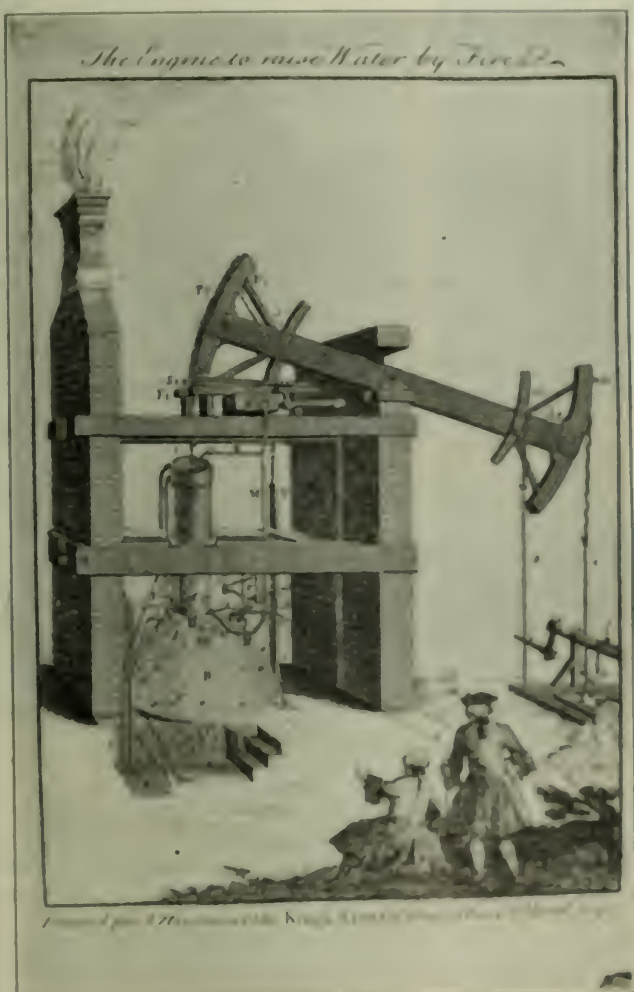

PLATE 1. THE NEWCOMEN ENGINE

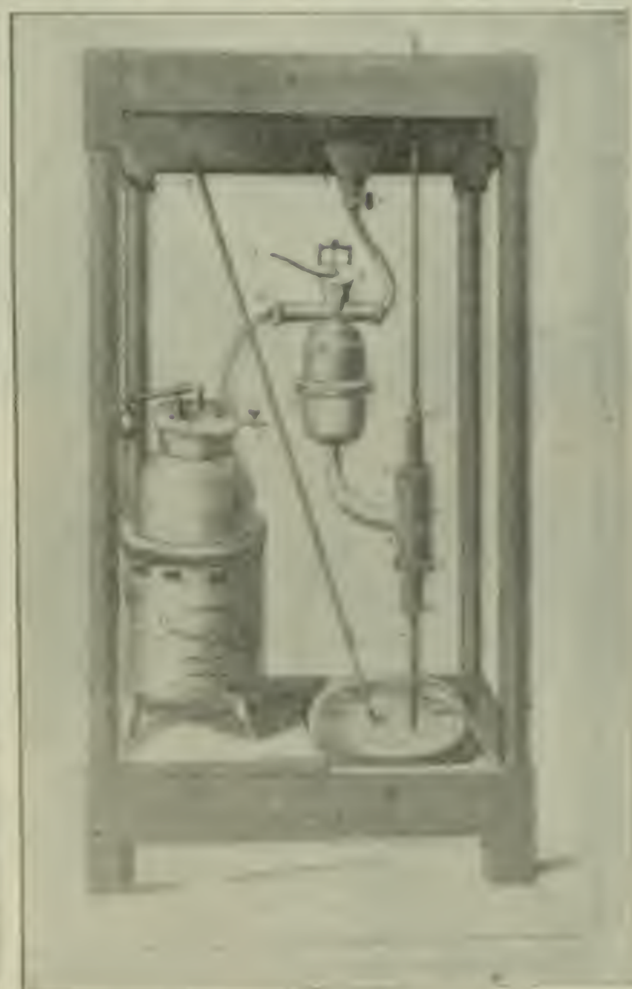

PLATE 2. THE SAVERY ENGINE

to raise the other end of the beam with its pump to discharge the water at *A*. And this whole operation of opening and shutting the steam-regulator and injection-cock, being performed in little more than 3 seconds, it will easily produce 16 strokes in 1 minute.

"The cistern *g* is supplied with water from a well or pit near the mouth [illegible], by means of pistons and the pump-rod *k*, fastened to the arch [illegible], and, that the leathers of the piston *C* may be always air-tight and supple, it is supplied with a small stream of water by the arm [illegible] from the pipe *M*. The *I* at the top of the cylinder is a cup or hollow to hold the water that lies on the piston, which if it water, all is right; but if both cocks give steam, then the surface is too low; or, if both give water, it is too high. Hence the cock which feeds the boiler at *F* may be opened to such a degree, as always to keep the surface of water to its proper height.

"*X Y Z* is the Eduction-pipe to carry off the cold water ejected into the cylinder to condense the steam. It is turned up at the bottom in the well *Y*, with a valve to prevent the air pressing up into the pipe, which might hinder the discharge of the water.

"*x* is the puppet-clack or a valve to try the strength of the steam; which, if it be too strong, or inconsiderably stronger [illegible] stronger than common air.

"The small pipe *q*, on which is a small cap, is called the snifting-clack, and serves to let out the air mixed with the water, [illegible] than the outward air.

"In the infancy of this mechanical invention, the regulator and injection-cock, as I should before, were managed by a man, [illegible]

"Thus you see a chain fixed to the arch *Z*, at a proper distance from the arch *P*, to which chain is hung a working-beam *Q*. This beam goes quite down into a hole in the ground, which it exactly fits. This piece has a long slit in it, and several pin-holes and pins, for the movement of several small levers, by which the said cocks are opened and shut, as the service requires. It is called the *Working-plug*; which being once set a going according to art, this engine is most harmless and manageable of all others.

"This machine thus prepared, and set a going, may work about five hours upon a stretch. It will of itself give notice when to stop working; for, if you perceive the *Gages*, as mentioned before give steam, you must replenish the boiler, or it will be in danger of bursting, for want of a due supply of water.

"I will therefore conclude this theory of the *Engine to raise water by Fire*, with practice; for with large boilers, the piston will make 20 or 25 strokes *per* minute; and a pump of nine inches bore will discharge more than 320 hogsheads per hour: So every other size in proportion."

AN EXAMPLE FOR THE USE OF THE TABLE.

Suppose you require 150 hogsheads per hour, at 90 yards deep; in the 7th column I find the nearest number 149; and against it, in the first column, I find a 7-inch bore for the pump; then under the depth 90, on the right hand, in the same line, I find 27 inches for the diameter of the cylinder, fit to raise 150 hogsheads per hour. And thus any other number in this table may be found.

Mr. *Henry Beighton's* most curious and useful table to calculate the power of fire-engines, according to the various diameters of the cylinder, and bore of the pump, that are capable of raising water from 48 to 440 hogsheads *per* hour, at any depth from 15 to 100 yards.

"He founds his calculation upon this principle, That the ale gallon of 282 cube inches of water weighs 10 pounds 3 ounces *avoirdupois*, and a superficial square inch is pressed with the weight of 14 pounds 13 ounces of air, when of a mean gravity. But, allowing for several frictions, and to give a considerable velocity to the engine, it is found by experience, that no more than 8 pounds of pressure must be allowed to an inch square on the piston in the cylinder, that it may make about 16 strokes, about six feet reach, in a minute.

"But it must be also observed that these calculations are only for common

The Savery Engine

Twenty-seven years after its account of the Newcomen engine, the *Universal Magazine*, February, 1774, contained a description of the older type of engine exploited by Capt. Savery. This later article cites the former one as if only a short interval had intervened since its publication, and the incident thus furnishes striking evidence of the lack of progress in steam engineering at that period—aside, of course, from Watt's researches, which are another story. Referring to Plate 2, I quote:

"The method of constructing a fire-engine according to the original institution of the Marquis of Worcester and Captain Savery, wherein the water was to be raised solely by the pressure of elastic vapor or steam, is very useful and very cheap in respect to the other sort, and, when the height to which the water is to be raised does not exceed one hundred or one hundred and fifty feet, then this engine is applicable with great advantage, it requiring but a small fire, not bigger than what is generally used in a parlour-chimney; is of a very simple and easy structure, and admirably adapted for supplying a Gentleman's house with water, and for playing of fountains to a very great height.

"*A* is a boiler; it has a copper cover screwed on, which contains the steam pipe *G G*, and two gage-pipes *C*; on the cover at *C* is a valve, over which lies a steelyard with its weight to keep it down, the strength of the vapour being this way most exactly estimated.

"The steam is carried from the boiler to a copper vessel *H* by means of the pipe *G G*, and is let into the same by turning the handle *L*.

"The receiver *H* communicates at bottom to the sucking pipe *I B* going down to the water in the well *R*, and above with the forcing pipe *O O*: Between these two pipes are two valves, *N P*, both opening upwards. The steam, being let in upon the water of the receiver *H*, forces it up through the valve *O* and the pipe *O O* to the reservoir *S*. The steam in the receiver is condensed by a jet of cold water coming from the forcing pipe by the small tube *X Y Z*; the handle turned from *Y* admits a passage to the steam into the copper receiver *H*: This steam in the receiver is condensed by a jet of cold water being let in and shut off by a cock at *Y*. The steam, being condensed by this jet, will be reduced within a very small space, and so make a vacuum, upon which the water in the well will rush up the forcing pipe to restore the equilibrium, and thus again fill the receiver *H*, the little air being compressed within a small compass at the top of the receiver *H*.

"*F F* are registers for regulating the fire in the furnace: *B* is a cock inserted into the boiler: *D* is the hearth, and *E* the ash-hole.

"*T V* is a pipe for carrying back the water in the reservoir *S*, when this instrument is used only for making experiments: *Q S*, is the frame of the instrument."

Improved Method of Applying the Power of a Newcomen Engine in Mining

In February, 1782, we find shown "A new Machine, or Fire Engine, invented by Mr. Hunt, of London, for draining Mines and Coal Works, and at the same Time raising the Ore or Coal from the Bottom of the Mine to Surface, without the assistance of any additional Fuel."

This improved mechanism dispensed with the use of a number of horses required under the older, and less economical system. To Plate 3 are given the following references:

"(*A*.) The common steam, or fire-engine, for draining mines and coal works.

"(B.) The force-pump, which receives the water that is raised from the mine by the main pump (C) and forces it up into the large back or cistern (D).

"(E.) The water wheel. The wheel is of a peculiar construction, having two tiers or rows of buckets, the one formed with their mouths upwards, the other

PLATE 4. COOKE'S ROTARY STEAM ENGINE

with their mouths downwards, by which means the wheel is made to move alternately by the right and left. On the same axis that carries this water-wheel, another wheel is fixed, (but of smaller dimensions) by which the rope is coiled or wound round, at the end of which are suspended the buckets that bring up the ore or coal. These buckets, by the alternate motion of the water wheel, constantly ascend and descend.

"(F.) A strong wooden lever, which being pressed hard against the sides of the water wheel, by means of a man pulling a rope, immediately stops its motion and gives time to the man who attends to unhook the loaded buckets.

"(G, G.) The two levers belonging to the sluice-gates, which being alternately pulled up, let out the water on the wheel or water-wheel.

"(I.) A strong wooden [illegible], [illegible] two feet below the surface of the earth, to receive the water that is [illegible] up from the mine or pit by the [illegible] pump. Into this cistern the lower end of the force pump is fixed."

John Cooke's Rotary Steam Engine

This single machine is found in the Universal Magazine, 179[illegible]. I illustrated it in Power, April, 1904, but it will bear repetition. Referring to Plate 4, the casing of the engine is a closed cylinder provided with hinged blades which open to a radial position or fold flat on the circumference as the wheel turns. Steam enters the casing at the lower left-hand corner

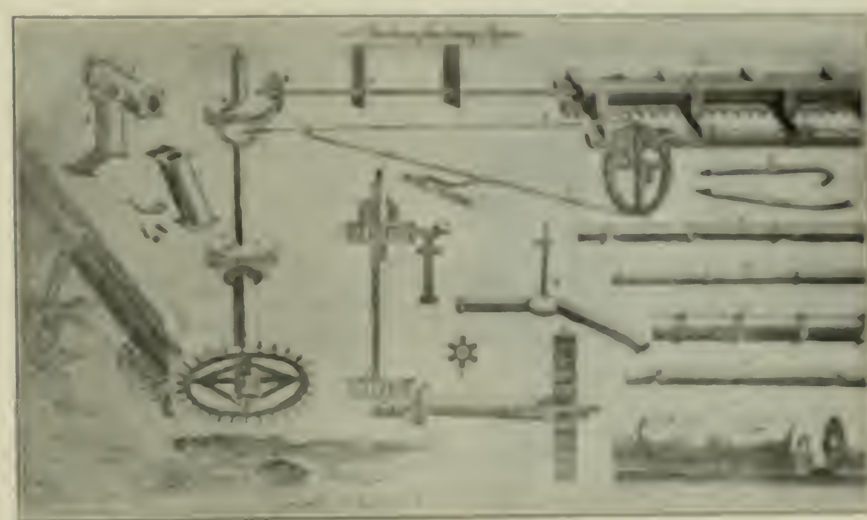

PLATE 5. [illegible] AND ITS MANUFACTURE

and is exhausted at the lower right-hand corner. The rod *h* is a connecting rod from a crank upon the axis, to work the condenser, i.e., (presumably) to drive a circulating pump.

The Art of Piping

A machine for boring pipes was described (February, 1754) and is shown in the accompanying Plate 5. The water wheel in the southwest corner of the picture drives a set of cog gearing with results which are pretty apparent upon inspection. The pipe is made of a wooden log laid on a carriage which is advanced to meet the auger by a ratchet and-pawl feed. The pawls *D*, *E*, which pull and push respectively, are shown in an enlarged detail view. The auger is 9 to 12 feet in length and "of a proportionable bigness."

The same plate contains figures showing several examples of piping used at the time it was published. *T* is [illegible] piping; *M* lead piping; *N* [illegible] iron pipes; *O* wooden piping; *P* wooden piping of a larger size. In the northeast corner will be seen some sections of iron pipes with bolts and screws indicating the manner in which they are to be coupled.

Holland's Quadruple Pump

An ingenious hydraulic machine was illustrated in August, 1755, designated as "Mr. Holland's Engine, at [illegible], for raising Water." We present it in Plate 6.

[illegible] the [illegible] of the [illegible] [illegible] in [illegible] [illegible] feet long and 24 inches diameter.

"C, C, C, C, an undershot wheel, 30 feet diameter, the ladles of [illegible] [illegible] feet [illegible] [illegible] feet [illegible].

"D, E, F, G, four moveable rings or cil[illegible] placed on the shaft, [illegible] [illegible] feet [illegible] inches [illegible].

"H, I, K, L, four [illegible], rising and falling alternately by means of these cil-

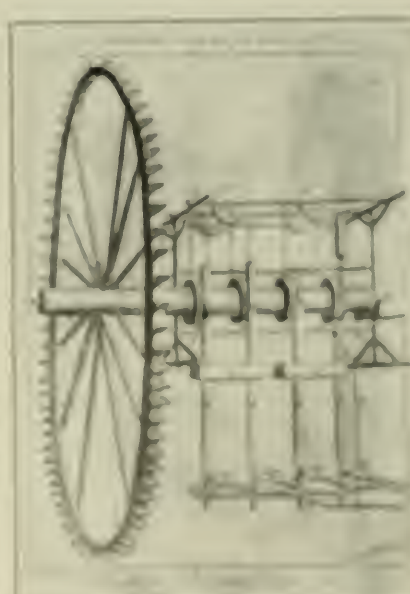

PLATE 6. HOLLAND'S QUADRUPLE PUMP

[illegible] [illegible] [illegible] [illegible] [illegible] by the [illegible] and the [illegible] of the [illegible] [illegible] [illegible] [illegible] at *D*, *E*, *F*, *G*. The [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]. As the [illegible] [illegible] [illegible], the wheel will [illegible] [illegible] [illegible] [illegible] [illegible] the [illegible] *F*, [illegible] of [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] *K* at *a* [illegible] [illegible] [illegible] end of the [illegible] in the [illegible] *L* [illegible] [illegible] [illegible] the [illegible] *K*, [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] the [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of the [illegible] *L*, and [illegible] the [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] half; by which time the collar G will have carried its trigger 2 up to the bar $i\,i$, which will unlock its trigger; and the trigger 3, in the collar F, will be brought backward down to Y, and there lock the collar F. Then, the motion continuing, K will be depressed four feet and a half, and the chain $I\,I$, over the pulley R, will raise L four feet and a half. And thus the two forcers and collars continuing ris-

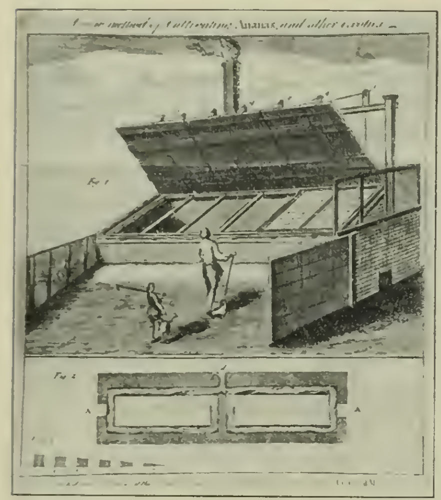

PLATE 7. HEATING A GREENHOUSE

ing and falling, moving forwards and backwards, locking and unlocking alternately.

"And in like manner, the other two collars, D & E, move with their forcers, H and I.

"But to prevent one collar's moving the backward way, faster than the other moves forwards, there is a gauge-chain 4, fixed to the collar G, passing over another pulley T, to the collar F at 5, which regulates their motions. These chains are lengthened or shortened by screws, as occasion requires.

"M, N, O, P, are four brass cylinders, or pumps, seven feet long; the bores of M and N are six inches diameter, and those of O and P seven inches and one-quarter; having, at l, l, l, l, each a valve below, which are for taking in the water; and at m, m, m, m, valves in the horizontal parts.

"The branches mn, mn, mn, mn, communicate the water of their two forcers by mn, mn, and so with two pipes, o, n. These two pipes o, n, join together, at a small distance beyond what is represented on the plate, so that the whole water is forced along one pipe; which makes a jet *d'eau* of seventy feet, and raises the water to the house about seventy feet perpendicular.

"Ninety-five hogsheads are forced up, per hour, to the jet *d'eau*, and forty-seven to the garden.

"g, h, are two cisterns, supplied by a pipe p, to keep the forcers or pistons always wet.

"$a\ b\ c\ d\ e\ f$ is a frame of wood to carry the pullies Q, R, S, T, and the bars i, i, and K, K.

"The water-wheel goes about five times per minute to force the water to the house; and three, when the water is raised eighty feet to the gardens."

I would respectfully call Mr. Holland's attention to a book of machines published by Agostino Ramelli in 1588, which shows a pump of startling similarity in appearance.

"Machine To Travel without Horses"

The foot-power cycle, even with some of its more complicated modern features, was known long ago. Several such vehicles are described in the *Universal Magazine*. One of them, illustrated in 1774, was the invention of Mr. Ovenden. It comprised a four-wheeled carriage in which one or two gentlemen could ride at pleasure while a footman, seated behind, trod upon levers actuating the rear axle by ratchet clutches after the manner of the old "Star" and "Springfield Roadster" bicycles of our boyhood days. "The above machine," says the writer, "is doubtless the best that has hitherto been invented, since it is capable of travelling with ease, six miles an hour; and, by a particular exertion of the footman, might travel nine or ten miles an hour on a good road, and even would go up a considerable hill where there is a sound bottom. But this carriage is in general only calculated for the exercise of Gentlemen in parks or gardens, for which it answers extremely well."

One might have supposed that it was the footman who got the exercise.

Furnace Construction, Ventilators, etc.

Long before the days of steam heating the art of warming greenhouses was known. From the magazine for March and May, 1751, are taken two illustrations showing hothouses with furnaces built into their walls, and the arrangement of the flues. See Plates 7 and 8.

Nor were there lacking power-driven blowers for ventilating purposes. Such a system was installed for changing the air of Newgate prison, which had become a stench in the noses of citizens dwelling in its vicinage and, worse yet, found its way into the courthouse, jeopardizing the health of honorable judges and counselors learned in the law. To these circumstances may be attributed the philanthropy which prompted the installation, for it would have been more consistent with the penal discipline of that period to pump foul air into the jail than to remove it.

The ventilating blowers, as described in the magazine for June, 1752, and April, 1764, comprised rectangular boxes with hinged diaphragms inside and crude valves. On the prison building, adorned with statues of Justice, Mercy, Truth and *Liberty*, was mounted a windmill to drive the blowers *when the wind blew*. The system did not prove a wild and delirious success.

I fear that the editor will not allow me space to describe any more of the antique mechanical contrivances that are found in the volumes of the old magazine. Among the subjects described and illustrated are a windmill in a smokestack; a testing outfit for "examining the goodness and strength of ropes;" a rolling and slitting mill; a paper mill; the working of iron mines; clock and watch manufacture and electrical experiments; also many improved agricultural machines.

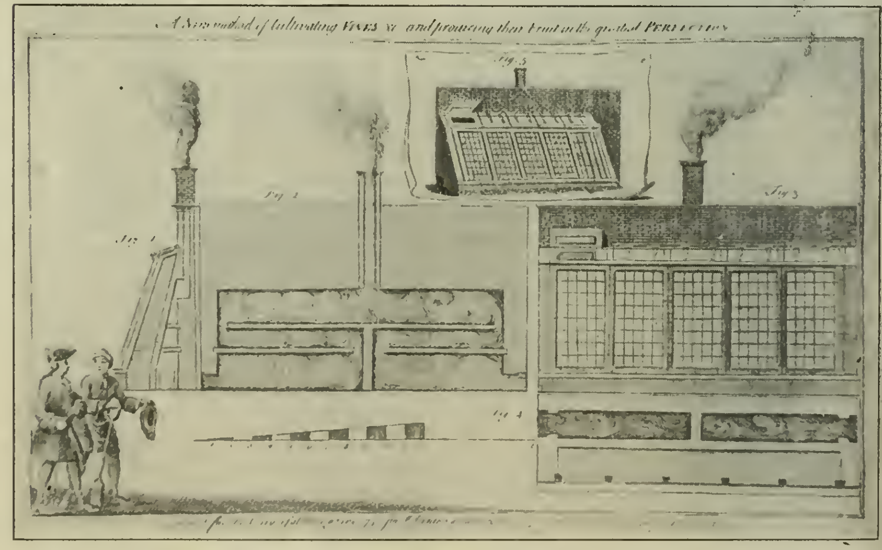

PLATE 8. ANOTHER GREENHOUSE HEATING SYSTEM

To the eighteenth century must be allowed credit for making the steam engine an accomplished fact, and that is no small praise. Yet otherwise we are impressed with the stagnancy of mechanical arts in that period. From the eighteenth to the nineteenth centuries engineering progress was vastly greater than for several hundred years previous.

Purge Device for Ammonia Condensers

By F. E. Matthews

Given two batteries of ammonia condensers, one of eight and the other of two stands, with ½-inch purge valves on the discharge lines leading to each separate stand of condensers: If the ½-inch valves be connected to a header leading to a vertical cylindrical tank 10 inches in diameter by 6 feet high, over which cooling water is run, would it be possible to blow off the air without shutting down the plant? Will the tank fill up with gaseous ammonia? Will the cooling water be necessary? Can the valve at the bottom of the tank be left open all the time?

In answer to these questions it may be said that the object of purge valves on an ammonia condenser is to enable the engineer to blow off the *permanent* gases that accumulate in the system. These gases may be of two different origins. They may be due to the decomposition of ammonia, in which case they constitute a mechanical mixture of hydrogen and nitrogen, or they may be little more than air which has got into the system accidentally when some part has been opened up for repairs, or through leaks around the ammonia rods when a vacuum has been pumped on the system.

Now, it is a common fallacy that air is lighter than ammonia and that it will accordingly flow to the highest point in the system, or more accurately speaking, that it will be freed to the top because of the tendency of the heavier gases to gravitate to the lower parts of the system. This fallacy is particularly in evidence in view of the fact that almost everyone implies a knowledge to the contrary by looking for more pure air near the floor when necessity requires that they work in an atmosphere heavily saturated with ammonia.

Compared to air the specific gravity of ammonia is 0.589, which means that, other things being equal, the ammonia of an air and ammonia mixture will flow to the top and the air to the bottom of the containing vessel. Air does, nevertheless, collect in the condenser whether it be the highest point in the system or not. The reason for this is that it is carried along with the ammonia gas, and the gas, being liquefied in the condenser under the proper conditions of temperature and pressure, leaves the air behind. It might tend to gravitate out of the condenser at the bottom, but it would be prevented from doing this by the presence of the liquid ammonia, which, although it is comparatively light for a liquid (having a specific gravity of 0.6 as compared with 1 for water), is still many times heavier than air. Furthermore, ammonia condensers are usually built so that the outlets are liquid-sealed, making the escape of a gas in that direction impossible.

As a matter of fact, the permanent gases most commonly encountered in ammonia-refrigerating systems are the hydrogen and nitrogen resulting from the decomposition of the ammonia. The hydrogen constituent will rise to the top of the condenser because of its lightness compared to nitrogen or even to the ammonia. As compared to air taken as unity, the specific gravity of hydrogen is 0.0692, that of nitrogen is 0.971 and that of ammonia 0.6.

From the preceding it will appear that there should be no difficulty in purging off the hydrogen content of the condenser, but that nitrogen and air would be somewhat more difficult to dispose of. It would also appear that such would also be the case if the purge line of the condensers was equipped with the device previously described. Even the hydrogen which enters the condenser with the ammonia in comparatively small quantities would find difficulty in separating itself from the ammonia sufficiently to enter the purge line as it is passing it on its way to the condenser, and it certainly would never find its way back against the tide of incoming gas while the system is in operation. The other gases would undoubtedly tend to enter the condenser and to settle gradually to the bottom pipes.

What would seem to be the rational method of getting rid of all the fixed gases, including not only the hydrogen, but also the air and nitrogen, would be to shut off one of the twelve stands of ammonia at a time. This would amount to only about 8 per cent. of the total condensing surface and would probably not result in a prohibitively high head pressure if the machine were allowed to operate at full speed. If the head pressure did become abnormal a reduction of speed of not to exceed 8 per cent. would remedy the trouble. The water should be left running over the closed condenser stand until it is thought that the ammonia gas is well liquefied. The purge valve may then be opened and the gases be allowed to escape, preferably through a small rubber hose, into a pail of water. The opening of the purge valve will produce a reduction in pressure within the condenser, and this reduction in pressure will allow some of the liquid ammonia lying in the bottom of the condenser to vaporize, expand and push the permanent gases to the upper coils of the condenser and out of the purge valve. On account of the small cross-section of the condenser pipe the tendency for commingling of the gases is but slight, and not only the lighter but the graver gases above the ammonia will be expelled. All of the permanent gases can be readily recognized, as they will escape in the form of bubbles from the water in the pail. The presence of ammonia in [illegible] [illegible] in the water with a sharp crackling noise and no bubbles will appear.

In more specific reply to the questions, it may be said that some of the hydrogen gas resulting from decomposition of the ammonia could undoubtedly be blown off from the tank while the plant is in operation, but it is doubtful if nitrogen, or perhaps even all of the hydrogen would find its way back from the condenser against the stream of incoming hot gas and the [illegible] other gases of greater specific gravity (except in the case of the hydrogen) and eventually collect in the purge chamber.

If such a device were employed there would be no objection to leaving the valve at the bottom between the tank and the purge header open all the time. In fact, the segregation of the permanent gases would be so slow that the tank would not be at all effective unless left open to the system for some time.

Washing and Coking of Rocky Mountain Coals

Investigations conducted at the fuel-testing plant of the United States Geological Survey at Denver, Colo., during the fiscal year 1908, into the washing and coking of the coals of the Rocky mountain region have just been reported upon by the survey. In the time that the plant has been in operation results have been achieved which will prove of the greatest importance to the entire western part of the country. Of 27 coals tested from the Rocky mountain region, all but three produced good coke under proper treatment, although a number of these had been considered noncoking.

A bulletin detailing the tests conducted at the Denver plant by A. W. Belden, E. [illegible] and J. W. [illegible] has just been issued by the technologic branch of the Geological Survey. In this bulletin the following general statement is made by Mr. Belden:

"The investigations described in this report were undertaken by the Government for the general purpose of increasing efficiency in the utilization of the fuel supply of the United States by devising improvements in washing and coking coals, these being two of the methods of conserving one of the country's most important mineral resources.

"Specifically, the washing tests of coal were made to determine the possibility of so improving the quality of the coal as to render it available for the production of coke, for the coal used in coking must be as free as possible from ash, sulphur and other impurities, because of the [illegible]

The coking tests were made to determine the possibility of utilizing the various coals in this way, or to devise improvements in coking practice. The washing tests have already demonstrated the fact that many coals which are too high in ash and sulphur for economical use under the steam boiler or for coking may be rendered of commercial value by proper treatment in the washery. The coking tests have demonstrated that many coals which were not supposed to be of economical value for coking purposes may be rendered so by proper treatment in the washery and coke oven. Of more than 100 coals from the Mississippi valley and the Eastern States, some of them regarded as noncoking, which had been tested at St. Louis in 1906, all except six had been found, when carefully manipulated, to make fairly good coke for foundry and other metallurgical purposes, and similar results with Western coals have been now obtained at Denver.

"The tests detailed in this bulletin are a continuation of the work started several years ago in St. Louis at the Government fuel-testing plant there. On the completion of the work at St. Louis the writer made a trip through the Rocky mountain region for the purpose of selecting a site for washing and coking tests on coals of the western half of the United States, with the hope of getting into closer touch with the fields from which little or no coal had been received at the testing plant in St. Louis.

"The different points available were visited, and after investigation Denver was selected as the most suitable on account of its central location and railroad facilities."

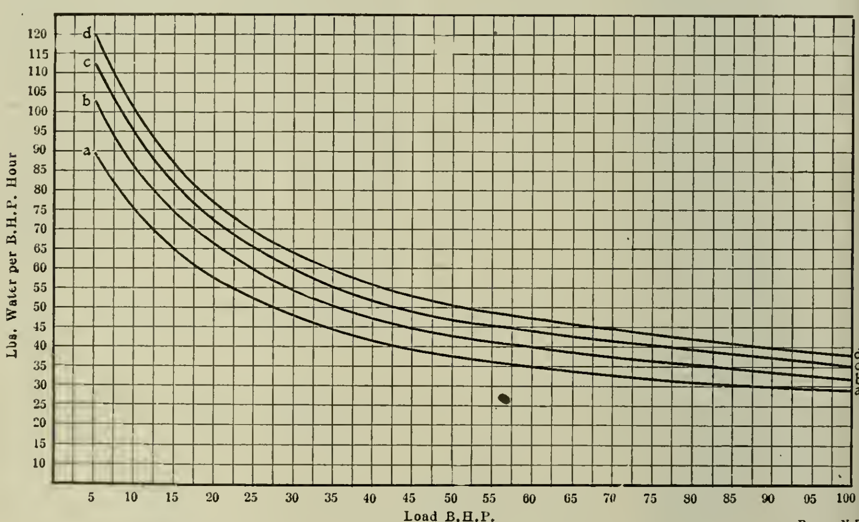
The Truth About the Small Reciprocating Engine

By William E. Snow

Ever since the days of Newcomen and Watt the minds of the ablest engineers have turned to the problem of the efficient transformation of heat energy into work. The efforts of such men as Corliss, Porter and Reynolds have made the reciprocating engine of today a perfect product. Question any present-day engine builder and he can tell you to a nicety just how many pounds of steam per horsepower his engine requires, and the advantages of superheat, vacuum, etc., and he can produce copies of tests galore to prove the correctness of his figures.

All this information is very interesting and is, in the case of medium- and large-sized engines, a fair indication of their performance under actual working conditions. In the case of the small engine, however, these figures are of little value to the prospective purchaser. In fact, in many cases they are extremely misleading, based as they are upon engines cutting off at 1/4 or 1/3 stroke, a condition under which small engines are seldom installed to operate. Keenness of competition has forced the manufacturer to install his small engines to operate on 1/2, 5/8 and in some cases even 3/4 cutoff. By this means a smaller engine can be used to deliver a given horsepower than when operating on the more economical cutoff of 1/4 or 1/3 stroke, and the engine can be sold at a correspondingly lower price.

The purchaser may be perfectly aware that his engine will use more steam on the longer cutoff, but does not know how much more, and therefore frequently tries to delude himself with the idea that the saving in initial cost effected with the smaller engine fully offsets the increase in steam consumption due to the later cutoff. Frequently not even the salesman knows the exact per cent. of increase in the steam consumption due to the later cutoff, his knowledge being obtained mainly from the standard-performance tables of the manufacturer, which are invariably based upon engines cutting off at 1/4 or 1/3 stroke and give no figures for the later cutoffs.



SHOWING RELATIVE INCREASE IN STEAM CONSUMPTION DUE TO LATER CUTOFFS

The relative increase in steam consumption due to these later cutoffs will be seen in the accompanying chart. The line *a* shows the steam consumption of simple, noncondensing engines ranging in size from 5 to 100 horsepower, when operating on a steam pressure of 125 pounds gage at 1/3 cutoff. The lines *b*, *c* and *d* show respectively the steam consumptions at 1/2, 5/8 and 3/4 cutoff.

What It Means to the Purchaser

To see what this means to the purchaser in actual dollars and cents, take the case of a 50-horsepower engine. The steam consumption of an engine of this capacity operating on 1/3 cutoff, as indicated by the line *a*, is 37 pounds per brake horsepower per hour. An engine of this capacity operating on 5/8 cutoff has a steam consumption, as indicated by the line *c*, of 47 pounds per brake horsepower per hour. In other words, it requires 21 per cent. more steam to produce 50 horsepower with a small engine operating on 5/8 cutoff than is required for a larger engine on 1/3 cutoff.

Assuming the engine to be operated 300 days a year, 10 hours per day, and requiring at 1/3 cutoff 4 pounds of coal per horsepower-hour, the total yearly coal would be $300 \times 10 \times 4 \times 50 = 600{,}000$ pounds. If the price of coal was $4 per ton the total yearly cost of coal would be $1071. The smaller engine, operating on 5/8 cutoff, would use 726,000 pounds of coal for the same service at a total yearly cost of $1296. From this it will be seen that the saving effected each year by the use of the larger engine at the more economical cutoff would be $225.

The average price of a simple, noncondensing 8x10 throttling engine, which is the size required to deliver 50 horsepower at 1/3 cutoff on a steam pressure of 125 pounds, is $510. This same power can be obtained from an 8x8 engine operating on 5/8 cutoff and this latter engine sells for $375.

It will be seen from the above that while the purchaser can save $135 on the initial cost by installing the smaller engine, he will in reality lose $90 the first year on account of the increased yearly cost of coal. Each succeeding year thereafter he will lose $225. In three years the amount he would lose would pay for the larger engine complete.

Until the engine builder sees fit to publish reliable tables showing the steam consumption of his smaller engines under the usual conditions of operation, namely, 1/2, 5/8 and 3/4 cutoff, the prospective purchaser will do well carefully to investigate this subject on his own account before deciding upon the particular size of engine best suited to his requirements. A dollar saved in initial cost at the expense of three in running expenses is a negative kind of economy at best.

Practical Letters from Practical Men

Don't Bother About the Style, but Write Just What You Think, Know or Want to Know About Your Work, and Help Each Other

WE PAY FOR USEFUL IDEAS

A Water Motor

The illustration shows something new in a water motor. It is designed to be placed perpendicularly in any running stream. The upright shaft in the center is stationary, with one sprocket wheel keyed onto it and connected to two blades by an endless chain running on a sprocket wheel placed on the top of each blade. When the small sprocket wheel between the blades acts as a tightener, blade *A* is across the stream and gets the full force of the water. Blade *B* is partly turned and might create some back pressure. Blade *C* is turned to cut through the water on the return revolution, and blade *D* is just coming across the stream.

MODEL OF A WATER MOTOR

The lever on top of the upright shaft in the center is to regulate the speed, as by turning the lever the blades can be placed at any angle to get the force of the water, and if turned far enough the motor will stop. It can readily be seen that a governor can be put on to regulate the speed.

The illustration shows a working model. It will develop a limited amount of power, and I thought it might interest fellow readers.

Bridgewalls

W. H. Wakeman, on page 452 of the March 9 number, has an article on the above subject, written from a very practical standpoint, and although in the main it is perfectly correct, the writer desires to take exception to one or two points. Having had considerable practical experience regarding the effects produced by varying the hight, position or shape of the bridgewall, especially with respect to troubles from leaky seams, the writer believes that some of Mr. Wakeman's statements are likely to mislead the inexperienced engineer.

First, Mr. Wakeman (as a great many other engineers do) uses the total area of the tubes as a guide to determine the proper area of other passages for the products of combustion to pass from the grate to chimney. That this is not a logical way to arrive at these areas will be made evident by a little reasoning.

The capacity of a horizontal tubular boiler is practically determined by its heating surface; that is, so far as the capacity of the boiler alone is concerned, and this capacity is directly proportional to the length of the boiler. For instance, if there are two boilers of the same diameter, containing the same number of tubes of the same size, but in one the tubes are 16 feet long while in the other they are 20 feet long, the larger boiler will have practically 25 per cent. greater capacity than the shorter one, while the areas for the passage of gases through the tubes are identically the same. To make the additional boiler capacity available there must be 25 per cent. additional furnace capacity under the larger boiler, which means that there will be about 25 per cent. additional volume of furnace gases to be handled, requiring 25 per cent. additional area for the same velocity. As the increased volume of gases must pass through the same area of tubes in a given time the velocity will be necessarily higher and the drop in draft through the tubes greater, which would require that the chimney draft be of greater intensity in the case of the longer tubes to produce similar results at the furnace. It can be seen that in the case cited (and the variations in capacity given are not at all unusual), if the gas passages were designed on the basis of tube areas, the larger boiler would be at a considerable disadvantage in obtaining maximum capacity.

It is not unusual in the vertical type of fire-tube boiler to have the same tube areas where the capacities vary as much as 100 per cent. The furnace capacity or amount of coal to be burned in some fixed interval of time is the correct basis upon which to figure the area of gas passages required, and if this is used, taking into account any unavoidable contraction of the area through the tubes, and length and shape of flue connection in determining the required chimney capacity, uniform results will be obtained in each case for the same furnace conditions.

Another point which the writer would like to draw attention to is the apparent intent of Mr. Wakeman's article to belittle the effect of shape, position or hight of the bridgewall on the steaming qualities of the boiler. Mr. Wakeman cites an instance where he reduced the distance between the bridgewall and shell of the boiler to 4 inches, and when leakage at the girth seams developed he remedied the trouble by changing the feed from the blowoff to the top of the boiler. Now anyone with wide experience in boiler operation knows that the bottom feed is a fruitful source of girth-seam leaks, but he also knows that there are thousands of boilers fed in this manner which never give trouble from leaking. It is probable that had Mr. Wakeman changed the hight, position or shape of his bridgewall, the trouble would have disappeared as effectually as it did by changing the feed.

It is very likely that the combination of bridgewall and bottom feed was the cause of the leak and both should have been changed to have the boiler operate under the best conditions. The kind of bridgewall illustrated in Mr. Wakeman's Fig. 6, if located with respect to the girth seam as shown, is very likely to cause trouble. Of course, a well built boiler that is kept perfectly clean internally can be run with such a bridgewall without showing evidences of distress, but that is no excuse for subjecting it to such treatment. The best methods of boiler setting cannot be determined very readily by single instances but by a wide experience with many different forms, with careful analysis from cause to effect in noting the results obtained in each case.

Power Increase Due to Compounding

When considering the discussion on the above subject, opened up some time ago by Mr. Wakeman, the accompanying indicator diagrams are worth inspecting. Those shown in Figs. 1 and 2 were taken from an 18 and 34 by 36-inch cross-compound Corliss engine, coupled in tandem to a four-stage air compressor before the valve gear was overhauled for repairs.

The constant for the high-pressure cylinder is 3.7 and for the low-pressure cylinder 13.2, which, under the conditions shown, give 270 and 145 horsepower, respectively, or a total of 415 for both sides. This with a cutoff of from 5/8 to 3/4 stroke.

Fig. 3 shows the original high-pressure card with additional dotted lines plotted for the maximum point of cutoff, and the counterpressure line, if this side were run as a simple engine against a 5-pound back pressure. In plotting these lines, the compression curves are omitted for the sake of clearness, but I think the contained area at either of the points of cutoff, *A* or *X*, indicates that the engine would be developing all the power that could reasonably be expected. Under the given conditions, and without going into the calculation from a laboratory standpoint, the power developed at 5/8 cutoff would be

$$87 \times 3.7 = 322$$

horsepower; and at 7/8 cutoff

$$93 \times 3.7 = 344$$

horsepower.

The increased power of the engine running compound over that when the high-pressure side is run simple, would be in the one case,

$$415 - 322 = 93$$

horsepower, or 29 per cent.; and in the other case

$$415 - 344 = 71$$

horsepower, or 20½ per cent.

In the January 19 number George W. Harding expresses the opinion that nearly all the power developed in the low-pressure cylinder of an engine is clear gain, and submits two sets of diagrams to bear out his contention. These diagrams, however, prove nothing more than that the load is fairly well divided between the two cylinders. Mr. Harding makes the mistake of overlooking the fact of the high-pressure cylinder exhausting against receiver pressure, and asks, "Why are engines compounded if not to develop more work by using the steam again that has done work in the high-pressure cylinder?"

The main reason is to lower the steam consumption for a given load carried, by reducing the temperature range, and the consequent condensation, in the two or more cylinders as compared with what this loss amounts to when the complete expansion takes place in one cylinder.

From either a mechanical or an economic standpoint it would seem to be the better way to get the increase of power required by compounding if possible, rather than by replacing the cylinder with a larger one, but this would be governed largely by local conditions.

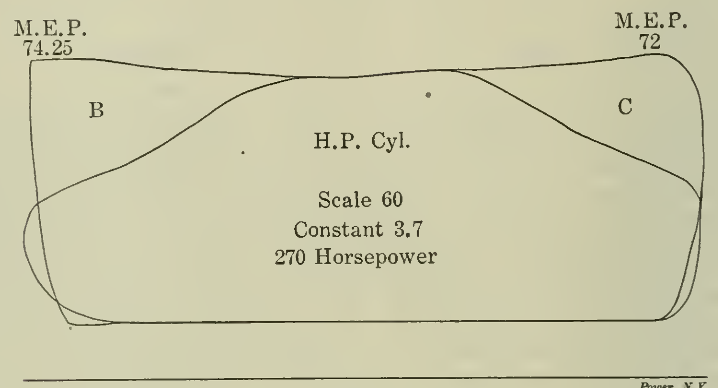

FIG. 1

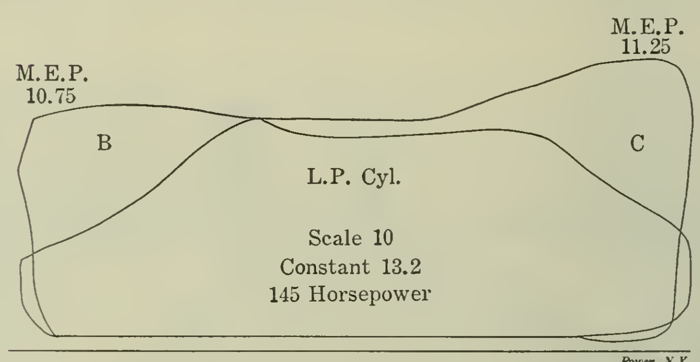

FIG. 2

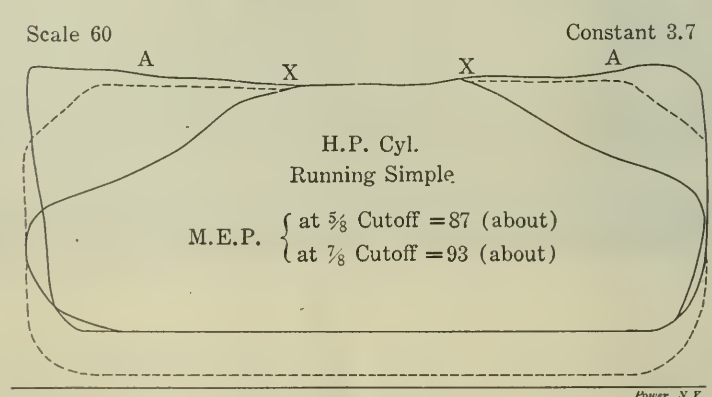

FIG. 3

It Should be Plus

In reading the March 9 number, I note on page 476, under the subject of "Safety Valves," the following formula:

$$A = \frac{22.5\,G}{P \times 8.62},$$

to be used in Philadelphia, given by Philip G. Darlington.

According to my understanding, the plus mark should be used instead of the multiplication sign, i.e., the pressure should have 8.62 added to it and not multiplied by 8.62. The correct formula should read

$$A = \frac{22.5\,G}{P + 8.62}.$$

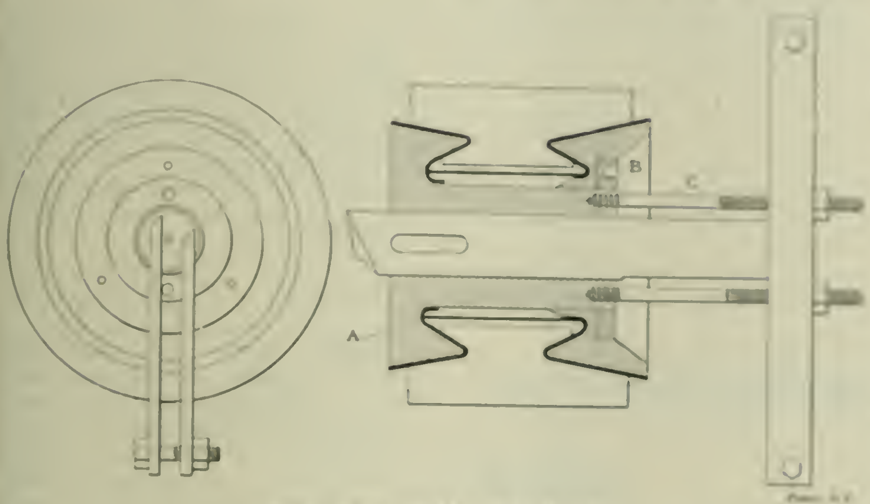
Philadelphia, Penn.

Removing Commutators

As a reply to question No. 924, "Catechism of Electricity," regarding the best method of removing commutators, I have used and found the following method successful:

Most commutators of small size—say on machines of less than 100 horsepower—are provided with holes of suitable size, generally ¾ inch or smaller, drilled and tapped in the front end of the commutator spider A (see sketch). If this method is used to draw the commutator, it takes all strain off of the clamping nut B. Commutators generally start hard, due to being forced on at the factory by means of an hydraulic press, under a pressure of from 10 to 20 tons. If the holes are not already provided, they can be easily drilled and tapped at any suitable distance from the shaft. The pulling studs C should be of cold-rolled steel to prevent stripping.

The pulling bar shown has been found to be very handy. To make it, take two pieces of [illegible]-inch bar iron, 16 inches long, and drill two 9/16-inch holes about 1 inch from each end. Put them together loosely with ½-inch bolts, 2¼ inches long. No matter what the distance may be between the centers of the holes in the commutator spider, if less than 14 inches this one bar will answer. The bolts at the end can be adjusted for a slip to open when ever size of stud is used.



METHOD OF REMOVING A COMMUTATOR

To start a tight commutator, put the studs under a fair tension with a wrench, then heat the studs to a dull red with a blowtorch and tighten the nuts. In cooling, the commutator starts, being easily removed by tightening the nuts on the studs.

Schenectady, N. Y.

Remedying a Packing Trouble

Recently it became necessary to use a small boiler feed steam pump in one plant on a job which subjected it to a greater pressure than it had been designed for. Very great attention [illegible] with the perception that the packing would not hold. In the accompanying sketch the packing at C, at the bridge separating the discharge and suction passages, would not hold high in resistance. I tried three different brands of packing, one with a wire-mesh composition, but each failed to hold, it split at the [illegible] that after each packing I "followed up" on the bolts.

Taking a small sized [illegible] at [illegible], as shown by the dotted lines, and after packing again found that the trouble had been remedied.

With the packing screwed down into the groove it became necessary for the rib thus formed to be sheared off before the packing could move.

For some time, now, I have been using different kinds of packing for the water pistons in small steam pumps, and I find that I get the best satisfaction and longest wear from rings cut from rubber belting. I purchase the regular rubber belt, made with two-ply canvas laid in rubber, and of a width that will cut economically. I cut the rings with an adjustable cutter inserted in a brace. Should it require more or less than a certain number of whole rings to fill the packing space, one of these rings can be separated to the desired thickness.

Brantford, Ont.

[illegible]

Regrinding Valves

In the January 5 number, page [illegible], Mr. Wakeman shows a type of globe valve (his Fig. 7) which he says is difficult to regrind. In reality they are as easy to regrind as any other type. To do so first remove the disk and place in the recess into which the stem fits a thin washer or small coin. Then replace the stem and screw in the collar which holds the disk to the stem. Then replace the disk, stem and bonnet and regrind by revolving back and forth through about one revolution, using the bonnet as a feed. That is, as the stem is turned in one direction, turn the bonnet in the same direction and just enough to keep the bonnet pressure [illegible] the disk and the seat. In this way the valve can be ground to a perfect fit.

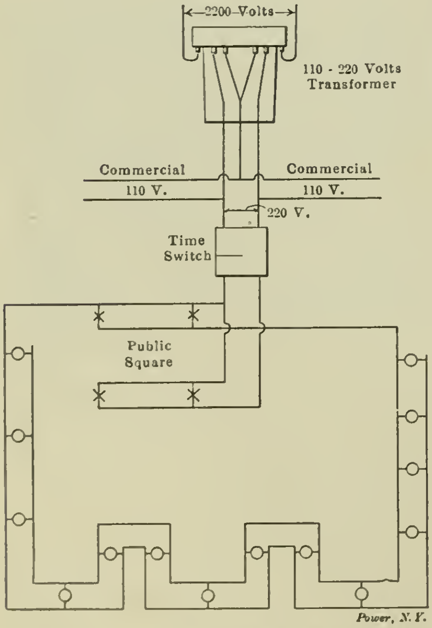
C. H. ROWLAND.

[illegible]

A Lighting Problem

In reply to Mr. Rolph's article in the February 2 number, I will say that his plan for street lighting would not be one which would give him satisfactory results. If the system is installed according to the accompanying diagram, very good results will be obtained. The street lighting is done entirely from the 220-volt wires, the incandescent system being so connected as to insure a very even drop of potential. No. 10 weatherproof wire will be suitable for the incandescent system, but if the poles are set very far apart it would be very desirable to use a No. 8 wire, as a No. 10 wire is not of sufficient strength to prevent it from stretching or breaking during winter storms. If desired, a time switch can be very easily installed, as shown.

The writer does not favor street lighting by the low-potential series system, owing to the fact that it is very hard to locate trouble; also, if one of the lights is cut out for any reason there is usually no way provided to keep the remaining lights from receiving an excess of current.



MR. BYLES' WIRING DIAGRAM

If the street lights are to be on the same poles with the wires used for house lighting, one of the house-light wires can be used to supply current to one side of the street lights, thereby dispensing with one of the street-light wires in the common multiple system. This scheme is only suitable for small installations and short lines.

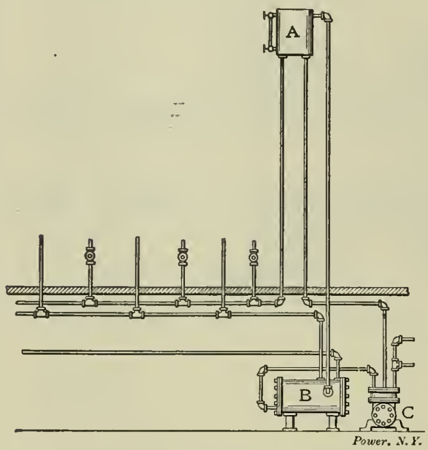
If the commercial system in the foregoing plan is to be of any magnitude the three-wire system should be used, at least on the main lines and the larger of the branch lines.

FRANK A. BYLES.

Bennington, N. H.

Gravity Feed Oiling System

In the illustration is shown a 100-gallon sheet-tin tank placed near the ceiling. It is fitted with a sight glass. In the basement, under the engine room, is located the filter *B*. The small pump *C* is so connected that it can be run with either steam or compressed air, and pumps oil from the filter to the tank *A*. An overflow pipe is connected at the top of the tank *A* and extends down to the filter.



GRAVITY-FEED OILING SYSTEM

A main pipe runs from the bottom of the tank *A* to the basement and along under the floor, where connections are made to each engine and auxiliary. Each engine and auxiliary has a separate valve just above the floor so that the oil can be shut off from any engine without disturbing the flow of the oil to any other engine or auxiliary. Pipes are run to each air-tight cup on the engine. They have the regular needle-point screws to regulate by. Each oil cup has a valve and can be cut out without affecting any other cup. We have cups placed on all parts of the valve gears where possible, and have very little use for the oil can.

We also have a return system. Each crankpit, foundation plate and eccentric pit has a pipe connection to one large pipe which leads to the filter. We run oil from a barrel in the storeroom into a can below and the oil flows to the filter and thus enters the system. In the can under the floor of the storeroom are coils of pipe through which steam circulates in cold weather. We do not, however, permit the oil to get hot enough to injure it.

This system is somewhat expensive in first cost, but there is hardly any operating cost and the great saving of oil in a short time will pay for the system.

I. Y. WHITE.

Handley, Tex.

Composition Disks for Globe Valves

In the February 16 number, Mr. Wakeman says that composition disks for globe valves are as good as they were 20 years ago, and suggests the superiority of globe over gate valves for big work, and then goes on to intimate that if gate valves are used composition disks can be made.

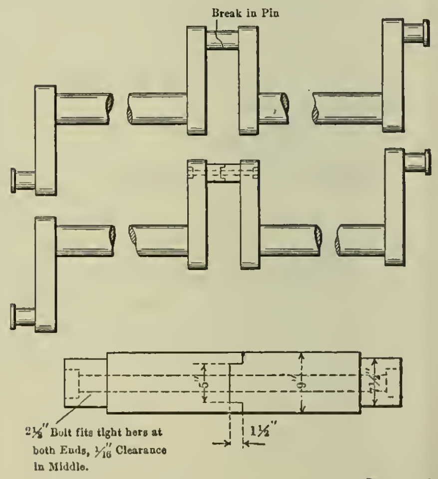
Things have changed in 20 years, and gate valves have the preference, and not only composition disks but bronze disks and seats have been changed for steel where superheat is used.

W. E. CRANE.

Broadalbin, N. Y.

Repairing a Center Crank

I repaired a center-crank engine two years ago and it has run nicely ever since. The pin of the center crank was broken, as shown in the sketch, and it had been bolted together and run in that way for about five years. The bolt was not fitted properly and the hole and pin were badly worn. I sent the shaft to a machine shop and had the shaft trued and the pin cut off. The crank-pin holes were bored out, also. Then we fitted both halves of a new pin to the holes and, after forcing one in, found that the bore was not in line. With both ends turned to size and no steel to make a new pin with, we had two steel thimbles forged and, after boring them out, shrank them on the pins. The crank shaft belongs to an ammonia compressor and runs twenty-four hours per day.



REPAIRING A CENTER CRANK

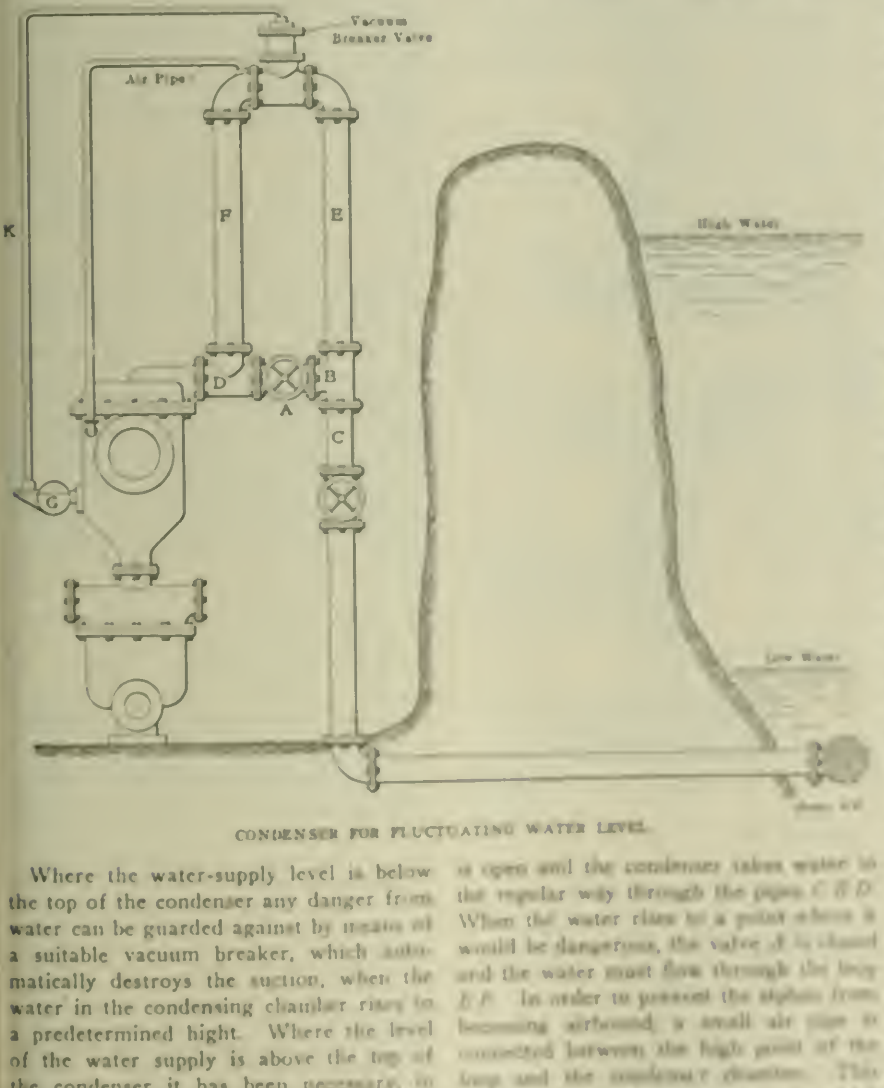
My theory for so many of these breakdowns is that the engine being horizontal and the compressors vertical the center bearings do not wear down as fast as the side bearings, the machine running only a short time until there is a springing action on the shaft, and it is only a matter of time until it breaks. I think my patched crank pin, considering this feature, is better than a new pin.

DENNIS HANLON.

Vincennes, Ind.

Condensers for Fluctuating Water Level

A jet condenser must always lift its own water, never take it under a head. Such has been the general rule in regard to the installation of these machines, the reason being that if the water came to the condenser under a head and for any reason the vacuum pump should stop or fail to remove it, there would be no means of preventing the water from overflowing into the exhaust pipe and back to the engine.



CONDENSER FOR FLUCTUATING WATER LEVEL

Where the water-supply level is below the top of the condenser any danger from water can be guarded against by means of a suitable vacuum breaker, which automatically destroys the suction, when the water in the condensing chamber rises to a predetermined hight. Where the level of the water supply is above the top of the condenser it has been necessary, in order to insure safety, to run the water into a well below the condenser level and have the condenser draft its supply from the well. An automatic float valve or an overflow serves to keep the well at the proper level.

Another condition that frequently occurs is that of a water supply fluctuating between widely varying levels. Many rivers have such a variation that a condenser set high enough to be out of danger at times of high water would be out of suction reach of the water at normal stages.

In order to meet either of the foregoing conditions the following scheme has been devised by the writer. The sketch and description refer to a fluctuating water level and some of the connections could be omitted in case of a constant water level higher than the condenser.

The vacuum pump and condenser are so located that the injection inlet is in the neighborhood of 18 or 20 feet above the low-water level. The injection pipe is arranged as shown, and is carried up so that the "vacuum breaker valve" is about 10 or 12 feet above the high-water level. So long as the water level remains below the injection opening, the valve *A* is open and the condenser takes water in the regular way through the pipes *C B D*. When the water rises to a point where it would be dangerous, the valve *A* is closed and the water must flow through the loop *E F*. In order to prevent the siphon from becoming airbound, a small air pipe is connected between the high point of the loop and the condenser chamber. This pipe serves to draw out the air which would otherwise collect at the top of the loop.

At *G* is located a chamber containing a copper float. If for any reason the pump should stop, the water would rise in the condensing chamber until it raised the float. This float actuates a small pilot valve controlling the pipe *K* and the rising of the float opens the valve and makes connection between the vacuum and the pipe *K*. The vacuum is thus applied to the top of a differential piston, which opens wide the vacuum-breaker valve, and thus allows the flow of air through a large opening into the top of the loop. This instantly breaks the siphon and stops the further flow of water into the condenser.

By means of a suitable number of crossover pipes, with valves, between the pipes *E* and *F*, the arrangement can be suited to any amount of fluctuation in water level.

H. M. CHASE.

Holyoke, Mass.

Heat in Steam

On page 213 of the January 26 number Joseph H. Hart, in his article, "Heat in Steam," makes the following statement: "After water is changed to steam, the steam then possesses practically nothing but specific heat, or, rather, increase in temperature means an addition only in the kinetic energy of the molecule. This is actually the case in what is known as superheated steam, in which case the steam behaves as a perfect gas and obeys Boyle's and Charles' laws absolutely."

The last statement of Mr. Hart is inaccurate, as superheated steam only when far removed from the point of saturation follows very nearly the laws of perfect gases. In the case of superheated steam in common practice, experimental investigations by Zeuner, Knoblauch, Battelli and others have proved that the combination of the laws of Boyle and Charles do not hold, i.e., that the ratio of the product of the volume and pressure to the temperature is not a constant. Several equations have been proposed to express the relation between pressure, volume and temperature of superheated vapors. The one best known is by Zeuner, which in the English system is expressed by the following formula:

$$PV = 93.5\,T - 971\,P^{\frac{1}{4}},$$

where

P = Pressure in pounds per square inch,

V = Volume of 1 pound in cubic feet,

T = Absolute temperature on the Fahrenheit scale.

The constants for this equation have been worked out on the supposition that the specific heat at constant pressure is a constant and is equal to 0.48.

Professor Peabody in his book on thermodynamics, gives some of the newer and more accurate formulas. Of these the one by Knoblauch is:

[illegible]

A simpler equation by Tumlirz is:

$$PV = 85.85\,T - 0.256\,P$$

This last equation has an error of about 1 per cent., as compared with that of Knoblauch.

Manhattan, Kan.

Keying Flywheels

In an ice plant having a 22x26-inch upright Corliss engine, connected to a 16x22-inch compressor, running at 58 revolutions per minute, the bolts of a marine-type connecting rod gave way and one of the boxes fell into the crankpit and stopped the crank, but the engine being under full steam pressure, and aided by the momentum of the flywheel, the shaft was twisted about 15 degrees before it came to a stop. The broken bolts of the connecting rod were 1½ inches in diameter, but the holes in the boxes were about 1¾ inches, and it was thought judicious to make stronger bolts. The butt and strap were reamed out, and the new bolts turned to fit the boxes snugly. The chief felt safe about them, but to his surprise they broke about two weeks later. A few weeks previous to their failure the piston rod had loosened and worked down into the crosshead until the piston struck the lower cylinder head. The pounding had been allowed to go on for some time, as the chief did not believe in stopping for such a trifle. I think this started a crack in one of the bolts and caused the breakdown. The new bolts had comparatively smooth running. The condenser pressure ran at times up to 200 pounds with about 25 pounds suction. The strain on the bolts was 35,850 pounds less the weight of the piston, crosshead and connecting rod, or about 14,500 pounds per square inch on the old and about 10,000 pounds on the new bolts. The new bolts showed dents on the butt and strap ends, indicating bending stresses; the old ones had clearance enough to avoid them. Faulty alinement is harder on connecting-rod bolts than the working strain.

Another cause of failure is the habit of cutting the threads too sharp at the bottom and allowing the tool to dig in at the end of the thread. A smaller pitch would be better practice than standard bolts. Bolts that have been in an accident and subjected to abnormal strains should be looked over very carefully before being used, but I would scrap them.

To insure a satisfactory job in securing a wheel to a shaft with a sunk key it is necessary that the bore of the wheel should fit the shaft reasonably tight, and that the keyway in the wheel should be of the same size, parallel to the keyseat of the shaft and not taper more than ⅛ inch to the foot. If the wheel bore is larger than the shaft by more than 0.004 inch it should not be used on that shaft. If the keyway is not parallel to the keyseat, it can be corrected in the following manner:

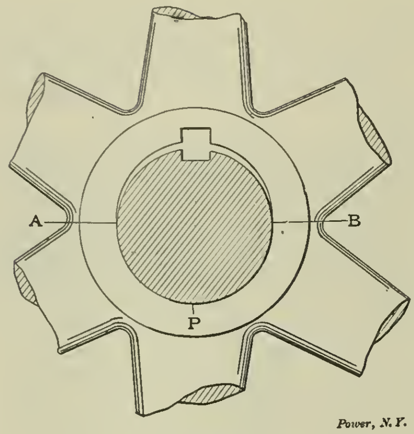

FIG. 1

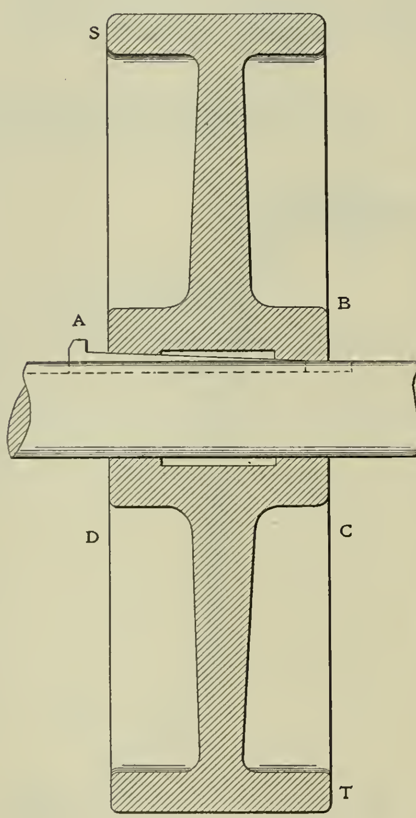

FIG. 2

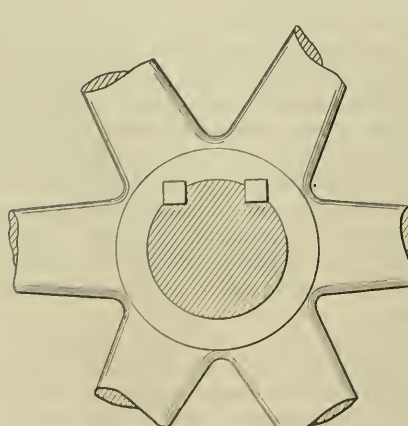

FIG. 3

Suppose a wheel with 7-inch bore is to be fitted to a shaft with a sunk key 1½ inches wide. The keyway of the wheel, when placed edge to edge on the keyseat of the shaft, is found to run to the left 1/16 inch at the other side. The wheel should then be turned 1/32 inch to the right, in order to divide up that divergence. The protruding edges, viz., right front and left back of the shaft and left front and right back of the wheel, should be carefully marked, as they must be filed or machined. A key 1 17/32 inches wide will now be necessary, and it can be fitted on all sides, as there are straight and even surfaces to deal with.

It is troublesome to make special keys in factories where keys of standard sizes are kept in stock and, besides, the work has to go out on regulation time, so it happens that the wheel, shaft and key are left as they are. It also happens that if the bore of the wheel is 1/100 inch or more larger than the shaft, it is used anyway.

The keyfitter or erecter in trying to make up for all these defects drives the key home as hard as he dares, thus setting up an undue strain in the hub. The key will bend the shaft and the wheel on the protruding edges only and the combination will look like Fig. 1. Such a wheel will soon begin to work, rubbing the shaft at *P* and battering it at *A* and *B*. It does not take long before it will cut at *P*, creating an additional strain in the hub, and if the speed is high and the reversals of force sudden something will happen. If the fitter has been careless or ignorant enough not to file the edges of the key before trying to fit it, matters will be worse, but the wheel after wearing away the edges will begin to pound and give notice of its bad condition.

Another bad practice is the attempt to remedy a wobbling wheel with the key. If a wheel has been sprung when clamped to the boring-mill table, during the operation of boring and facing, it will wobble when running on the shaft. If this wobble is in or near the radial direction of the key, as at *S* and *T*, Fig. 2, an attempt is sometimes made to throw the wheel in line by filing the key down in *B*, in order to make the wheel bear hard at *D* and *B* and loosen up a little at *A* and *C*. I have never seen it done successfully, but it is resorted to quite frequently. The drawback to the wheel is apparent. I would rather have a wheel wobble a little than have it "fixed up" in such a way. I do not know that "broad keys fitted upon flats" hold a wheel or even a pulley in place successfully, but I have experienced many cases where such keys had to be replaced by broader ones and finally by sunk keys before they gave satisfaction.

To use two keys, as shown in Fig. 3, is

no improvement over the single sunk key, as either one or the other key has to stand the strain, according to whether the wheel is receiving or giving up momentum. Such keys are, therefore, liable to work loose. I have seen set screws used to prevent it.

Set-screw holes drilled into the keyways are not desirable, as they weaken the hub through its least cross-section. I remember of two such wheels being cracked through the keyways. This method of keying is of advantage on governor wheels, where it is sometimes desirable to shift the wheel to suit the accurate position of the eccentric. This can easily be done to a certain limit by increasing the thickness of one key and reducing the other. To use a split wheel and clamp it down without a key can hardly be considered, as it would have to be tightened too often and the shaft would certainly suffer in a short time. A single sunk key in connection with a split wheel or hub is, in my judgment, the most convenient and efficient method of holding wheels.

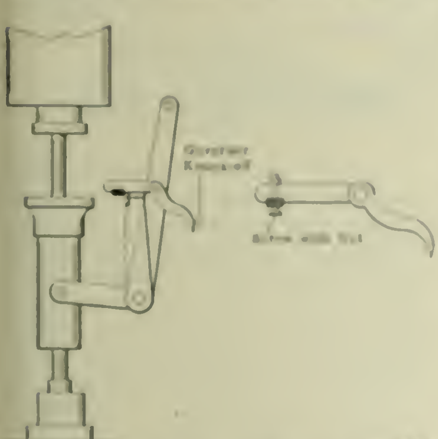
Cause of a Runaway Engine

One day my Slater engine started to run away, but I managed to stop it before any damage was done. The cause was due to one of two screws which held the steel hook-up block becoming unscrewed from the latch, allowing the valve to take steam full stroke on both ends, as it had



CURING THE CAUSE OF A RUNAWAY ENGINE

put the governor "out of commission."

The way I fixed the engine so that a like occurrence could not happen was to drill a hole clear through the hook-up latch, tapping and putting on a longer screw on which I placed a nut to prevent the screw from turning out.

East Bridgewater, Mass.

A Return Steam Trap

The accompanying sectional view is of a return-steam trap that has given satisfaction and one that can be manufactured at a very moderate cost. The trap is the invention of W. J. Sterling, Portsmouth, Va. The body is cast in two parts and bolted together. Located on the side of the upper portion is a brass cylinder connected by flanges. The condensed steam enters from the top and is discharged at the bottom. The copper float is made with a ½-inch pipe passing through its entire length, the ends of the pipe being brazed to the float so that it may move loosely on the stem and still be water-tight. The stem on which the float works is connected to a bell crank, which in turn connects to the valve stem operating the piston valve. The valve has a ⅛-inch hole passing through its entire length, so there will not be a vacuum formed behind the valve when it moves. All the fittings are made of brass and the body is of cast iron.

SECTIONAL VIEW OF A RETURN-STEAM TRAP

Will the Load on the Bolts Change?

Allow me to submit a problem for publication. The illustrations, Figs. 1 and 2, represent sectional views of one end of two separate steam cylinders.

Fig. 1 represents a cylinder and head having a ground joint between them. Fig. 2 represents a cylinder and head having some elastic material as packing. The area of both cylinders is [illegible] square inches, and each respective cylinder head is held on by 12 studs and nuts. Each nut on the 12 studs is screwed up to such a point that the studs are under an initial stress of [illegible] pounds.

If steam or other pressure is forced in so that the area of the head on the inside of the cylinder is subjected to [illegible] pounds pressure per square inch, will the

FIG. 1 FIG. 2

pressure on the bolts, in either case, increase, decrease or remain the same? In each case what is the load in pounds per bolt?

G. A. C[illegible]

Setting of Steam Eccentrics

[illegible]

[illegible]

the single wristplate. In those days engineers laid out and built the engines and they were built convenient to handle. The starting bar came out straight and was convenient to one hand, and the throttle to the other. The two new wristplates were thinner than the single one and were placed side by side, with slots in each, and a thin starting bar for each slot. One bar had an offset so that both bars were brought out parallel and the two together taken in one hand and operated as a single bar (the only sensible way), and I had a pair of wristplates operated by hand the same as the old single plate. Why should anyone do differently? At present most engines are laid out by draftsmen and starting bars stick out at all angles, sure to be the most inconvenient.

The change in the engine by giving the exhaust a clear release resulted in a marked saving in fuel. The lengthening in the range of cutting off made the speed steadier and also allowed more load to be put on the engine, which, after a time, was done. There was rolling-mill work done by this engine, with all kinds of load, and occasionally a card would be taken that showed the steam following three-fourths stroke, the steam eccentric set at 90 degrees.

When a piston is at the middle of the stroke its speed is so high that if the valve is tripped at that time the piston will have gone some distance before the valve is closed.

We had a 30x60 George Corliss engine and we asked a price from the builders for making the parts to fit it up the same way. They refused to make them, saying: "We don't want our engines run that way." So we got the parts from the Harris people. Of course, this was fitted up the same as the 28x60, and the two wristplates worked by hand as easily and nicely as the single one. There were no more valves to handle.

This engine was in a rolling mill and there was occasionally a card showing a three-fourths cutoff, so there was no question about getting a range of cutting off up to three-fourths stroke. This was before the days of compounds, although there had been a few built. One large mill corporation in Massachusetts had one mill separate from the rest and it was so fitted up that an accurate test could be made of any change made on the engines, which in this mill was a pair of cylinders on one shaft.

Mr. Babbitt, superintendent at the Harris shops, proposed fitting up this pair with the extra eccentrics and a contract was finally made that if the change made a saving of 10 per cent. the corporation was to pay a certain price. If there was not a saving of 10 per cent., nothing should be paid. The change was made and on the last day of the trial a check was mailed to pay for new parts. The blowing through on starting up did not appear to make much loss. In order to do away with it, have a little block and raise the governor sufficient to cut off and block it up. This is a good idea with a single as well, as much less steam is used when getting up to speed than at full stroke.

In 1892 our people were having a new engine built and among others that wanted the jŏb was the Corliss company, which was ready to put on two eccentrics. They got the order for a 28 and 52 by 72-inch engine, to run at 60 revolutions, and it was to be built just as I directed. After this engine was put in and before any large loads were put on I got through with this firm, so that I did not see any cards with heavy loads, but understand it has gone way beyond 2000 horsepower with 125 pounds steam pressure.

Along about 1895, Hewes & Phillips built a 16 and 30 by 42-inch engine and erected it in the lighting station at Elizabeth, N. J. It so happened that the load of the station was so adjusted that a peak load came on this engine for about two hours every evening, calling for a cutoff of about three-fourths stroke, and the little engine was right on the job every time.

The first that I heard that there was any trouble with that manner of setting the valves was about twenty years after I put on the first one. It seems that some street railway had put in too small an engine and the load would pull the governor right down on the pin, so they did away with their safety stop, put the eccentrip back and put in effect the 60-degree hitch-up.

This throws the stop-motion out of use and the only excuse is a man made a mistake.

After about 1894, builders turned their attention more to putting on two eccentrics and some of them could not believe that the piston at its highest speed in the cylinder could advance after the valve had been tripped, and they studied out the 60-degree arrangement and called it their long range of cutting off, but years before men had been getting the long range of three-fourths stroke with the eccentric at 90 degrees.

If three-fourths stroke can be obtained without crippling the engine in any way and allow it to be handled by the starting bar so as to do anything one wishes, what excuse is there for crippling it so that bars with a lot of men or tackle blocks have to be used?

When the steam eccentric is set at 60 degrees, if the valve is not tripped, the eccentric will not close it until the crank is 30 degrees beyond the center and the piston is one-fourth of its way on the return stroke. For this reason, with eccentrics set in this manner the valves must always trip before the eccentric has completed its full throw.

When the wristplate is at one-half travel, or vertical, the steam valve is wide open. But one steam valve can be hooked on at the same time and the wristplate cannot be held in its central position, but must be thrown over to nearly its full throw, so that the valve may be closed, as there is very little lap.

To start the engine is a simple matter, but to manipulate it and bring it to a stop at any point nicely is different. Let us suppose that less than one-half stroke is all that is required. The engine is brought to nearly the point, and how are you going to stop or throw steam into the opposite end of the cylinder? You have not got hold of the valve at the opposite end, and if you had it would have been wide open all the time and you would not have moved at all. To get hold of this valve you must throw the wristplate over and pick it up.

You cannot hold onto the starting bar strongly enough to move it and unhook the steam valve; besides, it would take time. The only way to do is to throw the wristplate over, but this also opens that valve wide during the operation.

Suppose that opening this steam valve wide for an instant has not carried the engine too far, which is highly improbable, and that you get hold of the other valve. Then you have to reach over somewhere and get hold of your exhaust valves and change them, and by this time the engine has either stopped or gone too far. If you have to make more than one revolution you are in a nice mess.

I once knew an erecting man who went home and told his people that he had started and stopped an engine of this character at any point. He had been very careful not to have anyone around when he did it.

W. E. Crane.

Broadalbin, N. Y.

Method of Cutting Nipples

In a recent number, F. E. Fick gives his method of cutting nipples which is all right, but I cut the long thread and screw the coupling on it, and then screw the nipple into that. Then instead of reversing the dies, I select a bushing large enough to take in the coupling. If the bushing is of the adjustable type this is very simple, but in case the bushing is of the ordinary type it may be necessary to wrap the coupling with paper. If a very short nipple is wanted the bushing may sometimes be put on the longer piece of pipe and the coupling will come between the bushing and the dies.

Some Useful Lessons of Limewater

A Series of Interesting Practical Experiments with Oxygen: What an Atmosphere of Pure Oxygen Would Mean to the Animal Kingdom

BY CHARLES S. PALMER

In the last chapter we laid out the ground for making oxygen, planning the apparatus as shown in the various figures, and anticipating as far as possible some of the most important tests which you will make with this gas. You will want at least two jars of the gas—ordinary quart fruit jars—and if you can collect three or four jars of gas so much the better. Here you will want to note that oxygen is a trifle heavier than the air, and the jars of oxygen can be kept for some few moments by covering them with the square pieces of cardboard used to remove them from the water, and which should be put over the mouth of the jar while it is still under water. This is done by grasping the jar firmly with one hand, and with the other slipping the cardboard down into the water over the mouth of the jar, then raising the whole, turning it right side up and setting it down mouth upward, with the cardboard left for a cover.

There is one other point that you should notice, and that is that if you start with your wash-dish pneumatic trough half full of water, the water from the jars, by displacement of the oxygen, will flow out into the wash dish and will fill it an inch or two deeper, and hence the jar will get a little unsteady in the increased depth of water and will tend to float and tip over unless you hold it down or weight it. The gas in the jar sinks to a lower level than that of the open water in the wash dish, as shown in Fig. 1. This caution about steadying the jar will be particularly necessary if you put several jars, full of water, inverted mouth downward in the same wash dish preparatory to filling them with oxygen. Frequently the water escaping from the jars, as the oxygen is led into them, will fill the wash dish to overflowing, a circumstance which does not matter as long as you keep your eye on getting the oxygen into the jars and keeping them from tipping over.

Experiments with the Oxygen

The first experiment you will try will be the testing of the oxygen in one of the jars with one of the splinters of soft pine wood 8 or 10 inches long, which you have got ready. Light the splinter and, removing the cardboard cover from the jar of oxygen, quickly thrust the glowing splinter down into the jar. You will note the increased brilliancy of its burning and you can instantly remove it, replacing the cardboard cover on the jar. Now blow out the flame of the splinter, leaving only a glowing coal at the end, and thrust this again into the jar, when the splinter will burst into a flame as though by magic.

If you do not let the splinter remain burning in the jar too long, you can repeat the experiment a number of times before the oxygen in the jar is exhausted. With a little practice one can easily ignite a glowing splinter in the jar, remove it, blow out the flame, thrust it into the jar again to relight it [illegible] When the jar is exhausted so that it will no longer re-ignite the glowing splinter, cover the jar with cardboard and set it aside [illegible]. However, before you go on to the next jar of oxygen, just note that the splinter burns in the air with a fairly bright but slightly smoky flame, while it burns in the oxygen with a brilliant white and smokeless flame.

The next test will be performed on another jar of oxygen, using instead of a splinter some of the match ends fastened together with a wire handle 8 or 10 inches long. If you use the common "night day" sulphur match, you will note the bright blue flame of the burning sulphur; if you use parlor matches, say not over half a dozen in the bunch, you will note the brilliant burning of the phosphorus, together with some copious white fumes called phosphoric anhydride, that is, the anhydride or water-free residue of phosphoric acid, the acid found in bones in combination with the lime [illegible]

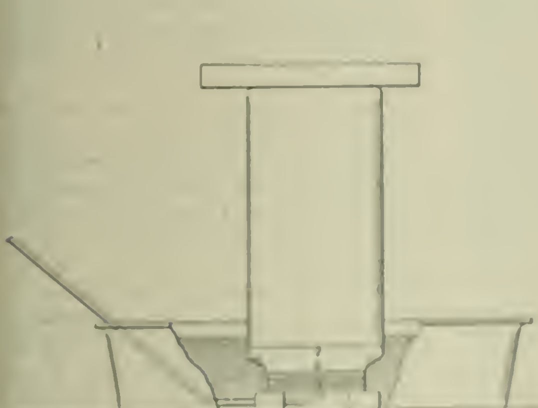

FIG. 1

FIG. 2

FIG. 3

[illegible]

Of course, your common sense will [illegible] glass.

You will also want to [illegible]

it should happen that the iron wire which binds the match ends together, as shown in Fig. 2, should itself take fire, thereby anticipating the next test, do not worry, for all sorts of possibilities may happen; but it is well to anticipate what may happen so that you can understand it.

The next test refers to the burning of the iron picture cord, prepared according to the directions given in the last lesson: heating it. dipping it into flour of sulphur, and wrapping a bit of cotton wool or cotton waste around the sulphur while hot. In this experiment, as shown in Fig. 3, you will have two pasteboard covers, one already on the jar and another perforated with a small hole through which the prepared picture wire extends. This cardboard and wire are grasped in the right hand, holding the cardboard between the thumb and the first finger or fingers, and folding the third and fourth fingers under the cardboard to hold the wire so that it will extend down straight into the jar as you swap covers. The picture wire should extend some 4 or 5 inches below the cardboard when the latter is placed on the mouth of the jar; and, if the experiment succeeds well, you will see the cotton which you lit before thrusting the wire into the jar burn brightly, which will light the sulphur, and this in turn will ignite the iron picture cord.

The picture wire will burn with bright sparks or scintillations thrown off in every direction from the burning tip. Moreover, as the picture wire burns up, you will push the part above down through, feeding it to the flame in the oxygen. Also, you will notice that as the iron burns there will be an accumulation of molten globules at the end of the wire. Some of these molten globules will almost certainly be jarred off the wire by the trembling of your hand, or by the violence of the burning, and will fall to the bottom of the glass jar, cracking the glass unless you had the forethought to protect the bottom of the jar with something like a layer of sand.

Therefore, remember that *before* you start this third experiment with oxygen, you will want to sprinkle into the jar enough clean sand to cover the bottom of the jar evenly, about 1/4 or 1/2 inch deep.

Magnetic Oxide of Iron

You will note, in addition to the black globules, some brownish particles and, of course, you will understand without being told that both the red particles and the black globules are the rust or oxides of iron produced by its burning in the oxygen. This black globule, by the way, is the magnetic oxide of iron, Fe_3O_4 (F-e-3-O-4). This magnetic oxide of iron is naturally magnetic without being put near a magnet; just as water is naturally wet, gold yellow and coal black.

Incidentally, you will find it interesting to gather some of these particles afterward and test them with a magnet, the handiest magnet being the large blade of your jackknife which, of course, you can easily magnetize at any direct-current generator in any power house. You will find this magnetized jackknife very convenient in making many tests which otherwise you might have to neglect.

There are many other experiments which you can try with oxygen, but perhaps those that I have given here will be all that you can handle just at present; but, you do want to be sure to make a spark on a wooden splinter burst into a flame, on the one hand, and on the other hand you want to be sure to get the iron to burn. In a few moments we will go back to examine the contents of each of the used jars of oxygen; but just at present you want to notice that you yourself have answered the question, proposed and discussed in the last lessons, as to what would happen if the nitrogen of the air were removed and its place were taken by oxygen.

The conditions and the results of the burning of the splinter, the matches and the picture wire in the jars of oxygen show that an atmosphere of pure oxygen would be the basis for a very dangerous and destructive conflagration. If we could live safely in an atmosphere of oxygen, and if you should build a fire in your cast-iron stove in an atmosphere of pure oxygen, you would see the stove itself take fire and burn like butter. As to the ability of a man to live in an atmosphere of oxygen, there would be nothing poisonous about it, but the body would be consumed as by a fever, probably faster than he could eat food and digest it to supply material for the good red blood. There used to be an experiment in this line, illustrated by catching a mouse in a trap which does not injure the little animal and letting him loose in a jar of oxygen. If you should try this, you would undoubtedly see the mouse jumping about in a state of great nervous excitement, where he probably is not really suffering pain, but is simply, literally, "burning his candle at both ends." An animal in such a condition would probably not live many hours, but would quickly exhaust the food supply in the blood and tissues by the over-combustion and excessive burning due to the extra supply of oxygen.

In this connection, you will probably begin to get interested in the atmosphere, as you will read about the remarkable way in which animals exhaust the oxygen of the atmosphere, and the equally remarkable way in which green plants replenish the oxygen of the atmosphere by absorbing the carbonic-acid gas of the air, retaining the carbon and giving back a part, at least, of the oxygen to the air.

The Atmosphere Once Held Much Less Oxygen than Now

There probably was a time in the history of our globe when the atmosphere contained very much less oxygen than at present, and the fairly good supply that we now have has been accumulated through long ages by the continuous action of the bright sun shining on green (chlorophyll-bearing) plants. The present condition of the oxygen in the atmosphere, making about one-fifth by volume of the air, is well suited for the support of both plants and animals, and also for the safe burning of the coal under your boiler. If there were very much less oxygen in the atmosphere, the burning would be much more sluggish; and if there were much more oxygen in the atmosphere, the burning, as shown by the experiments you have made with your jars of oxygen, would be much more violent, dangerous and difficult of control.

Before we close this lesson let us go back and examine the first jar of oxygen in which you burnt the wood splinter. Pour in a few teaspoonfuls of limewater, and you will get the same milky precipitate of plain carbonate of calcium that you got in your earlier experiments, and with which you are now getting pretty well acquainted. Of course, you can treat this plain carbonate of calcium in the same way that you did before, namely, by blowing in air from the lungs, and changing it to the soluble extra or bicarbonate of calcium, although there may be carbonic-acid gas enough in the jar from the burning of the wood splinter to do this without any blowing.

The next jar to test is that in which you burned the match ends. In this you will pour a little water, or if you poured water in at first to protect the bottom, that will do. Throw in two pieces of litmus paper, both the red and blue, and you will probably see that the burning of the sulphur or the phosphorus in the oxygen produced the same acid-like substances that you previously got by burning sulphur or phosphorus in the air. If you pour in a little limewater you may get a white milky precipitate, or indeed a mixture of two or three precipitates. These white precipitates are largely the sulphites, the sulphates and the phosphates of calcium; although the wood of the match ends in burning will also have produced some carbonic-acid gas, which again will give you your friend, plain carbonate of calcium.

The test with the jar in which you burned the iron wire will probably not give you very much to note, either with limewater or with litmus, because the sand at the bottom of the jar will interfere with the tests; but at all events you want to collect some of the fused globules of magnetic oxide, which you will notice are really bubbles, not solid shot; and you will also want to preserve the burnt end of the picture wire with its globule of molten magnetite.

This set of experiments will start you still farther on the right road for the examination of the atmosphere, and will give you many things to think of. If there are any questions which you want explained, just write them in a simple inquiry to POWER, and I will answer them to the best of my ability.

We have now studied something about the atmosphere and about oxygen, and this is a very good start in laying the broad foundations of chemistry, for oxygen is found in many substances, and yet it represents only one side of chemical action, namely, that of oxidizers. The other side, contrasted with that of oxidizers, is that of reducers, which are well represented by hydrogen, which we will study next. Hydrogen is found in water, in all acids, and in many other substances; and in the next two lessons we will consider the subject of hydrogen, first the making, and then the testing of it. All of this you can easily do in the homemade laboratory of your boiler room.

Illinois Fuel Conference

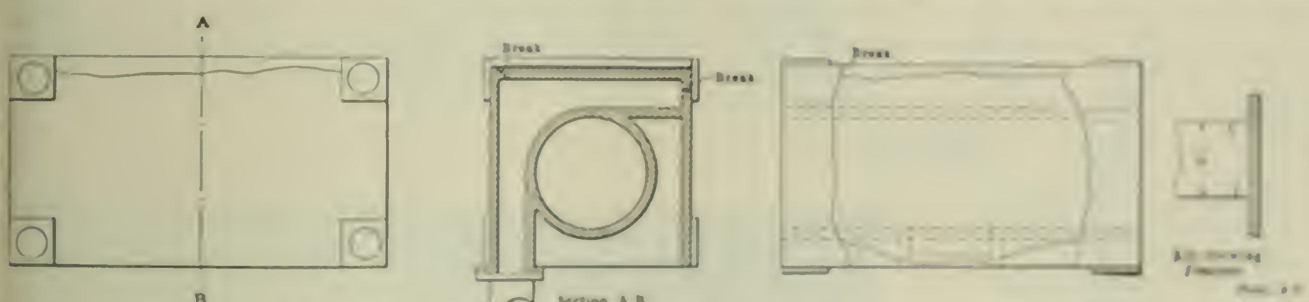
The first Illinois Fuel Conference took place at the University of Illinois, Champaign, March 11, 12 and 13. The conference brought together a varied representation of those interested in coal mining, not only as miners and operators, but also as engineers and geologists. The purpose of the conference was to find means for reducing the dangers incident to coal mining and to conserve the natural resources of the State by improved methods of mining, and to utilize to better advantage the coal after being mined. Many of the ablest men associated with that question, both from the practical and theoretical standpoints, attended the conference and participated freely in the discussions.

The United States Geological Survey, in coöperation with the State Geological Survey, has established at the College of Engineering, University of Illinois, a mine-explosion and rescue station. The purpose of the station is to instruct mine operators and inspectors in the economical value of such modern appliances as oxygen helmets and resuscitation apparatus as adjuncts to the normal equipment of mines. The station will also [illegible] itself with the training of mine bosses and others in the uses of such apparatus. Its service is to be rendered gratuitously and, so far as possible, to all in Illinois, Indiana, Michigan, western Kentucky, Iowa and Missouri who may desire the benefits therefrom. The formal opening of the station constituted part of the proceedings of the conference.

Top of Cylinder Blown Off

A very peculiar accident recently occurred to an 18 and 36 by 36-inch cross-compound Whitehill-Corliss engine at the Poughkeepsie Heat, Light and Power Company's plant, Poughkeepsie, N. Y. The entire top of the low-pressure cylinder between the valve chambers was blown out, part of the casting going through the roof.

The engine was started at 7:20 a.m. in the usual way and had been running until 10 o'clock, when the rupture occurred. No valves had been touched, nor connections interfered with, and all receiver valves and line valves were sealed open.



SHOWING BREAK IN LOW-PRESSURE CYLINDER OF ENGINE AT POUGHKEEPSIE

The engine was running on 125 pounds pressure from a battery of horizontal-tubular boilers, and low receiver pressure, usually 15 pounds, with a 26-inch vacuum showing on the gage board.

Just before the accident the generator was running on about half load, or 200 kilowatts. Part of the flying metal cut the belt, which displaced the gage board and wrecked the governor gear. Aside from this, there was little damage done to either the engine or the building.

Close examination of the metal around the outside of the fracture showed a clean new break, with a minimum thickness of 1¼ inches, but the two ribs [illegible] old breaks, as shown in the sketch. One rib left on one side, which was blown out, showed several cracks in the [illegible] which showed that where the cracks were the metal was stronger than at the other end of the rib. The two ribs shown are of [illegible] [illegible]-inch section.

This engine has been running off and on for 10 years, but a great part of that time was idle. On account of the [illegible] of the year, which made it [illegible] necessary to get some work done by the engine, the high-pressure cylinder was used at 120 pounds boiler pressure, in [illegible] and was run in this way when needed for about a month [illegible] was done to the low-pressure cylinder. The engineer had oiled the engine for the evening run and had started to warm up the cylinder by opening the throttle valve a "crack" to admit steam to the cylinder. A few seconds afterward a loud report was heard and the top of the high-pressure cylinder passed through the roof in the same manner as the low-pressure cylinder. The cause was attributed to water hammer, as the engine had not moved, and it seems very likely that such was the case, as upon dismantling the throttle valve part of the body of the valve was found to have been carried away. Thus, although the valve was closed, had permitted steam to leak into the engine and it is very probable that in starting up the large body of water which had accumulated was not taken into consideration.

As in the case of the low-pressure cylinder, no damage was done to anything outside of the engine with the exception of a lubricator and a few small fittings. The rib in the center of the cylinder and the webs all around showed a clean and new break and there were no flaws or blowholes showing.

A report published in the Provincial Engineer deals with a fatality due to the rupture of a boiler fitting [illegible] [illegible] of a vertical boiler [illegible] [illegible] [illegible] while lying in the [illegible] of [illegible] on [illegible] [illegible] The door, which was made of cast iron and measured [illegible] inches, was secured to the [illegible] [illegible] [illegible] of a stud and dog, but the door was so [illegible] [illegible] which led to its being [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] This led to the [illegible] of the boiler being [illegible] [illegible] [illegible] the [illegible] of the [illegible] [illegible] [illegible] [illegible] up the top of the [illegible] and so [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible]

The Lee Smokeless Furnace Under a Modified Continental Boiler

Something new in furnace, or rather stoker, construction has been invented by Thomas F. F. Lee, a lawyer of some note in Brooklyn. The stoker consists of two side grates, arranged on the arc of a circle and conforming nearly to the outline of the boiler shell, and also a flat grate immediately beneath the boiler. The element of which the side grates are composed is a bar 14 inches in length and of the cross-section shown in Fig. 1, that is, four fingers with spaces between for the admission of air. The grate bars are mounted in series, usually four, on a square bearing bar running the length of the furnace and projecting through the boiler front, so that by means of a special wrench, or automatically, as indicated at the left of Fig. 1, the bars may be given a slight movement and gradually push the coal toward the bottom grate. The fuel is introduced at the side of the boiler, and as it gradually finds its way toward the bottom of the furnace, disappears as gas through the uptake and in the form of a very fine ash through the bottom grate. There are no clinkers, but fine particles of carbon drop through the small openings in the grate. It is the intention at some future date to arrange a fine sieve below the bottom grate and by means of a conveyer of special design return the coke to the furnace, leaving nothing but the fine white ashes, which are so light that a small proportion of them are carried by the draft through the furnace flue to a pit arranged at the rear of the boiler.

There is provision for admittance of air at two points on the sides of the furnace and also through the fuel at the top. The greater portion of the air passes through the admission at the floor line and a part of the air enters downwardly through the fuel and at the tops of the side grates. This latter admission is necessary to draw the fire up through the columns of fuel. A damper is provided, as shown, to regulate the amount of air passing through the side grates. With this arrangement the coal is coked in the upper part of the side grates, and the volatile gases driven off are carried through and over a bed of incandescent fuel before they can enter the boiler. By the time the coal reaches the active portion of the grate, it is completely dried, so that there is no opportunity for the production of smoke, and almost perfect combustion is obtained. From the top of the stack, which is only 25 feet above the boiler, there is positively no trace of smoke.

FIG. 4. THE OLD AND THE NEW STACK

The boiler itself, which is shown in longitudinal cross-section in Fig. 2, is simply a modification of the Continental boiler, containing a large corrugated flue to carry the gases to the rear, and a few more tubes than is usual in this type of boiler. The gases enter the furnace flue through a narrow neck at the bottom, of the same length as the grate and about 9 inches wide, wind around the large flue to the rear of the boiler and pass out through the tubes to the stack. The boiler is set on the floor line, with a pit in front about 3 feet deep to accommodate the boiler front, giving room for the ashpit and space for the boiler tender or fireman to give the side grates the slight upward movement regulating the feed of the coal, also to remove the ashes from the bottom doors visible in Fig. 2.

An installation of this type of boiler and furnace, Fig. 3, was made at the Dover Boiler Works, Dover, N. J., April 1, 1907, and from September 1, 1907, has been in continual operation, displacing two 48-inch by 16-foot boilers of the locomotive type, rated at 50 and 60 horsepower, respectively. The works contains a Clayton air compressor, 10x16x16x10x10 inches, a second air compressor, 8x12

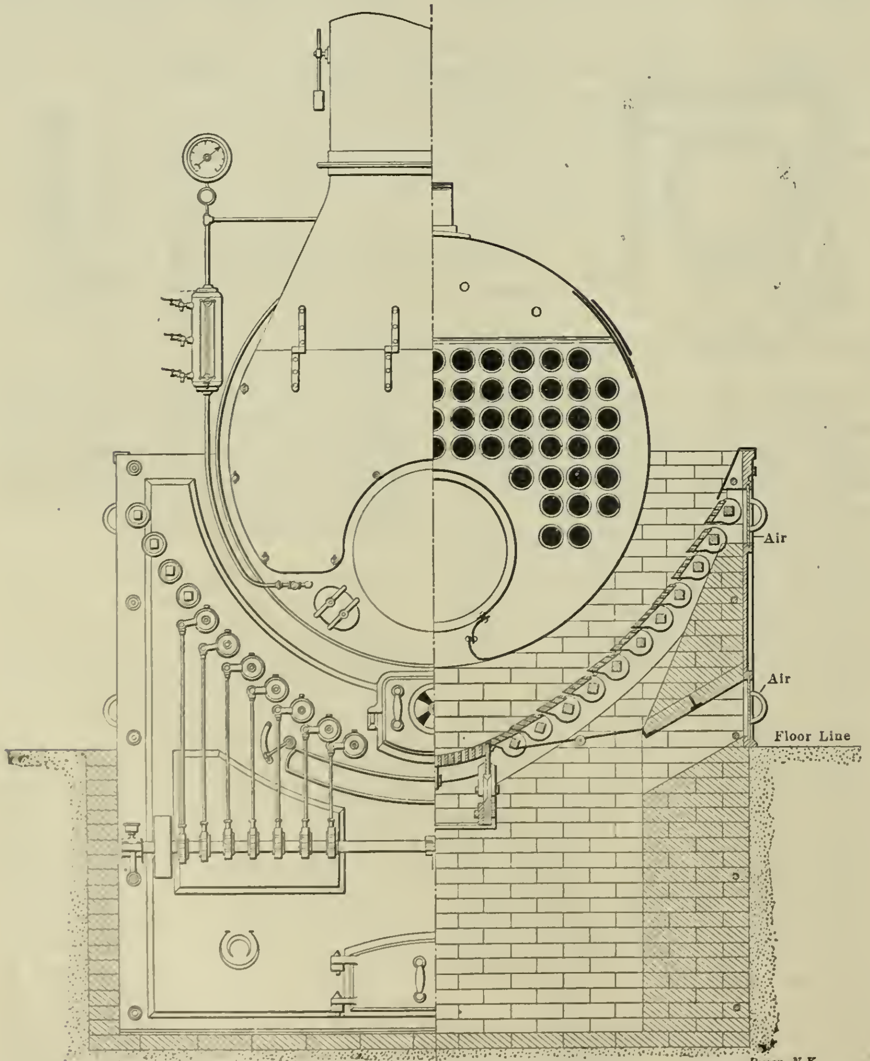


FIG. 1. THE LEE SMOKELESS FURNACE AND BOILER

inches, a 50-horsepower Corliss belted engine and a 25-horsepower engine belted to a dynamo. Frequently this machinery is all running at the same time, and the boiler in operation has handled the load since its installation with no difficulty whatever.

The boiler is 6 feet in diameter and 11 feet 6 inches long; contains eighty-four 3-inch tubes, a 25-inch Morrison furnace flue, and operates on a steam pressure of 110 pounds per square inch. The back is 50 inches long by 9 inches wide, and the [illegible]

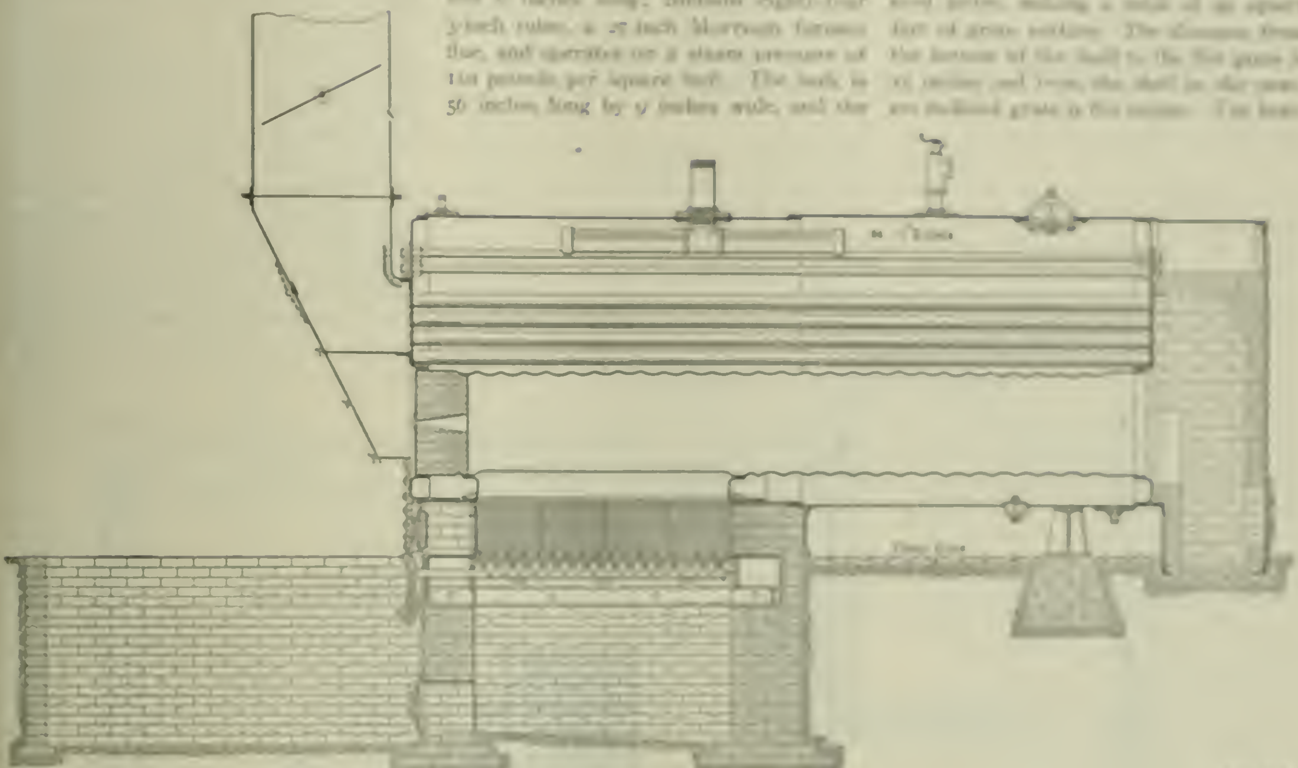

FIG. 2. LONGITUDINAL SECTION THROUGH BOILER AND FURNACE

FIG. 3. INSTALLATION AT [illegible] BOILER WORKS

[illegible]

coal per square foot of grate, or nearly 0.2 pound of coal per square foot of heating surface.

Shortly after the plant was installed at Dover a 10-hour test was made by J. M. Whitham, of Philadelphia, with the following results: Evaporation from and at 212 degrees Fahrenheit, 11.67 per pound of dry combustible; horsepower developed, 98.5; moisture in coal, 8.25 per cent.; dry ash and refuse, 19.38 per cent.; ash by analysis, 13.4 per cent.; draft at damper in stack, 0.038 inch of water; draft in furnace, 0.0651 inch.

Subsequently two tests of 10 hours each with the same coal and under similar conditions were made by Charles W. Scribner, of New York City, and the average result was an evaporation from and at 212 degrees Fahrenheit of 12.8 pounds of water per pound of dry combustible. These figures are extremely high, in fact almost bordering on the theoretical.

It is claimed, however, that they are substantially maintained in ordinary, everyday operation. The appearance of the stack would indicate almost perfect combustion, and the evaporative figure an unusually high efficiency. The absence of smoke and the simplicity of the grate are also points in favor of this construction.

It is also claimed that by regulating the supply of air under the side grates, or in reality varying the active portion of the side grates, the boiler will run just as economically at 40 or 50 horsepower as at its normal rating. The short stack is a feature worthy of note, and is probably allowable on account of the thin fuel bed and the low rate of combustion, although the inventor has some remarkable theories in this regard.

More recent installations of this type of boiler have been made at the plant of the Singleton Silk Mill Manufacturing Company, Luxemburg, N. J., which has installed a 125-horsepower boiler; at the plant of the Buffalo Dredging Company, foot of Porter avenue, Buffalo, N. Y., containing a 100-horsepower boiler, and at the Murray Electric Light and Power Company's plant, Monticello, N. Y., which has installed a 175-horsepower boiler. In all of these plants the side grates are regulated by hand, but it is the intention in future designs to provide the shaft indicated in Fig. 1 and operate the grates by cam movement. It is also planned to in-

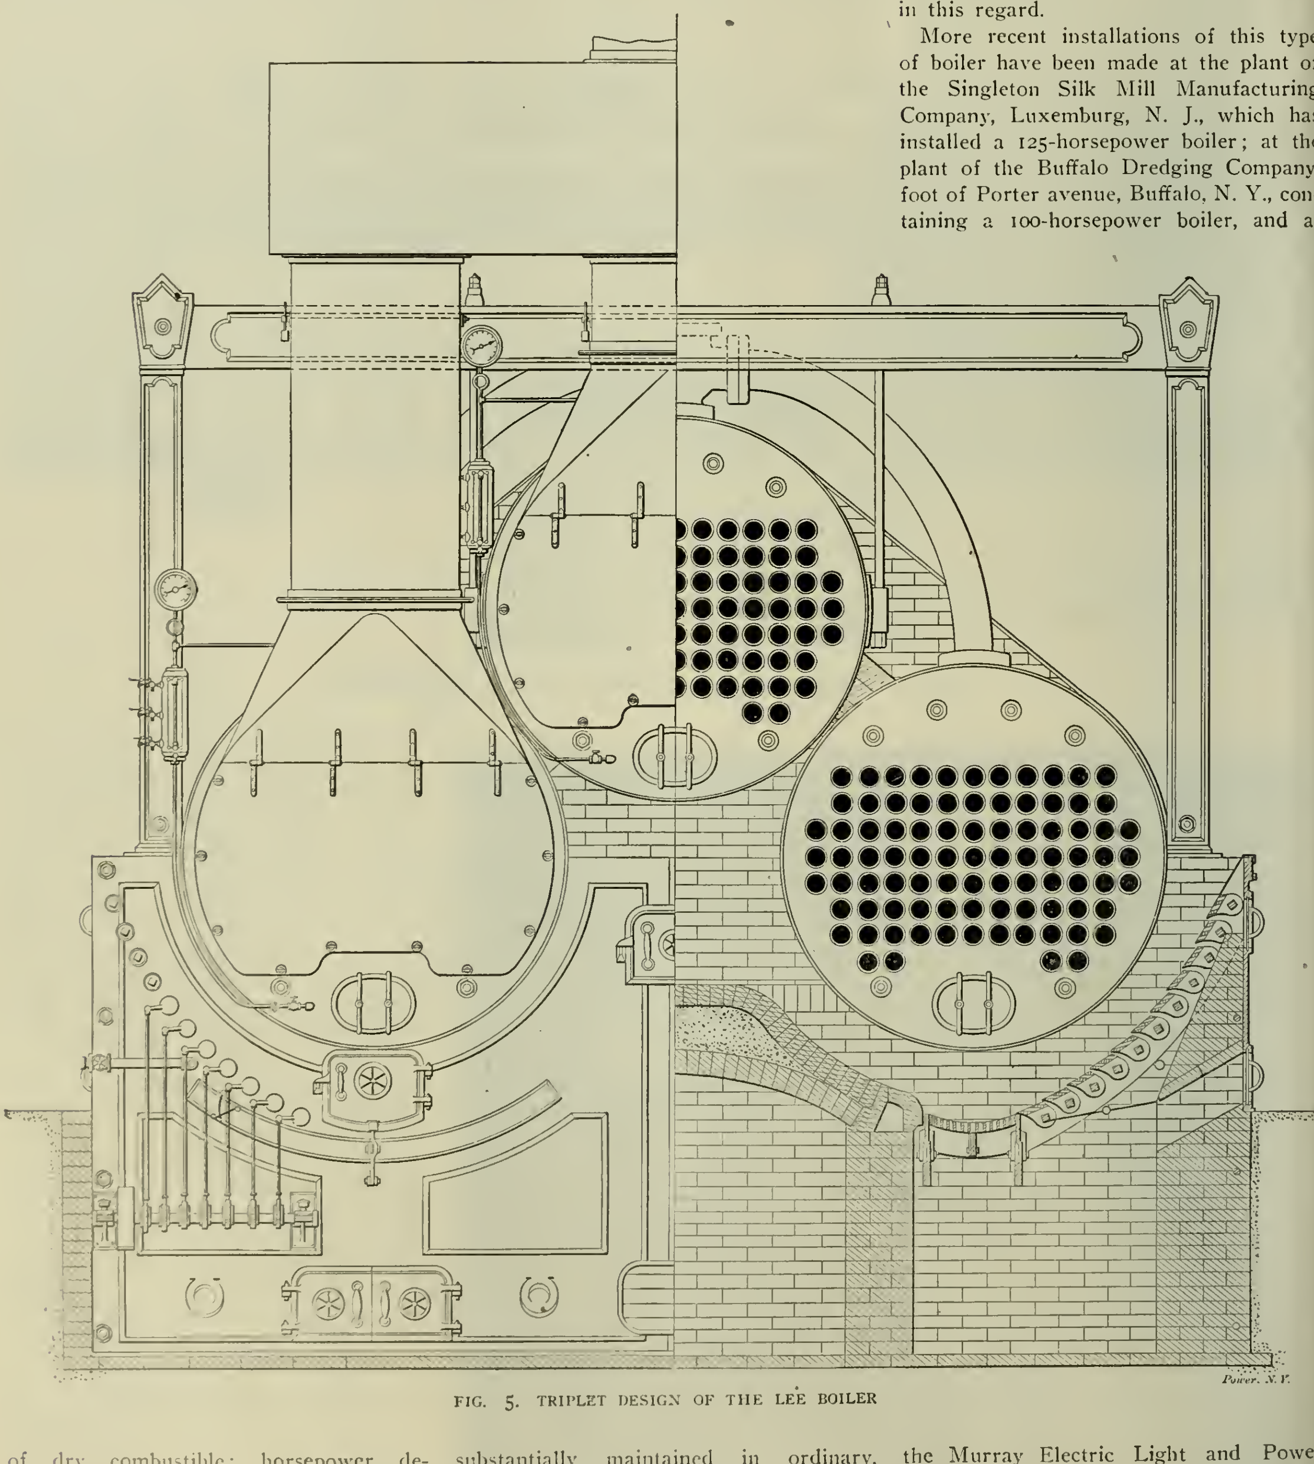

FIG. 5. TRIPLET DESIGN OF THE LEE BOILER

stall the sieve under the flat-bottom grate and the small conveyer previously mentioned. Another innovation is to arrange the boilers in twin or triplet design, a view of the latter arrangement being shown in Fig. 5. For the twin design the two lower boilers are brought closer together and the space occupied by the third boiler in the triplet design is arched over with firebrick. Boilers of the usual design are to be used and the arrangement of the gas passage is indicated in the drawing. The Smokeless Furnace and Boiler Company, 44 Court street, Brooklyn, N. Y., is to control the manufacture of these boilers and stokers, every feature of which is covered by application for patent.

Experience with Gas Power in a Grist Mill

By H. B. Messenger

Following is a presentation of actual results obtained in six months' operation of an 85 horsepower Jacobson producer-gas engine and a ——— suction-gas producer in a flour mill, operated entirely by men who have never had the slightest previous experience with gas engines or producers of any sort. This engine took the place of a good automatic steam engine, rated at 100 horsepower, maximum, and easily capable of delivering 90 horsepower continuously. It was supplied with steam by two horizontal return tubular boilers, one 60 inches and the other 66 inches in diameter, and both 16 feet long and rated respectively at 80 and 100 horsepower. These boilers were kept thoroughly clean inside and the tubes were scraped daily. The feed water entered the boilers at nearly the boiling point and 100 pounds boiler pressure was carried. The main steam pipe to the engine was short, of ample capacity and well jacketed.

At times it took very good firing to keep the engine supplied with steam with both boilers running, and it was impossible to run all the machinery in the mill to its full capacity; the engine would not drive it at full speed. The normal coal consumption, using the best grades of Georges creek soft coal, was in the neighborhood of two tons per day, varying, of course, with the amount of work being done, the condition of the boilers, etc. The gas engine installed to displace the steam engine is rated by the builders at from 75 to 85 horsepower. It is a tandem engine, with cylinders of 14 inches bore and 18 inches stroke. It is very heavy throughout, the engine with flywheels, mounted, weighing in the neighborhood of 14 tons. The shock of the explosion of charges is well absorbed in consequence, and the engine runs very steadily and smoothly. The speed is 220 revolutions per minute.

The engine was started July 22, 1908, on its regular work, beginning that day upon a new carload of pea anthracite. Since then it has run steadily with very few interruptions, and has proved fully capable of driving the entire mill to its capacity and at full speed. Some of the hardest running machinery in the mill, a line taking at least 20 horsepower to operate at full capacity, is thrown in and out without affecting the engine or producer apparently in any way. It is not found necessary or even advisable to notify the operator when this heavy load is to be added, the producer and the engine both taking care of the added load without any attention. The speed regulation is of the best, it being impossible, once the engine is fairly at work, to notice any variation, upon adding the work in large units, without using a speed indicator.

The producer used with this plant was built by the Smith Gas Power Company, Lexington, O. It is 10 feet high and 5 feet in diameter on the outside, lined with firebrick about 8 inches in thickness, making the inside diameter about 4½ feet. The ashpit is about a foot in depth, and the gas-collecting ring in the top occupies very little space. It is only necessary to charge this producer or to work on the fire once each day ordinarily, but if the engine is running heavily loaded it is sometimes advisable to settle the coal down compactly about the middle of the day. From 500 to 1000 pounds of coal is put in once per day, this being sufficient for an 11-hour run and to keep the fire over night. Very little heat is thrown out, the top of the producer feels warm to the hand, but not hot when the fire is in proper order. The water in the seal at the top will last all day without renewal. While the producer will run all day without attention, it has been found that a little attention to the fire about the middle of the day will give better results as to regularity in the quality of the gas; also that a little judicious work in cleaning and poking down the fire about closing time will save work and time in starting in the morning.

The time required to get started in the morning depends almost entirely upon the management of the fire by the operator. We have started on Monday, the fire having been kept over from Saturday night, in fifty minutes from the time of entering the engine room, and it seems probable that with a little more experience and care this time can be still further reduced.

Some few minutes are required after the engine is started before all the load can be thrown on. It is good policy to have the engine and producer in operation for thirty minutes before attempting to carry the full load or to throw parts of the load on and off without variation in the speed, owing to the fact that the production of gas is not fully under way.

More grain has been ground in this mill since the installation of this plant than ever before in the same length of time.

Three cars of coal have been taken in by the use of this producer, the aggregate weight of the three cars being a little under 80½ tons. No other coal has been used in its operation; some coal has been sold and several tons were on hand on January 1, when the stock was first measured. The consumption has been about 80 tons in six months, or a little over 13 tons per month. The mill runs 11 hours per day.

Fire has been kept the entire time, over night and over Sunday. Some coal has been wasted by the inexperience of the operator, and one car of the coal proved to be not suited to the work, requiring the consumption of about one-third more coal per day than the coal in either of the other cars.

The guarantee of 1½ pounds of coal per horsepower-hour has been found to cover a wide margin of safety, and besides the saving in coal, the labor and attention are very much less than were required for the steam power. One man does the work, as he did with the steam plant, but he is able to do a great deal of outside work and has time to spare. He has been known to come to the office in cool weather to get warm, there not being enough heat and work in the engine room to accomplish that result. It is needless to say that in warm weather his position has changed from a very undesirable one to one of the best about the mill.

The miller is also highly pleased with the change. He can now operate any or all of his machinery at any time and the mill never lags, avoiding much trouble by chokeups, etc. The mill runs with much less attention, and does better work and more of it. In short, no one about the plant, from the proprietor down, would contemplate a change back to steam with any degree of pleasure, but all would most heartily oppose such a change.

Lecture on Water Tube Boilers

On Tuesday evening, March 16, F. C. [illegible] delivered an illustrated lecture before the Students' Engineers Club of Brooklyn on the subject of water-tube boilers. Much of the lecture was historical and the earliest forms of water-tube boilers, with boiling water, [illegible] from the time of Watt. After these came illustrations showing the work of the earlier modern designers, beginning with Rumsey in 1788 and taking up in turn the work of Stevens, [illegible]; Perkins and his son, [illegible]; Gurney, [illegible]; Fox, [illegible]; Twibill, [illegible] and Field, [illegible].

The balance of the lecture was given over mainly to showing the development of the water-tube boiler as manufactured by the Babcock & Wilcox Company. Following the lecture an interesting discussion [illegible] took place.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for February, 1909, was (weekly and monthly) 151,000.

March 2	42,000
March 9	37,000
March 16	37,000
March 23	37,000
March 30	37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

The Boiler Inspector

Sometimes an inspector's report makes absurd demands or recommendations, but this is no more reason why the engineer should condemn the principle of inspection than that he should refuse to consult a physician when some member of his family is sick, simply because some "dub of a doctor" had cut open a friend to remove his appendix and found the trouble to be caused by his kidneys.

With men who are equal as regards the gift of observation and the ability to reason from cause to effect, the boiler inspector has opportunities to perfect himself in diagnosing boiler troubles so far superior to those of the operating engineer that comparison seems absurd. A boiler inspector sees thousands of boilers where the engineer sees one.

Instead of looking forward to the inspector's visit as an unpleasant duty, to be got through with as soon as possible, and with the least trouble, look upon it as an opportunity to add to your store of knowledge, and the possibility of your finding some contemplated change in your equipment which will be worth while.

No one has a corner on ideas, and it is very likely that John Smith, who has a plant almost the same as yours, is a progressive engineer like yourself, and is always scheming to add to the economy of his plant. Possibly some of the same changes have occurred to him as being beneficial that you now have under consideration, and it may be that he has tried some of them with success, while others proved failures. You cannot avail yourself directly of Mr. Smith's experience, because you do not know him, and are not likely to meet him, his plant being located in another State.

Now, the inspector who goes to Smith's plant also comes to yours, and Smith has told him, with pride, of the different improvements he has made, and if he is a real broad-gaged engineer he has also told him of his failures; and if you will only make a friend and confidant of the inspector you will have much of Smith's experience at your command, as well as that of a great many other engineers. You can never gain the inspector's good will by making his duties hard. Boiler inspecting at best is a tiresome and dirty job and you do not gain the inspector's respect or good will by making him crawl through three feet of ashes or drag himself through a lot of mud in the bottom of your boilers to make his inspection.

Make his labors as easy as possible, and what adds as much to his comfort as properly preparing your boilers for inspection is to show him by your manner that you are glad to have him visit your plant, and appreciate the points he can give you regarding the kinks your brother engineers are using. No matter how you regard the inspector's opinion, never try to deceive him regarding the condition of your plant, and do not leave him to find a defect which you know to exist, but tell him of it. By such tactics you at once gain the confidence of the inspector and at the same time disarm him in his position to give you information, regarding your plant, which you as the responsible head should be aware of yourself. The inspector has nothing to gain by making you his enemy, and the chances are, by long odds, that if he turns in a report regarding your plant which you do not consider good, he thoroughly believes he is right and is merely doing his duty to his company and your employer as he sees it.

Never take exception to an inspector's report unless you are prepared to show conclusively that you are right, for if the inspector is right (and in the great majority of cases he *is* right), and he can prove it, your objections merely strengthen his position with your employer, and will greatly injure yours in any future controversy.

Boiler Room Supervision

If you were conducting a chemical works in which some fifty dollars worth of chemicals were converted per hour by a process which, with reasonable care, would yield eighty per cent., but which might easily, through the personal factor, be dropped to fifty, would you go out to the dump and hire the cheapest laborer who could handle a shovel and put him in charge of the department? The burning of coal is a complicated chemical process. The transfering of the heat which is generated by that combustion into water and the production thereby of steam is a process which affords opportunities for economy or waste. The apparatus in which these processes are conducted is usually under high pressure, a source of danger if carelessly or ignorantly handled, however safe and adequate it may be in competent hands, subject to rapid deterioration and costly repairs largely avoidable by skilled and intelligent manipulation.

We do not advocate the placing of the boiler room in charge of a professional chemist, but there are men who are specialists in this line who can save a very considerable proportion of the coal which is fired in the average plant, men who know how much coal a fireman can and ought to handle per shift, and how he ought to fire it; men who are capable of determining the value of the coal which you get, and of the composition of the flue gases; capable of getting the largest amount of steam per dollar's worth of coal, of keeping down leaks and repairs and of forestalling accidents and shutdowns. But this class of man does not work for a dollar and a half a day and would not be content to hang his clothes on a buckstave bolt and wash in a pail.

Firing is dirty work, but there is enough clean money to be saved by doing it right to make it worth while to pay a high-class man, and the physical conditions can be improved to such an extent that they will not repel men of that character.

Coal Consumption and Power Plant Economy

One of the first questions a visiting engineer naturally asks is: "What is your coal consumption per kilowatt or per horsepower hour?" He wishes to find this out so he can compare the work of his plant with that of others.

It is well to remember that the coal consumption per unit of output is, at best, only a partial indication of the efficiency of a power station, although it depends greatly upon the way in which the boilers, auxiliaries and engines are handled, with respect to the load variations. It is far more important to approximate, if possible, the total cost of power production per unit, including the principal items of fuel, labor, water, oil, waste, repairs and, in some cases, sundry items of purely operating equipment or tools. Of course, the total cost cannot be known until the fixed charges are figured.

The total coal consumption per kilowatt-hour may be higher one year than another, and yet the total power cost exclusive of fixed charges may be less. In one case, the coal consumption was 3.45 pounds per kilowatt-hour one year, and 3.26 pounds the next. The cost of power manufactured in the first year, however, was 1.22 cents per kilowatt-hour and the second year 1.24 cents. Thus, quite a noticeable difference in the amount of coal used per unit of output really produced little effect on the plant cost of operation as a whole. This does not mean that the coal consumption was unimportant at any time, however, for it is only by pruning down all excess quantities in plant operation that the total cost runs low enough to make a good showing. The chief reasons why the cost was a little greater in this plant in the year when the coal consumption per kilowatt-hour was the least were an increase of 11 cents per ton in the coal cost at the plant, an increase in the water cost of $900, an increase of $700 in steam-plant repairs and an increase of $1000 in electric-plant repairs. The labor cost was actually a little less per kilowatt-hour during the year when the total expense of production was higher.

During another year in this same station the coal used per kilowatt-hour was the same as in the first year cited, 3.45 pounds, but the total cost of production was 1.32 cents, as compared with 1.22 cents during the first year. The plant turned out 25 per cent. more energy during the year when the cost was lower. [illegible] was certainly an important factor in the decreased expense. The cost of coal per ton in the less expensive year was 10 cents less than in the higher cost year. What made the difference then? Going over the records of the plant in detail we find that the total cost of manufacture was $7000 less in the higher cost year, so that the saving was practically all due to the gain in load.

One of the chief difficulties of economical operation in electric-power plants is due to load variation, making it far from easy to operate the machinery at the capacities for which it was designed. There is scarcely any form of equipment known in power plant engineering which will operate efficiently at low outputs, compared with the results which can be obtained when the machinery is run close to its rating. The steam engine will not do its best work when underloaded. The turbine is less affected by a reduction of load from 75 to 50 per cent. of normal, but when its operation with auxiliaries is taken into account, and this is the only way of actually finding out what a steam-turbine installation will do, it will soon be seen that operation at as near full load as possible is required for the highest economy of power production.

Neither can the gas-engine plant be operated at underloads with any prospect of securing the best results in operating efficiency, and in all plants the larger the output for a given equipment, the less will be the station labor and repair cost per unit.

Is Material or Method Responsible for Lap Joint Cracks?

The memorandum of C. E. Stromeyer, chief engineer of the Manchester Steam Users' Association, for 1907, refers to numerous samples of boiler plate which were tested in an endeavor to ascertain if mild steel possessed aging qualities. Among these samples were three taken from boilers that had cracked or exploded in service, and the history relative to one set of these samples is very interesting as possibly throwing some light on the question of the cause of the so-called lap-joint cracks.

From this report it appears that in 1888 nine boilers were built by one maker and installed in a plant, and although they were built at the same time, four different makes of steel were used in their construction, all four makers being considered of equally high grade. Two of the boilers were constructed of make A, one of make B, one of make C and the remaining two of make D. After about four years of service an inspection revealed two cracks in the [illegible] in different boilers, one being constructed of steel A and one of steel C. Subsequent inspections about a year later revealed the same kind of cracks in two boilers of steels C and D, after which the entire nine boilers were abandoned. Shortly afterward a hydrostatic test developed an additional crack in one boiler constructed of steel B, and all of the rivets in the longitudinal seams of this boiler were removed, but no additional cracks were found and the plate did not appear to be brittle.

It would appear from the facts in this case that the quality of the material was not a factor in the formation of the cracks, for in the five boilers each of the four different makes of steel was represented. This apparently leaves the method of manufacture or manner of laying up the seams to account for the failures. While this case is rather unusual, in that it affords an opportunity for comparison between different makes of steel, in boilers for a single plant, made by one manufacturer at the same time, it must be admitted that the evidence is very good that the quality of the plate was not the cause of the cracks. The evidence in this case also coincides with the experience of an engineer who has gathered considerable data relative to this type of boiler failure in one section of the country.

It was found that while the make of plate concerned in such failures was apparently well distributed among the steel manufacturers, the distribution of the failures among the boiler makers which supplied the sections in question was not uniform, but was confined to a very limited number. This would indicate that the method of manipulation is a more important factor in the formation of such cracks than the quality of the plate used. The real cause or causes of the formation of the lap-joint crack are probably not yet thoroughly understood.

It is evident from the report that Mr. Stromeyer does not regard the use of the lap joint in the same light that it is being viewed by numerous engineers in the United States, for in commenting on the apparent good qualities of the steel found in the three cases of failure that came under his notice he has the following to say:

"It should be mentioned that although lap joints are very common in stationary boilers and give perfect satisfaction, they seem to have been the cause of many locomotive explosions in the past, and the [illegible] [illegible]"

Power Plant Machinery and Appliances

Original Descriptions of Power Devices
No Manufacturers' Cuts or Write-ups Used

MUST BE NEW OR INTERESTING

Lagonda Feeding Device

We illustrate herewith a new device that permits the operator to sit in a comfortable position on a platform or scaffold outside the boiler and with very little physical effort feed the turbine tube cleaner into one tube after another. Instead of supporting a heavy weight of hose and cleaner, the hose responds to his will by his merely turning the crank. After a tube is finished, the operator draws the turbine into the funnel shown at the end, and by a new setting of the feeding device the funnel is centered over the next tube to be cleaned. The adjustment requires only a moment and the water need not be turned off until all the tubes are cleaned, thus effecting a great saving of time.

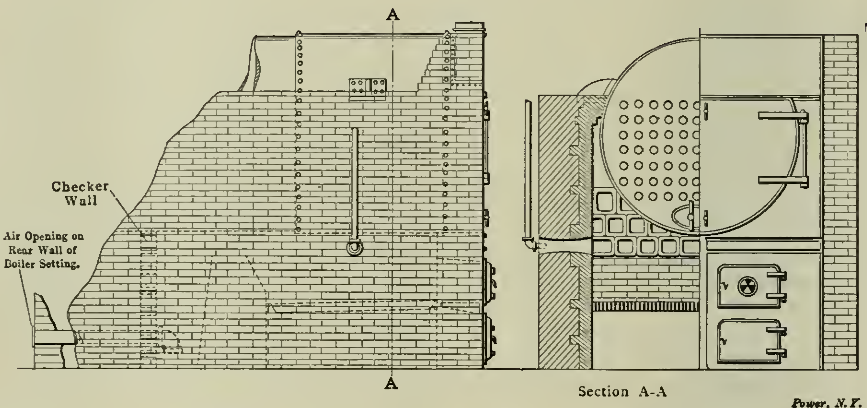

FIG. 1. HOW THE M'GIEHAN DEVICE IS INSTALLED

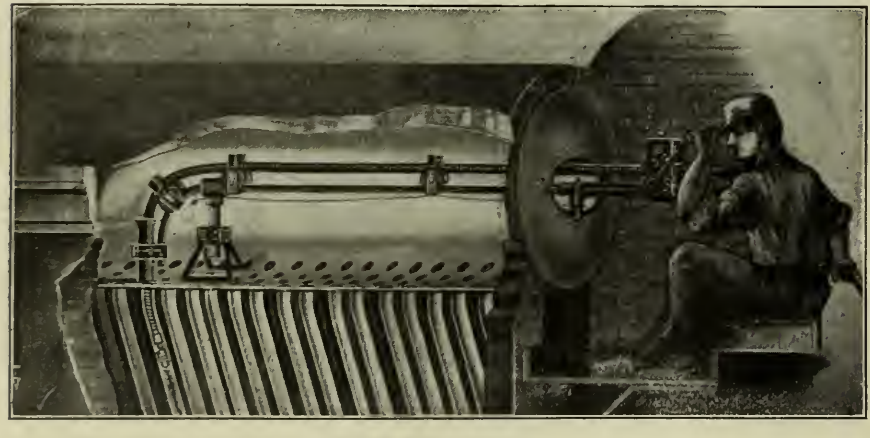

LAGONDA FEEDING DEVICE

The mechanism of this device consists of a funnel through which the cleaner is guided into the tube, a stand and shafting to support the funnel and hose, and to provide adjustment over the different tubes. The shafting is jointed and snapped together with triggers, so that the sections can easily be handled and used in the limited space between the boilers. On each section of shaft are a spool and rack on which the hose is rolled. The shafting is held in the center of the manhole by a tripod rigidly braced from the edge of the manhole. Extending from this tripod is the feeding device proper for feeding the hose into the tube. There are two capstan-shaped rolls which inclose and grip the hose, and which are geared together so that when one is turned by the crank the other turns.

The Lagonda feeding device may be used with any make of turbine cleaner, and is manufactured by the Lagonda Manufacturing Company, of Springfield, Ohio.

The McGiehan "Smoke Eliminating" Furnace

Another device designed to eliminate smoke when burning bituminous coal, and to increase the efficiency of steam boilers, is illustrated herewith. It is known as the "McGiehan patent smoke-eliminating

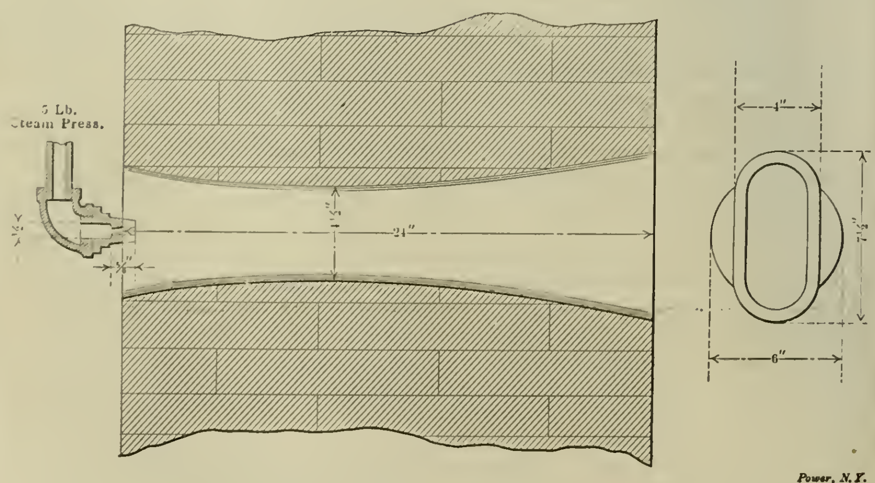

FIG. 2. SHOWING THE STEAM NOZZLE

furnace," designed by P. H. McGehan, Garnerville, N. Y., and handled by W. H. Howard, 90 West street, New York City. The device can be installed with any type of boiler.

Under the boiler, between the bridge-wall and the rear wall of the setting, is a checker wall, as shown in Fig. 1. Extending from the rear end of the boiler, through the combustion chamber and checker wall is a pipe, on the end of which is a tee, turned down as shown, for the purpose of admitting air in a heated state, between the bridgewall and the checker wall, in passing through the combustion chamber. The pipe is covered with firebrick.

To assist in the combustion of the fuel a steam nozzle is introduced on the side of the furnace, constructed as shown in Fig. 2. It is shaped something like a double-ended telephone receiver, the outer end being the larger—about 6 inches in diameter—the inner end being oblong, 4 inches wide and 7½ inches long.

This device can be seen in operation under sixteen 7x18-foot return-tubular boilers at the Rockland Print Works, Garnerville, N. Y. From observations made by the writer it is working satisfactorily,

FIG. 3. RESULTS WITH AND WITHOUT USING THE McGEHAN DEVICE

the mechanical engineer at the plant stating that as high as 170 per cent. of the boiler rating has been obtained and he has been able to evaporate from 11 to 12 pounds of water from and at 212 degrees Fahrenheit per pound of combustible. As a smoke consumer it would seem to be a [illegible] Fig. 3. [illegible]

Personal

Robert Thurston Kent has resigned as engineering editor of the *Iron Trade Review*, Cleveland, Ohio, to become managing editor of *Industrial Engineering*, Pittsburg, Penn., a new paper devoted to mechanical-engineering subjects. Mr. Kent has been with the *Iron Trade Review* since 1905, and prior to that time was associate editor of the *Electrical Review*.

The engineer and another were killed and a laborer injured by the explosion of a boiler at the [illegible] ice houses of the American Ice Company, at Farmingdale, Me., on March 14. The boiler was said to be 30 years old.

SATURDAY, MARCH 6, ON INVITATION OF THE MANAGEMENT, MEMBERS AND FRIENDS OF THE [illegible]

Anniversary and Presentation

The twelfth anniversary of the Engineers' Blue Club of Jersey City, N. J., was celebrated by an entertainment and ball at Columbia hall on Wednesday evening, March 17. An exceptionally good vaudeville program was followed by dancing. During the evening William Cronley called to the stage John J. Callahan and presented him a very handsome badge.

Business Items

The Dakota Gas, Electric Light and Power Company, Wagner, S. D., has purchased from the Minneapolis Steel and Machinery Company an 80-horsepower Muenzel producer-gas engine and suction gas-producer plant. This outfit will be installed in the electric-light plant at Wagner, where there is already one Muenzel unit in operation.

Tripp metallic packing, manufactured by William B. Merrill & Co., Boston, Mass., has recently been applied to the 48-inch plungers at the Dorchester pumping station, City of Boston. Two more sets of the same diameter are now in process of construction for the same station. The large diameters of these plungers demonstrates what this type of packing will do on this class of work.

The first fountain-pen plant in Canada has just been placed in operation by the L. E. Waterman Company, at St. Lambert, Que. The plant is entirely electrically driven, the current being generated on the premises. The generator is a Crocker-Wheeler belt-type three-phase 60-kilovolt-ampere 600-volt 60-cycle machine, running at 1200 revolutions per minute, furnished by the Canadian Crocker-Wheeler Company, Ltd., of Montreal. It is driven by a Bellis & Morcan English vertical engine. This machine was installed for immediate use, and the plant will be doubled before it is completed. The exhaust steam is used for heating the buildings.

Recently the Crocker-Wheeler Company has had a large call for direct-current motors. One of the largest orders of the year in this line is that received from the Sprague-Warner Company, Chicago, for 31 small motors ranging from ½ to 20 horsepower, and aggregating about 150 horsepower. An order for 21 motors for 1-5 to 10 horsepower to drive printing machinery has been placed by Clark & Courts, Galveston, Tex. The Pittsburg Steel Company, Monessen, Penn., has placed an order for two 75-horsepower 500-volt motors to drive draw benches. The American Auto Course Company, Chicago, has ordered 15 small motors of ¾ horsepower each, and the Newton Machine Tool Company has ordered a 22-horsepower adjustable-speed motor, with 1:2 speed ratio. An order for nine crane motors has been received from the King Bridge Company, of Cleveland. A large number of orders for single motors have also been booked.

The new 1909 catalog of the Nelson Valve Company, of Philadelphia, has been issued and contains 220 pages bound in cloth. The catalog shows gate, globe, angle and check valves made in large variety of metals. Among the new features are included the newly patented bronze, swing, check valves and hydraulically and electrically operated gate valves. The listing of steel gate and globe valves for high pressures and superheated steam marks a new era in high-class valve construction. Another new departure of note is the listing of open-hearth steel fittings. The use of engravings showing both inside and outside views is generous; the descriptive articles and dimensioned lists immediately opposite the engravings facilitate easy and critical study of each valve. Test pressures as well as the working pressures are given in each case, so that the valve user has a definite basis for selection of the valve he wants. While this catalog is extensively published, it is offered free on request of any reader.

The Morehead Manufacturing Company, of Detroit, Mich., has sold some of its Morehead vacuum traps for use in connection with steam-turbine service to J. G. White & Co., Inc., engineers and contractors, of New York, who employ this trap for draining the exhaust line between the turbine engines and the condenser at the new power plant of the Delaware & Hudson Company, Mechanicsville, N. Y. Two No. 4 Morehead vacuum traps are used at this plant, the two installations being in duplicate. These traps are used in conjunction with a 2000-kilowatt vertical turbine of the Curtis type. The inside dimension of the exhaust pipe is 7 feet 9 inches wide and 2 feet deep. The vertical distance from center of outlet to center of outlet is 25 feet 7¾ inches. The horizontal distance from face to face of the flanges of the exhaust duct is 9 feet 6 inches. The condenser is of the Worthington barometric-tube type. The approximate vertical fall from the receiver on the exhaust duct to the water line in the trap is about 8 feet. The tray discharges directly into the discharge conduit from condensers. The water of condensation discharged from the trap is thrown away. J. G. White & Co. have just completed a series of exhaustive tests in the working of these Morehead vacuum traps and report satisfactory operation in every respect.

New Equipment

The Philadelphia (Penn.) Warehousing and Cold Storage Company will build an eight-story cold storage and freezing plant as addition to the present plant.

The Toms River (N. J.) Ice Company has been incorporated by J. P. Haines, Chas. B. Mathis and Caleb Falkenbaugh to manufacture ice. Capital, $20,000.

The People's Electric Light and Power Company, Silver Creek, N. Y., is in the market for two gas engines, 60- and 80-horsepower. Henry H. Brand, chief engineer.

The Charleston Light and Power Company, Charleston, Miss., has been incorporated by J. H. Caldwell, W. B. Burke, E. D. Dinkins and others. Capital, $10,000.

The council of the city of Columbus has authorized the issuing of $45,000 bonds to install a 2000 kilowatt turbo-generator. G. H. Gamper is superintendent, department of lighting.

The Berkeley Ice and Storage Company, Martinsburg, W. Va., has been organized by George Showers, H. P. Thorn and others, to establish ice and cold-storage plant. Capital, $50,000

The Elizabeth & Perth Amboy Traction Co. is being formed to construct an electric railway from Elizabeth to Perth Amboy, N. J. Chas. A. Trimble, Elizabeth, N. J., is one of the incorporators.

The City Council, Tacoma, Wash., has authorized the Commission of Public Works to advertise for bids for furnishing two compressors, one air receiver and two electric motors for Station C.

Analysis of Steam and Inertia Forces

Inertia Forces of a Tandem-Compound Engine and Their Combination with the Steam Forces in Each Cylinder Expressed Graphically

BY F. W. HOLLMANN

In engines operating with a high piston speed, it is desirable to know how much the inertia of the moving parts affects the driving effort and the crank- and wrist-pin pressures. If an engine knocks on the centers, it is easily explained, but when a knock occurs in a later period of the stroke, it might cause some guessing. In starting and stopping the piston, with its rod and crosshead, energy is consumed and given up. The amount consumed is theoretically equal to the amount given up, and therefore should not affect the power of the engine, but in some cases the forces caused by the starting and stopping of masses moving at high speeds exceed the useful steam forces and cause parts to be subjected to great stresses. The accompanying diagrams show such a case which, although not very common, is of interest because the heaviest stresses exist when the lightest would be expected. A few words might be said in regard to the way in which diagrams of this sort are plotted.

If the mass of reciprocating weight were concentrated at the crank pin and considered to revolve with it, it would exert a centrifugal force which would be equal to

$$\frac{W v^2}{g R},$$

where

W = Weight in pounds,

v = Velocity of crank pin in feet per second,

g = 32.2, and

R = Radius in feet.

FIG. 1. METHOD OF OBTAINING INERTIA VALUES

Again, if the mass be connected to the crank pin by an infinitely long connecting rod, the mass will be accelerated from the inner center up to the 90-degree position, at which it will have its maximum velocity, and then it will be retarded until the 180-degree position is reached. At the zero and 180-degree points the force exerted by the positive and negative accelerations will be equal to the centrifugal force which would result if the mass revolved in the path of the crank pin. At any intermediate position the value of the force which will be required to give it the necessary acceleration will be equal to this same value times the cosine of the angle which the crank makes with the line through the inner and outer centers.

The length of the connecting rod, however, exerts an influence upon the value of these inertia forces. A formula representing these values can be deduced by the aid of calculus, which will give these values. The formula is

$$Force = \frac{W v^2}{g R}\left(\cos\theta \pm \frac{R}{L}\cos 2\theta\right).$$

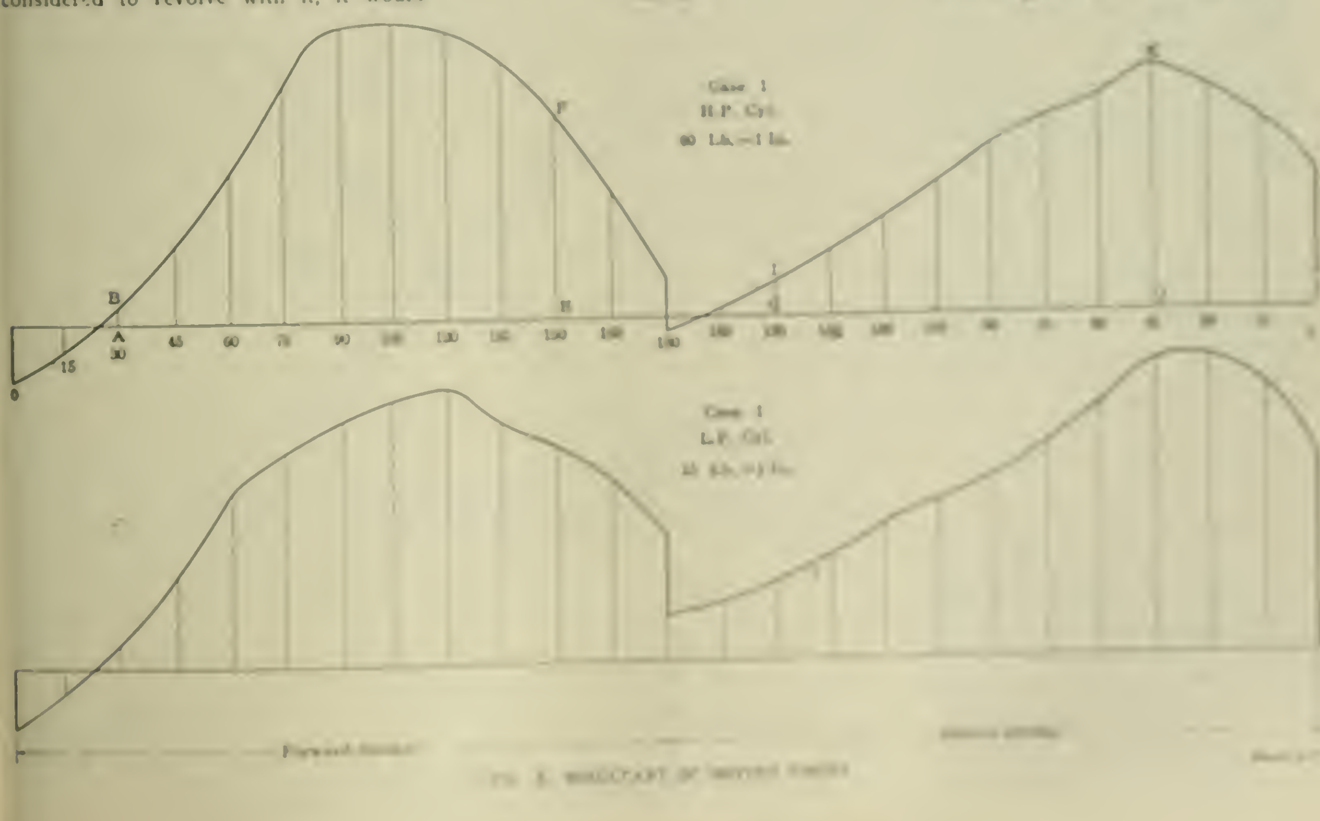

FIG. 2. [illegible] OF INERTIA FORCES

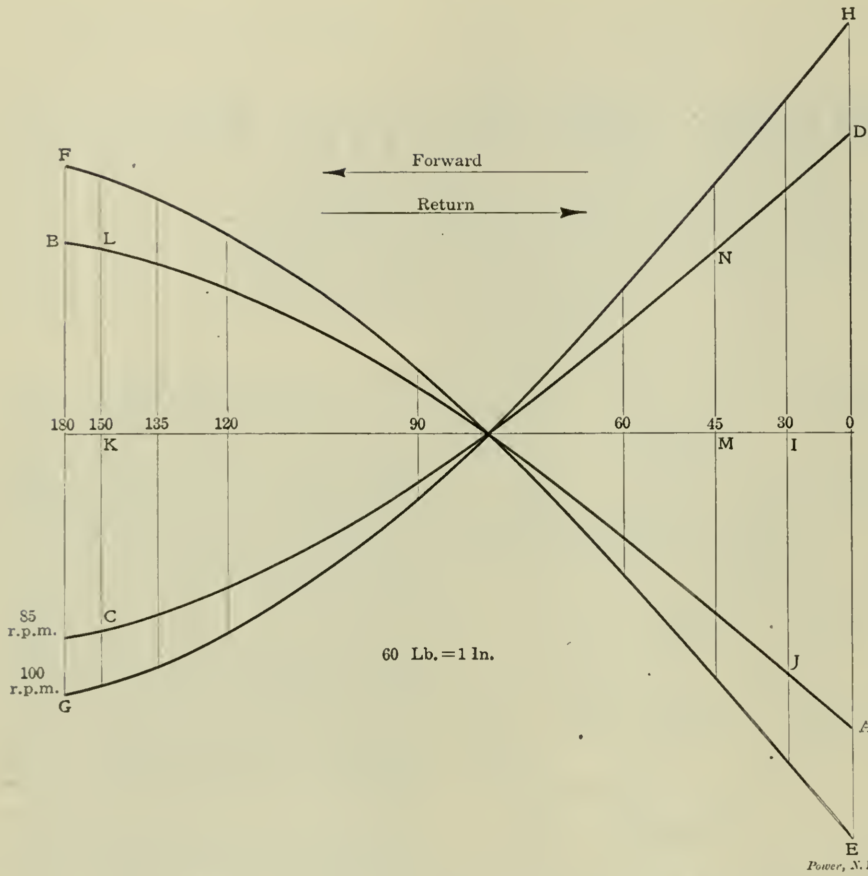

FIG. 2. INERTIA DIAGRAMS OF HIGH-PRESSURE RECIPROCATING WEIGHT

where

$\frac{W v^2}{g R}$ = Centrifugal force mentioned,

θ = Angle which the crank makes with the center line,

$\frac{R}{L}$ = Ratio of crank to connecting rod.

The sign + is used for the forward stroke and — for the return stroke.

Another formula which gives the corresponding piston position for the angle θ is

$$S = R\left[(1 - \cos\theta) \pm \tfrac{1}{2}\frac{R}{L}\sin^2\theta\right],$$

where S is the distance from dead center, + is used when measuring from the inner center and — when measuring from the outer center.

Substituting in formula (1) 0 and 180 degrees for θ gives

$$F = \frac{W v^2}{g R}\left(1 + \frac{R}{L}\right);$$

$$F = \frac{W v^2}{g R}\left(1 - \frac{R}{L}\right).$$

Let $\frac{W v^2}{g R} = F_0$ and in order to express the inertia forces in terms of pressures per square inch of piston area, divide the values by the area of the piston. Then

$$\frac{F}{A} = \frac{F_0}{A}\left(1 + \frac{R}{L}\right).$$

If a radius CA, Fig. 1, were taken equal to the value $\frac{F_0}{A}$ to the same scale as the indicator diagram, and a circle described, then solving equation (1), first dividing both sides by the area of the piston, for various angles of θ and plotting these values from the ends of the radii on lines horizontally as GK, a parabolic curve BOD would result. This will be nearly an arc of a circle, except for very short connecting rods. Having described the circle with radius CA, lay off

$$CO = DE = BF = \frac{R}{L} CA,$$

and through these points draw an arc of a circle DOB. Then for any crank angle GCI the inertia value GK is obtained, and for HCA the inertia value KH. The force GK multiplied by the area of the piston would be required to accelerate the reciprocating mass, and HK multiplied by the area of the piston would be required to retard the mass at its respective velocity, assuming the crank pin to revolve at a uniform rate.

To get the corresponding piston position for the angle θ, describe another circle with a radius equal to half the length of the indicator card, and from the point where the radius CG or CH inter-

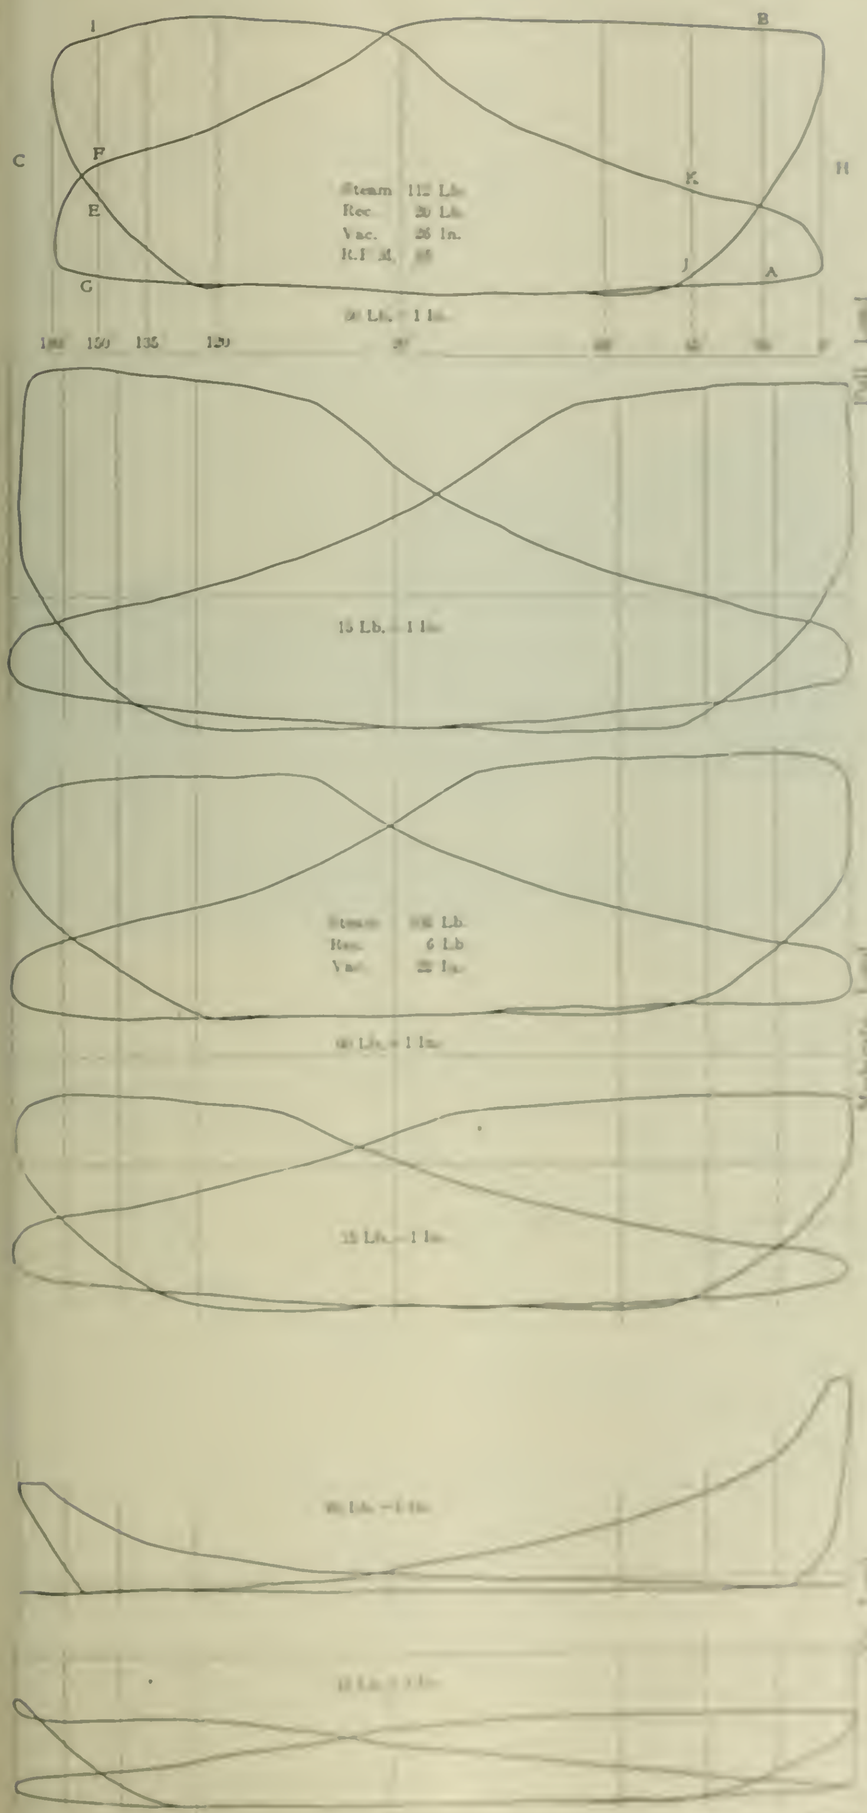

FIG. 4. INDICATOR DIAGRAMS FOR DIFFERENT LOADS

erty in taking the arc [illegible] equal to $\frac{L}{R}$ C N, the [illegible] of the arc being on the line [illegible] N produced. Then N I will give the piston position for the angle I C N and N E will give the piston position for the angle N C P.

Fig. 2 gives the inertia diagrams for the high-pressure reciprocating weights, which includes the piston, piston rod, half the connecting rod, crosshead and half the intermediate crosshead. The curve A B gives the values for the forward stroke and C D for the return stroke at 85 revolutions per minute. Similarly E F and G H give the values for 100 revolutions per minute. The values at the beginning are taken as negative and laid off below the line, because these forces are required to start the piston, while those later on are required to stop the piston, and therefore are considered as positive.

Fig. 3 gives the same diagrams for the low-pressure cylinder, whose reciprocating weight is half the intermediate crosshead, the piston, the rod and the tail-rod crosshead.

Fig. 4 gives the indicator diagrams for three different conditions. The diagrams were not all taken with the same valve settings, but that does not affect the analysis. Fig. 5 gives the forces which result when the steam and inertia diagrams are combined. In this figure the points are laid off in crank angles, while in Fig. 4 the piston positions are taken for corresponding crank angles. The steam force is measured from the back-pressure line of the opposite end and to this is added or subtracted the inertia force, depending upon whether it is positive or negative. Take the high-pressure full-load card in Fig. 4 and the inertia card of Fig. 2. In the forward stroke from the steam force A B the inertia force [illegible] is subtracted and the curve [illegible] in Fig. 5 results. Similarly the steam force [illegible] is added to the inertia force [illegible] and [illegible] in Fig. 5 results. So also in the return stroke [illegible] is subtracted from [illegible] and [illegible] is added as [illegible]. Similarly the low-pressure card is combined with its inertia diagram. The high- and low-pressure diagrams are then combined by adding each corresponding pressure and inertia

MAXIMUM CRANK AND WRIST-PIN [illegible]

[illegible]	[illegible]	[illegible]	[illegible]

tiplying it by the piston area in each case and adding the resulting values together.

Fig. 6 gives the results of the three cases. The table on page 625 gives the maximum crank- and wrist-pin pressures in the different cases. The wrist-pin pressures are a trifle larger than they should be, because half the connecting-rod weight was taken as the reciprocating weight. The crank-pin pressures are a trifle low, because the centrifugal force due to the revolving weight of the rod was neglected.

Fig. 7 gives diagrams of the points of maximum crank-pin pressures and points at which pressure reversals take place.

Standpipes on a Water Power Supply

By W. E. Crane

Several years ago the writer was called upon to solve a problem in hydraulics on a water power plant, which is of sufficient interest to warrant a description.

There were two pipes, each 7½ feet in diameter and 3000 feet long, the total head being 102 feet. Attached to one pipe were two 1000-horsepower wheels and a 45-horsepower exciter wheel; and to the other, a 1000-horsepower wheel, two wheels for lighting, two for direct-current power and another exciter wheel. The wheels were 17 feet above the tail race, so that they were 85 feet below the crest of the dam, and the total head was made up by the draft tubes.

The wheels were all direct-connected to generators and the exciters, the large wheels to alternators and those for railroad work and extreme varying loads to direct-current generators. The pipes were brought to the generator house by a civil engineer and there the writer took them and applied them to the power and it became his duty to take care of the thrust of the water when the regulators closed.

There were but two of the large wheels and one direct-current wheel on variable load running at one time. The point that could be expected would be a velocity in the pipes of 4 feet per second, but usually not over 2 feet per second was obtained. There was none too much water during a portion of the year, and it was important that as little as possible should be wasted.

It was finally decided to erect a standpipe 6 feet in diameter for each pipe. The question was, how much higher than the crest of the dam should be the top of the pipe? With a flow of 2 to 4 feet per second, 85 feet head and 3000 feet of flowing water, ought the draft tubes to be taken into account? It was finally concluded that if the pipes were 10 feet higher than the crest of the dam there would be no [illegible] loss of water and no serious water hammer. At this time the power [illegible] manufacturers objected, saying that if the head was going to change so fast every time one or two gates stopped, he would not guarantee to [illegible] the lighting wheels, so the light was finally compromised on, 10 feet above the crest of the dam. This worked out very well, as the pipe overflowed but two or three times a day and the loss of water was but a small percentage. There was more trouble, however, in cold weather when ice formed on the top of the standpipe and prevented water from overflowing for a week, or until the pressure was great enough to [illegible] out the ice.

It is interesting to note that in recent installations standpipes are becoming general, and that their value has been improved by adding a large tank at the top, which would secure a very [illegible] change in head. [illegible] In the case of the two 7½-foot pipes, an expert recommended [illegible]

FIG. 1. THE TWO 7½-FOOT PIPE LINES

FIG. 3. [illegible]

FIG. 2. LAYOUT OF PIPING FROM DAM TO PLANT

FIG. 4. [illegible]

vents, and these were installed, although the writer advised pipes at least 5 feet in diameter, as the temperature in that locality was liable to be 20 degrees below zero for a month at a time.

One night it was proposed to shut off one of the pipes, and a man going that way volunteered to close the gate at the dam. The chief electrician took it upon himself to open all the gates on that pipe to draw off the water as quickly as possible. It so happened that both vents were frozen up, and about 300 feet of the pipe near the dam, which was ¼ inch thick, collapsed into the form shown in Fig. 3.

Explosion of a Rendering Tank

Herewith are the particulars of an explosion of a rendering tank at the plant of the St. Louis Hide and Tallow Company, St. Louis, Mo.

The explosion occurred at about 4 o'clock in the morning. There were ten tanks, fed from a boiler, the safety valve of which was set at 45 pounds, the tanks being operated at a pressure of about 40 pounds. It was No. 1 tank which exploded, and an examination showed that the tank apparently failed at the vertical seam, as it was found that the metal along this seam was so reduced by corrosion as to be only about 1/16 inch thick. The plate was torn down the seam in question, outside of the calking edge, nearly the full length, from about 3 feet from the top to and around the bottom head, which was blown some distance away. The original thickness of the plate was ⅜ inch. The damage will amount to at least $20,000. Fig. 1 shows the wrecked condition of the plant. Fig. 2 shows the torn condition of a section of shell.

It was arranged to inspect the tanks a week before the accident, but for some unknown reason the tanks could not be given to the inspector. This risk had just been assumed by the Casualty Company of America, and had heretofore been carried by another inspection and insurance company. It is stated that the reports on file at the plant showed that no internal inspection had been made of this particular tank since June, 1908, and it was reported at that time that the shell plates and rivet heads in the tank which exploded were deteriorated.

Some Notes on Firing Boilers

By Victor White

The working of boiler fires, while much more a matter of practical experience than theory, is governed by certain rules. The furnace fire acts at the same time as a gas producer, a gas igniter, an air filter and a refuse holder. It is by bearing this in mind that the rules for firing are evolved. Other things being equal, gas is much more readily liberated from coal the smaller the size of the lump. For this reason dust firing, i.e., blowing powdered coal with an air blast into an incandescent chamber, has been recommended. Washed slack, however, forms a good fuel for furnace fires. Large coal, by inclosing the gas until the lump breaks open, acts as a gas retort, and unless the coal cleaves or opens out very evenly, irregular admixture of gas with air and possible smoke is produced. This particularly applies to coking coal. Lump coal is more unwieldy to handle than slack, and extra labor has sometimes to be employed in breaking it up into sizes small enough for convenient firing. On the other hand, the interstices between slack coal are smaller than in lump; the air has more difficulty in passing through; the use of small coal necessitates the reduction of the spaces between the firebars to keep the coal from falling into the ashpit; too strong a draft is not permissible for fear of carrying the smaller particles into the flues; hence a very thin "filter bed" of coal to obstruct the air must be maintained.

Thin Fire Essential with Small Coal

Since the fires must be kept thin with slack coal, more skilful firing is required than with thick fires of lump coal; any irregularity of firing produces weak places in the fire, which later develop into holes under the action of the draft, letting colder air (which will obviously pass in greater quantity through the weakest resistance) pass the fire without penetrating the incandescent material. A thin, even fire is essential in using small coal. The thickness varies with the intensity of draft and quality and size of coal used (not with load on the boiler), but after being experimentally determined should be strictly adhered to. With a draft of 1/2 inch and good anthracite slack, a depth of about 4 inches of fire is necessary. Increasing the depth by injudiciously heavy firing chokes the fire and is a sure method of dropping the pressure. In hand firing the correct method of stoking small coal is to distribute it in light sprinkles, by slightly twisting the wrist of the hand holding the shovel handle at the moment of firing, over the grate in an even shower. Eight or ten shovelfuls are sufficient at each firing over a grate area of 30 or 36 square feet, the firings succeeding each other at intervals necessary to keep steam and therefore varying with the load. Firemen must be carefully watched on this point; their tendency, particularly when from the navy, is to fire heavily and then take a quarter of an hour's spell, producing in this way much smoke and waste.

Close Grids on Firing Doors

Another practice in frequent use which leads to inefficiency is that of opening the grids on the firing doors of the furnace front, allowing cold air to draw in over the fire, with the object of mixing this air with unburnt gas and avoiding smoke. The diminution of smoke, where effected, is gained at the sacrifice of furnace temperature unless the grate area is too small to allow a sufficient quantity of air to pass through; the proper way to produce smokeless combustion is to keep the correct thinness of fire all over the grate, and to fire lightly and often. Where the furnace is divided into two grates, alternately firing one grate and then the other gives the best results, one fire being incandescent when the other is emitting unconsumed gas, and causing its ignition, and water circulation in the boiler also appears to be improved. The admission of air during hand firing cannot be avoided; it is seen that quick handling of shovels tends to economy.

Avoid Frequent Changes in Variety of Coal

The behavior of the coal in the fire should be carefully studied. Bituminous coking coal is apt first to form slabs of semi-molten material, and then to break into fissures allowing cold air to pass through. It therefore requires slicing or mixing occasionally; still more does a coal having a heavy proportion of clinker. On the other hand, anthracite gives a good clean ash and little clinker, needs very little slicing; disturbance of the fire would send unburnt fuel through the firebars. Coking coal is sometimes pierced with the poker.

In using fuel giving intense local heat, such as coke or hard anthracite, it is well to have the ashpit supplied with a water tray, the downward heat of the fire slowly evaporating this water. The steam passing up through the firebars will keep them from overheating, especially if they are thin and deep. Long flaming coals, whose heat is developed to a large degree away from the fire, do not need this precaution, and if possible it should be done without, as heat is wasted in superheating the steam so generated.

In considering the claims of those furnaces which induce a strong draft of air through the fire by means of steam blowers, it must be borne in mind that the advantage of increased circulation of air is to some extent neutralized both by the waste of high-pressure steam and the loss of fuel energy in dissociating that steam. It is worth noticing in passing that to mix two different qualities of coal is not usually satisfactory. Anthracite and bituminous slack do not, for example, burn well together, as they require different treatment.

Frequently changing from one variety of coal to another should be avoided; it is always found that a particular coal will burn best in a certain type of furnace. Boilers having cramped space above the grate, for example, give their best performance with coal giving intense local heat and little flame, such as anthracite, while boilers having ample combustion space go best with long flaming coals. Change of coal probably means alteration of the furnace, at the very least as regards pitch of the firebars, and in the writer's opinion the difficulty of getting a fireman to alter his method of stoking with one class of coal given to him, and the ensuing waste until he has learned how to handle it, is often underestimated by boiler managers.

Cleaning Fires

The dampers and the air doors together provide an efficient means of following the load with the fires by means of draft, combined with intelligent firing. The dampers should be the rough adjustment, the air doors the fine. The firing performance must always be judged in relation to the steam pressure and water level. A good steam line should be kept on the pressure chart without blowing off at the safety valves or undue checking and shutting of boiler-feed valves. When the coal clinkers on fixed grates the disposal of this incombustible is sometimes difficult. The top layer of burning material must first be removed, either by pushing back or "winging" the fire. The first method consists of piling up the burning coal at the back of the grate, exposing the clinker; the latter is pushing the fuel to one side and then the other of the grate, leaving the clinker of each half uncovered. This clinker is then pulled out through the front doors of the furnace by means of the rake, when it is quenched with water. In the pushing-back method the clinker under the coal must be dislodged and dragged out as well as possible by the slice and rake.

Before cleaning a fire it should be burned down as much as possible, the bulk of the firing being done on the other boilers. In any case the damper and bottom air doors should be shut while the fires are laid bare. It is obvious that quickness in this work is of first importance. In the writer's experience two men were able to clean 114 square feet of grate area in ten minutes, heavy fires having been carried previously. This included turning the fires back and removing the "bars." No attempt was made to clean the clinker off the furnace bricks, and the coal used was fairly clean. In case the clinker sticks to the firebars and bricks of the furnace, the slice must be used to detach it. Care must be taken not to bring down any of the brickwork, which may have become loose through alternate expansion and contraction, in this operation. A fire whose waste material is almost pure ash will not require much disturbance, the ash, if small, mostly clearing itself through the firebars, especially if helped occasionally with the poker.

The intervals required between cleanings are gaged by experience, being dependent on the class of coal used and the loads carried by the boiler. As the time for cleaning approaches the fireman will experience more and more difficulty in keeping his steam without excessive slicing and poking of the fires. Not more than one grate in a twin boiler, or bank of boilers, should be cleaned at one time.

Banking Fires

When a boiler is taken out of action the fires are slackened until the coal on them is consumed, the dampers being gradually closed. If the boiler is not required again, the ash and clinker are drawn and quenched, the air and firing doors being then closed up. If the boiler is shortly wanted for work again the fires should be banked. After cleaning and closing the damper the fire should be completely covered with a layer of fresh coal about 3 inches deep, the front doors being then closed. The fire is sometimes drawn together into a heap. This will then smolder, and, with the addition of a few shovelfuls of [illegible] every few hours, will keep the furnace warm until a fire is again required. The man in charge of the boilers should [illegible] determine for himself the number of hours that a fire can be banked [illegible] without undue [illegible]. He must take care to ensure that a fire that has been banked [illegible] is not closed too long [illegible]. The danger of [illegible] acute when the damper doors are perfectly air-tight—a condition unfortunately not often realized owing to the warping action of the heat on sheet metal. Should such danger be apprehended, however, a small hole may be drilled in the damper, and the air holes in the firing doors be left a little open, to sweep away all gases generated.

Mechanical Stokers

These are divided into two classes according to their method of working, "sprinkling" and "coking" stokers. The former attempt to imitate the light sprinkle of coal given equally to all parts of a fire by a skilled fireman. The general method of regulation is the same as for hand firing, the only difference being the substitution of machine for hand labor. The second type of stoker adopts the more scientific method of dividing the gas production from the gas ignition. The coal is fed steadily into the furnace from the front of the firebars, being deposited on a dead plate, and is then gradually carried backward by a movement of the bars, until the unconsumed remainder falls over the back end of the bars into the pit.

On first entering the red-hot furnace the coal is heated and its volatile gases given off, the fixed carbon and incombustibles remaining. These gases sweep backward along the fire and upward to the heating surfaces, and the portion of the coal which has been for some time in the furnace, and which is now coked and incandescent, ignites the gases, the sheet of flame spreading up against the heating surfaces. By this gradual and systematic ignition the full heat value of the coal is realized. The main duty of the attendant on a coking stoker, when it is in good order, is to proportion the rate of feed of coal onto the bar and the rate of travel of fuel to the ashpit to the load carried by the boiler; to see that no unconsumed fuel is carried over to the ashpit by too quick a travel, and to make sure that the coal on falling onto the dead plate really does ignite. For this latter purpose inspection doors are provided in the front or side walls of the furnace.

The saving of labor may be roughly gaged by the fact that whereas a skilled fireman could not well dispose of more than two tons of slack coal per hour on a peak load, doing nothing else but firing, and would be exhausted if worked at this rate for eight hours, a man working with mechanical stokers in good order can continuously dispose of seven to eight tons per hour, his duties including the disposal of ash and clinker (if the ash heap is not far distant) and the regulation of feed water.

The method of starting fires in a mechanically stoked boiler is the same as for a hand-fired plant. With dampers a quarter open several shovelfuls of brightly burning coal are fed equally over the bars, or kindlings of wood, oily waste and paraffin may be used, and the furnace lightly hand fired, the dampers being opened a little as the fire increases. The automatic gear is then put into operation. Mechanical stokers, though not so flexible as hand firing, can with proper supervision be made to follow sharply varying loads, such as are met in electric-light and power stations, with entire satisfaction.

Catechism of Electricity

1010. *What is the test for voltage in the supply wires?*

Connect a voltmeter across them and see if there is a deflection of the pointer. If a voltmeter is not at hand and the current is normally supplied at 220 volts, connect two ordinary incandescent lamps in series and then connect them temporarily across the supply wires. If they light, the current supply is all right; if they do not light and their filaments are not broken, there is no current in the supply wires or the voltage is much too low. On a 500-volt circuit five lamps must be used in series instead of two.

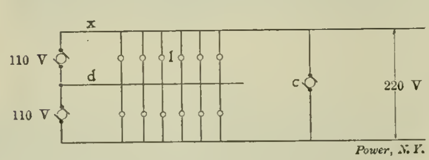

FIG. 285. DIAGRAM SHOWING HOW A MOTOR MAY OPERATE UNDER MISLEADING CONDITIONS ON A THREE-WIRE SYSTEM

1011. *What is the method of procedure in case the motor is improperly connected?*

If the motor fails to start by reason of being improperly connected, its armature can be freely turned by hand; the connections, however, may all be secure and there may be current in the supply wires. If the field circuit of a shunt-wound motor is properly connected, the pole pieces should be strongly magnetic when the main switch is closed. Farther than this no definite rules can be given that will apply in every case. Unless the attendant is perfectly familiar with the wiring of the particular motor giving trouble he should consult the diagram of connections accompanying the machine and from it learn if the connections are as they should be.

1012. *On a three-wire system is it not possible for lamps to burn properly but the conditions of the circuit to be such as to prevent the running of a motor?*

Yes. If one of the two generators supplying the system becomes reversed, both the outside wires of the supply circuit will be of the same polarity. Although lamps connected between either outside wire and the center wire of the system will light, a motor connected to the outside wires of the system will not run.

1013. *Are there any other misleading conditions of a similar nature on a three-wire system?*

Yes. One of the outside wires of a three-wire system, Fig. 285, may be open at *x* and yet a motor *c* connected beyond the break may get current at 110 volts through the lamps *l* connected between the outside wire on the same side as the break and the center wire. A 220-volt motor operating in this way will not be able to run anywhere near full speed owing to the supply voltage being 110 instead of 220, and the resistance of the lamps *l* being in series with it.

The center wire *d* of a three-wire system may be open and yet not affect the operation of a motor at *c* because the motor is connected to the outside wires only.

1014. *If it is suspected that friction trouble is preventing the motor from starting, what should be done?*

The cause of the friction should be ascertained and removed as previously instructed, before an attempt is made to run the motor. In starting up a motor after a trouble of this kind, it is advisable to switch on the current just long enough to see if the trouble has been entirely removed before leaving it on permanently.

1015. *What are the indications that the motor will not start on account of too heavy a load?*

The fuses melt or the circuit-breaker operates; an ammeter connected in circuit with the motor indicates a larger current than that required by the motor at full load; the insulation on the armature begins to smoke. An overload on a series-wound motor does no harm, as the motor will start up as soon as the load is reduced. On a shunt-wound motor, however, an overload is a more serious matter because the armature is liable to burn out.

1016. *What should be done when it is found that the motor will not start by reason of too much load?*

The main switch should be opened at once and the load reduced. If the fuses have melted they must be replaced with new ones, or if the circuit-breaker has opened it must be closed, before closing the main switch preparatory to starting up under a smaller load.

Tube Tiles Used to Form Furnace Roofs

Encircling the Lower Row of Tubes in a Water-tube Boiler with Refractory Firebrick Tiles to Increase Efficiency and Prevent Smoke

B Y   A .   B E M E N T

When the fire is located directly under the exposed tubes of a water tube boiler, the volatile gases arise immediately among the tubes, with the result that the temperature of the gases is so quickly reduced that no further combustion takes place. In this way a large amount of smoke is produced, especially if high volatile coal is used, and at the same time a considerable heat loss results from the failure to burn all of the gas. This fact is one that has been recognized for many years, but it is only within the last five or six that a systematic attempt has been made to correct the condition by better furnace construction. A scheme now extensively employed for this purpose consists in encircling the lower row of tubes in the boiler with refractory firebrick tiles, which produces a furnace roof equivalent for all practical purposes to that of a firebrick arch, under which combustion of the gases takes place, so when the fuel is fed at a reasonably uniform rate, the volatile gas is entirely burned. Thus not only is the full realization of heat secured, but there is no production of smoke.

The tiles employed are usually 1 foot in length and of a width sufficient to cover one-half of a tube; thus two tiles are required to inclose the tube for each foot of its length and, joining together back to back, fill the space across the boiler, while additional rows give the requisite length to the roof, a space being left at the back end of the roof, so that the gases, after having passed underneath, may enter among the tubes of the boiler at its rear. This scheme of employing tiles applied in this manner, originated in Chicago some six or seven years ago with W. L. Abbott, the operating engineer of the Commonwealth Edison Company. The initial application was to Heine boilers, shown by longitudinal section, Fig. 1, and cross-section, Fig. 2, wherein the tile roof supported by the lower row of boiler tubes is clearly indicated. Another feature not found in the regular Heine boiler is a gas baffle which rests upon the lower row of tubes from the tile roof as shown. While this gas baffle had no connection with the tile roof, its purpose [illegible] in the illustration [illegible]. It was first inserted by Mr. Abbott with the object of improving the efficiency of the boiler, or in other words [illegible] capacity [illegible] increase of efficiency obtained of about 10 per cent., while at the same time the capacity was increased about 5 per cent. over what had been obtained before that gas baffle was inserted.

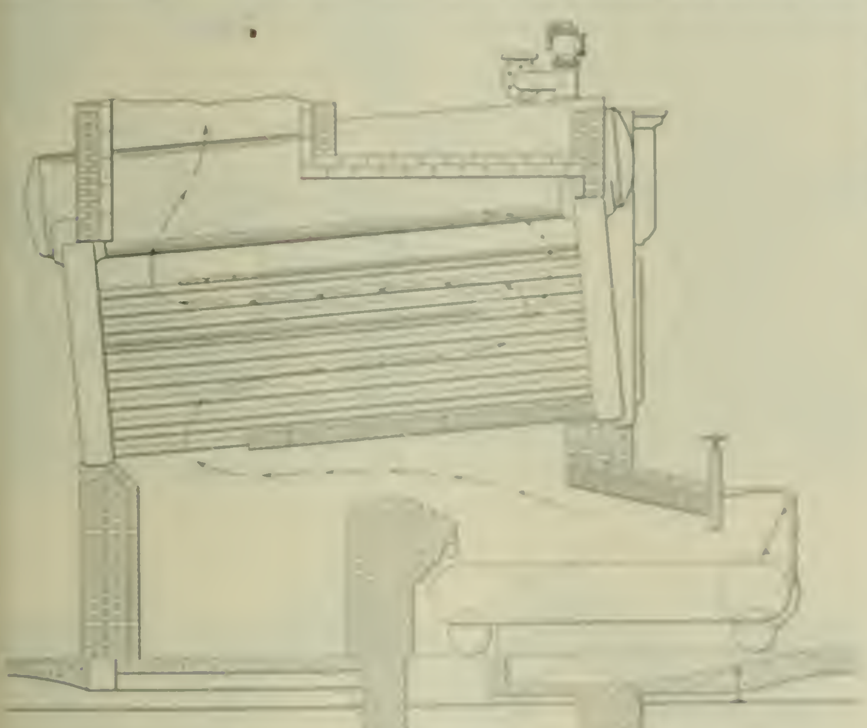

FIG. 1. ORIGINAL APPLICATION OF TILE FURNACE ROOF TO WATER-TUBE BOILER

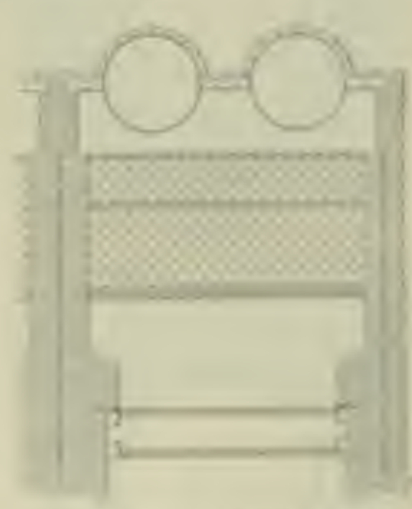

FIG. 2. TRANSVERSE SECTION OF BOILER

The original design for tiles is shown by Fig. 3. The trouble attendant upon the employment of these tiles, not only as affecting combustion and lessening smoke, however, but protection afforded the tubes of the boiler, caused the makers of the boiler to design, adopt and install a tile shown in Fig. 4, which has been extensively employed and called a C tile. The small amount of stock used in the lower part resulted, however, in a section so thin as to cause the tile to soon fail by breakage, as illustrated by Fig. 5. This led the writer to make the design shown in Figs. 6 and 7, designated as an encircling tile, which has come to be extensively used.

The wear of these roof tiles is not uniform, some of them being exposed to higher temperature and greater strength than others, which results in an irregular wearing away, and [illegible]

8, 9, 10, 11 and 12. It is semicircular in shape, in order that it may be put in place of a single pair of encircling tiles. Thus if the roof fails at one point, the damaged encircling tiles may be removed with no other disturbance, and the round repair tile substituted. The first operation after the encircling tile has been broken out and removed is shown by Fig. 8, one of the tiles being set in place below the tube. It is then turned around until it rests on the top of the tube as shown in Fig. 9, after which the lower part is added as shown by Fig. 10, then both tiles are revolved into the position shown by Fig. 11, which also shows the repair as it would appear in the roof in series with the encircling tile.

Many other designs of roof tile have been made by various people for application to different boilers. Fig. 12 illustrates one reported to have been used on boilers, it consisting of blocks supported by an iron stem molded therein and held in place by a rod, passing through a hole in the stem and hanging across from one tube to another. To the writer's knowledge, however, this scheme has never been permanently employed. The tile which the Babcock & Wilcox Company has recently adopted for use on its boilers is the writer's design, shown by Figs. 6 and 7. The Babcock & Wilcox and the Heine boilers, having a tube spacing of 7-inch centers, with tubes of 3.5- and 4-inch diameter, allows the use of the designs of tile previously mentioned. There are boilers, however, where the tubes are spaced more closely together, for which some different form of tile is required, and Fig. 13 illustrates the form employed by the Lyons Boiler Works, consisting of a tile of the cross-section shown and about 1 foot long, having a thin section extending up between the tubes, held in place by an iron rod which is passed through a hole in the upper part of the tile and resting across the tubes.

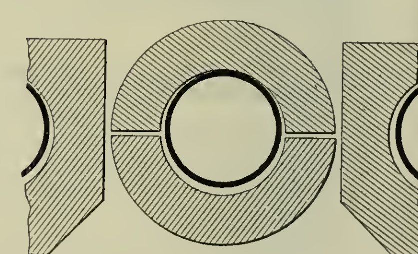

FIG. 10. SHOWING ADDITION OF SECOND PORTION OF REPAIR TILE

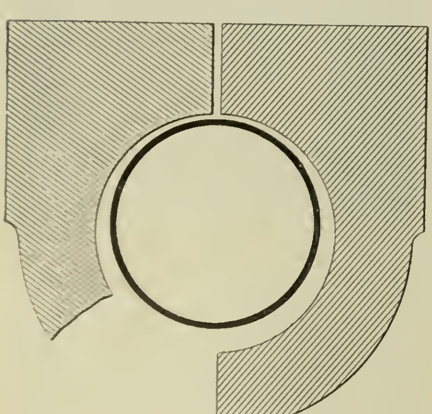

FIG. 5. COMMON FORM OF BREAKAGE OCCURRING WITH C TILE

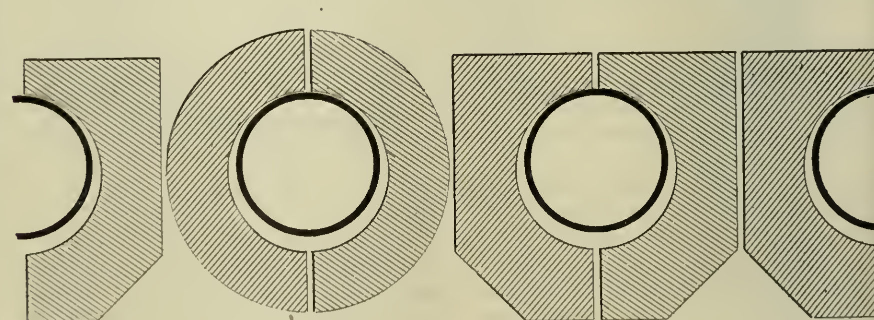

FIG. 11. ENCIRCLING TILE ASSEMBLED IN POSITION IN FURNACE ROOF

The form used by the S. Freeman & Sons Manufacturing Company, in Racine, Wis., is illustrated by Fig. 14, which shows a design requiring only one tile for completely covering the tube. Fig. 15 is a design made by George L. Dieterich, of the Chicago Retort and Fire Brick Company, which shows a tile suspended by a hook-shaped upper section, which hangs from the tube. In the formation of furnace roofs with these tiles, they are first applied individually to the tube at the rear, and then moved forward into place. Experience has shown that when made from good material of the proper shape they have a long life, and their use is attended with satisfaction. It is necessary, however, to call special attention to the fact that it is requisite to specify a clay which is of high grade and not easily fusible. It is also [illegible] that care be taken by the maker to prevent the shape of the tiles being distorted in handling between the molds and the kiln, so as in this way good tiles may be easily ensured. Bracing Dome Heads

By [illegible]

While the steam dome is considered by [illegible] as a [illegible] to a steam boiler, [illegible] it is still [illegible]. When a flat head is used the bracing of the head

FIG. 1

is almost invariably as illustrated in Fig. 1. This type of bracing has been advocated by practically all authors on the

FIG. 2

subject of boiler construction, and the writer is not aware of any who have advised attaching the braces to the portion

FIG. 3

of the shell inclosed by the dome, as illustrated in Fig. 3. This portion of the shell [illegible] attached to this portion of the shell, they should be considered valueless. The writer believes that the above views on this form of bracing have been the result of following the lead of someone who was considered an authority on the subject, without any attempt at analysis of the stresses that are actually present in this form of construction. It is also believed that head braces attached to the neutral surface, as in Fig. 8, are actually an improvement over the customary method of attaching them to the shell of the dome.

In the first place, domes are relatively short compared to their diameter, mak-

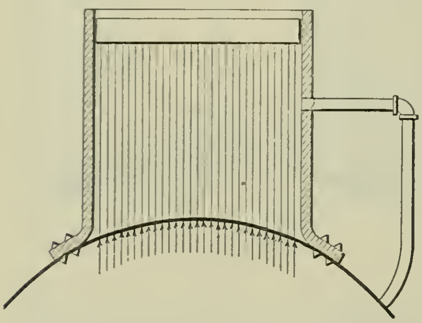

FIG. 4

ing the use of short braces necessary. The feet of the braces are required to be located well in toward the center of the head to get proper distribution, and the resulting angularity of the braces detracts considerably from their holding power. Again, there is a decided tendency to leak at the joint where the dome is attached to the shell, due to distortion of the shell at this point, and after a leak has once started it is extremely difficult to stop

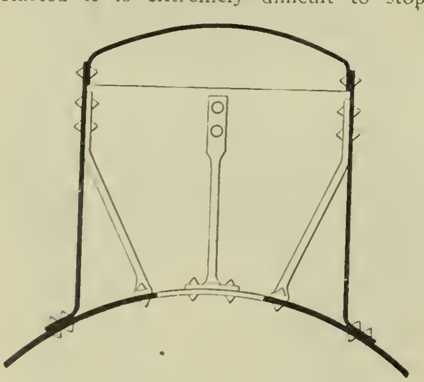

FIG. 5

owing to the continual working of the surfaces. One of the principal causes for distortion at this seam is the lack of support of the neutral surface to keep it of true cylindrical form, the stresses in the shell at the sides of the dome, as may be seen from Fig. 2, tending to pull the neutral surface out flat as indicated by the dotted lines. This causes a bending action along the flange of the dome where it is riveted to the shell. That flexure at this point is the cause of leaking is also indicated by the great superiority of a double-riveted seam over a single-riveted seam for tightness, the double row of rivets adding to the stiffness of the construction considerably.

If the neutral surface could be supported so that it would retain its cylindrical form, as effectually as the pressure supports the other portions of the shell, there would be no tendency for the connecting seam to be distorted and the only weakening effect introduced would be the removal of the metal for the rivet holes, or the conditions would be identical with those which would exist if a circular patch the same size as the dome had been riveted on at this point.

To illustrate how head braces attached to the neutral surface may approximate this condition, assume a shell, as illustrated in Fig. 3, with a cylinder similar to a dome riveted to the top of the shell but with no communication from the shell of the boiler to the dome space. If the inside of this cylinder was bored out, it could be fitted with a piston free to move up and down. Assume that each square inch of piston area is connected with each square inch of the projected area of the neutral surface by a rod screwed through

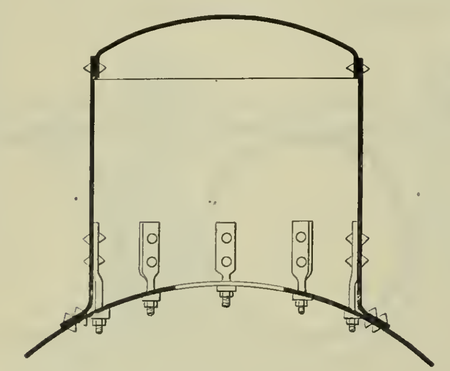

FIG. 6

the shell and into the piston. If it is now assumed that the boiler is under 100 pounds pressure, but with no pressure in the dome space, the portion of the shell under the dome would be pushed outwardly with a pressure of 100 pounds on each square inch of area, as indicated by the arrows, the same as the other portions of the shell, and there would be no tendency to deform if the shell was a true cylinder at the start.

Suppose now that the valve on the pipe communicating with the dome space were opened and pressure admitted. The conditions as regards the portion of the shell beneath the dome will remain unchanged, as long as the stay rods care for the pressure admitted to this space, for no matter whether the pressure is in excess of, or less than the pressure in the boiler, it will place only a tensile strain on the rods, and the neutral surface will be in equilibrium as regards the pressure in the dome, and there will be no tendency for it to assume any other shape than its original form.

If it is now considered that instead of the pressure in the dome coming from some external source, it is connected with the boiler shell as shown in Fig. 4, conditions would be obtained similar to boiler practice, except that the opening instead of being through a pipe connection is cut in the shell directly into the dome. It is seen that the surface of the shell inclosed by the dome, instead of being neutral, is actually forced out with the same pressure that any other portion of the shell of similar size is, and the tendency to deform is therefore eliminated. Of course the head of a dome does not offer the same flexibility as the piston head con-

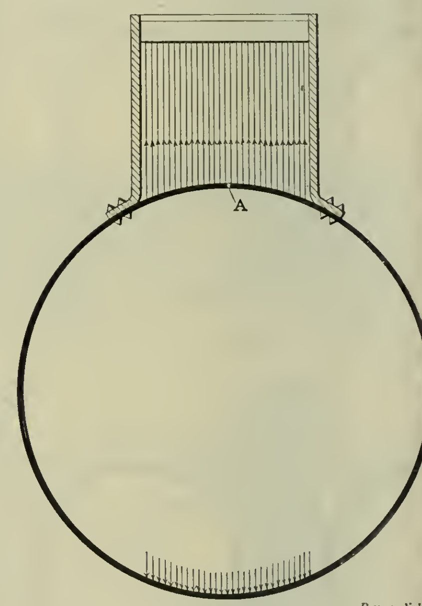

FIG. 7

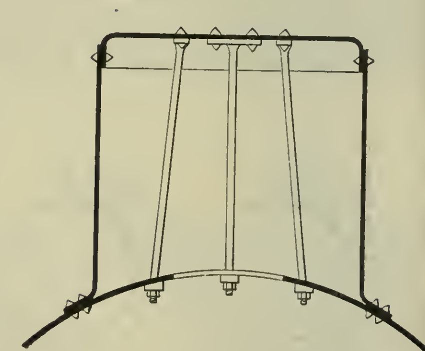

FIG. 8

sidered, and the dome shell must transmit a large portion of the pull due to pressure on the dome head to the shell of the boiler. However, the writer believes that if the braces required on the head were attached directly to the so-called neutral surface of the shell, the tendency for the shell to deform and produce leaking at the dome flange would be greatly lessened. A form of bracing that would accomplish the same result as regards the neutral surface, where it is desired to use a bumped dome head which is not braced, is shown in Fig. 5.

The method of bracing shown in Fig.

6 is often met with in high-pressure boilers which are equipped with domes. These braces accomplish in a very limited way what the braces shown in Fig. 5 are intended to do, but it is evident that they are not used with this purpose in view.

Another way of looking at the problem of the stresses involved in this construction is illustrated in Fig. 7. Here *A* is a hole drilled through the shell and communicating with the dome space, and although the pressure on each side of the neutral surface is equal, there is a pull on the rods of 100 pounds per square inch of piston surface (assuming the pressure in the shell to be 100 pounds), which produces the same effect in retaining the cylindrical form of the neutral surface as a like amount of pressure beneath the surface would. The pressure on the piston is balanced by the pressure on a similar area on the other side of the shell, as indicated by the lower arrows.

A new engineers' organization was formed on January 25 last at Baltimore, Md., known as the Engineers' Exchange, its home being at 413 Fayette street. The present membership is 150, with applications constantly coming in. The aim of the Exchange is to bring engineers of all of the associations into closer relations. The first floor of the building has been fitted up as a reading room, in which spaces are rented to various manufacturers and supply houses as a permanent exhibit.

On the evening of March 22 the Exchange was formally opened, with an appropriate social session. The officers are George L. Sleight, president; James Gardner, first vice-president; D. J. Murray, second vice-president; H. A. Phillips, secretary; H. A. Kries, treasurer.

The Elektra Steam Turbine

By Frank C. Perkins

A new type of German steam turbine has recently been constructed for operating direct- and alternating-current generators, ventilators and pumps, as well as for boat service, which is of more than passing interest. The accompanying drawing, Fig. 1, shows a single-casing steam turbine of this type, designed to work with a condenser, while Fig. 2 shows a double-casing compound turbine for operation with condensers. The details of construction of the single-casing turbine are shown in Fig. 3. This turbine was designed and constructed at Karlsruhe, in Baden, Germany, by the Gesellschaft Fur Elektrische Industrie. The Elektra turbine is essentially a high-speed steam turbine and means for reducing the speed is frequently necessary for boat service, and for the operation of machinery in [illegible], while for driving dynamos the maximum

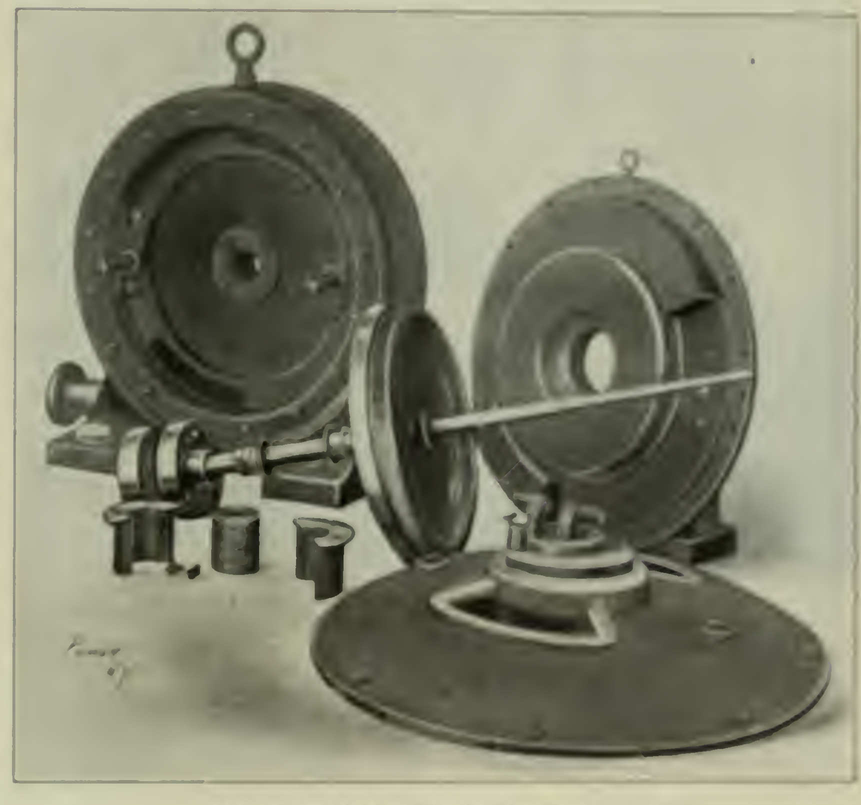

FIG. 3. DETAILS OF SINGLE-CASING TURBINE

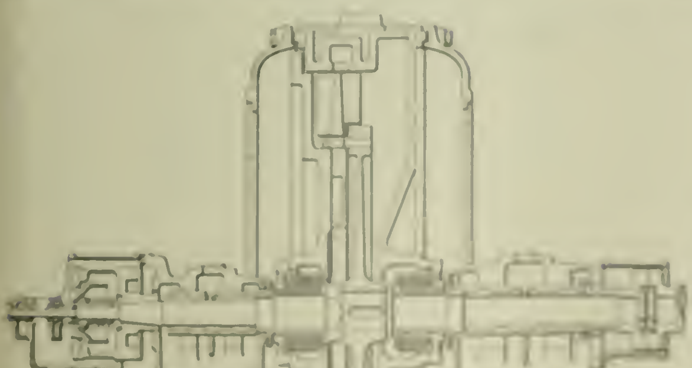

FIG. 1. SINGLE-CASING TURBINE

FIG. 2. [illegible] TURBINE WITH TWO CASINGS

may be directly coupled and operate successfully at the high speeds required.

The two turbines shown in Fig. 4 are of the compound type, each having a capacity of 100 horsepower. These turbines are directly coupled to three-phase alternators driven at a speed of 3000 revolutions per minute. Similar turbines have been built of 300 horsepower capacity, directly coupled to Drehstrom dynamos rated at 200 kilowatts and supplying a three-phase current of 2000 volts pressure. These units occupy a floor space of 3.3x8.6 feet, the total hight measuring 4.16 feet.

For operating boats, these turbines are said to have given excellent satisfaction, a special design having been provided for reversing. One of these units of 35 horsepower capacity operating at a steam pressure of nine atmospheres and at a speed of 3000 revolutions per minute, with reducing gear for lowering the speed to 500 revolutions per minute required for the propeller, occupies a floor space of 2.67x4.83 feet, with a total hight of 3.67 feet. The Elektra turbine is handled in America by the Alberger Condenser Company.

The Canadian Government has appropriated £3000 for the erection in Ottawa of a fuel-testing plant. It will deal chiefly with peat, with the object of solving the problem of utilizing the peat bogs by converting peat into producer gas from which electricity can in turn be generated. A peat bog will also be secured and a plant laid down to demonstrate the best methods of converting the raw material into fuel. Peat occurs in immense quantities in Ontario and Quebec.

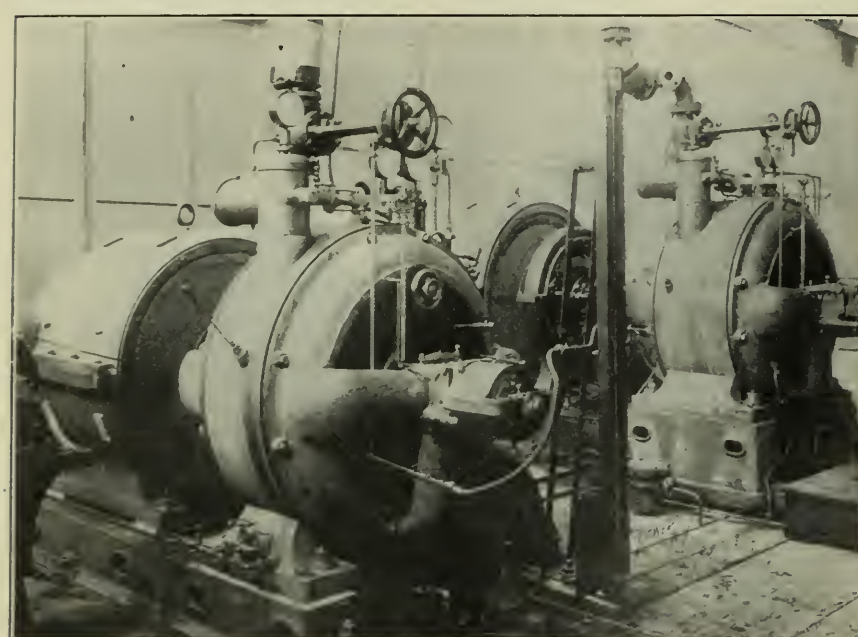

FIG. 4. COMPOUND TURBINES WITH CAPACITY OF 100 HORSEPOWER EACH

Test of a Vertical Gas Engine

The accompanying chart, Fig. 1, presents the principal items of a test, made a few months ago, of a Rathbun two-cylinder vertical gas engine. The test was not run for the purpose of obtaining complete data for the heat-balance sheet, but merely to determine the regulation and fuel rate.

The engine was the standard single-acting type built by the Rathbun-Jones Engineering Company, of Toledo, Ohio, with cylinders of 12½ inches bore and 13 inches stroke, rated at 100 horsepower on natural gas and designed to run at 290 revolutions per minute. The governor controlled the speed by throttling the mixture and also adjusted the timing of the ignition, advancing the firing point when it reduced the quantity of mixture admitted and *vice versa*. It is largely due to this feature that the engine shows ability to carry overloads without being underrated at normal full load; another potent factor which contributes to this result is the relatively high compression used—about 145 pounds absolute at full rated load. For the engine under consideration this is the most efficient compression pressure; consequently, any increase in compression tends to decrease the efficiency.

It will be noted by reference to the chart that the gas consumption at full load was 7.85 cubic feet per brake horsepower-hour and 7.95 cubic feet at 10 per cent. overload. The speed was a trifle high at rated load, coming down to the designed rate only at the maximum overload; or, to express it more fairly, the engine yielded 10 per cent. more than its rated power at its rated speed. The regulation was obviously about 4¼ per cent. between 35 horsepower and rated load; the test was not carried below 35 horsepower.

The gas averaged about 1100 B.t.u. per cubic foot at the temperature at which it

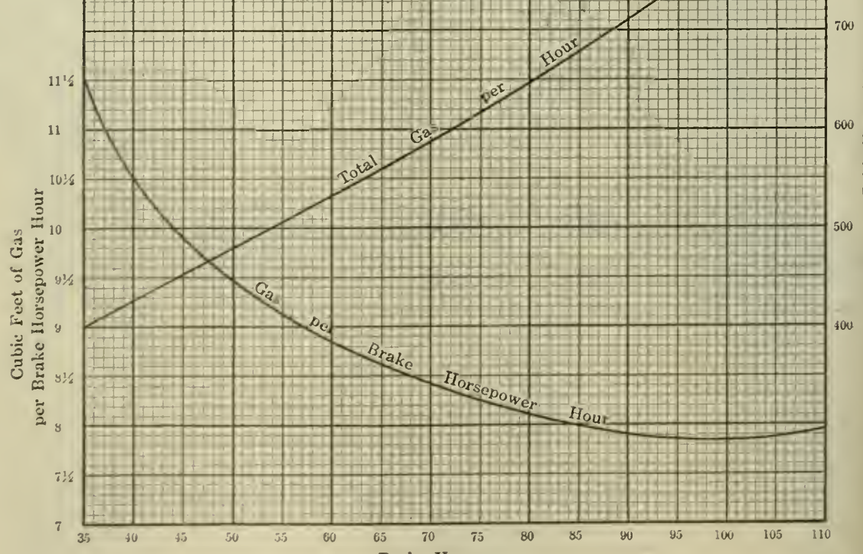

FIG. 1. PRINCIPAL RESULTS OF A TEST OF A RATHBUN TWO-CYLINDER VERTICAL GAS ENGINE

passed the meter, so that the thermal efficiency of actual output was practically 30 per cent.

The cooling of this engine is unusually effective and well distributed, which makes for overload ability by facilitating the extra compression thereby entailed.

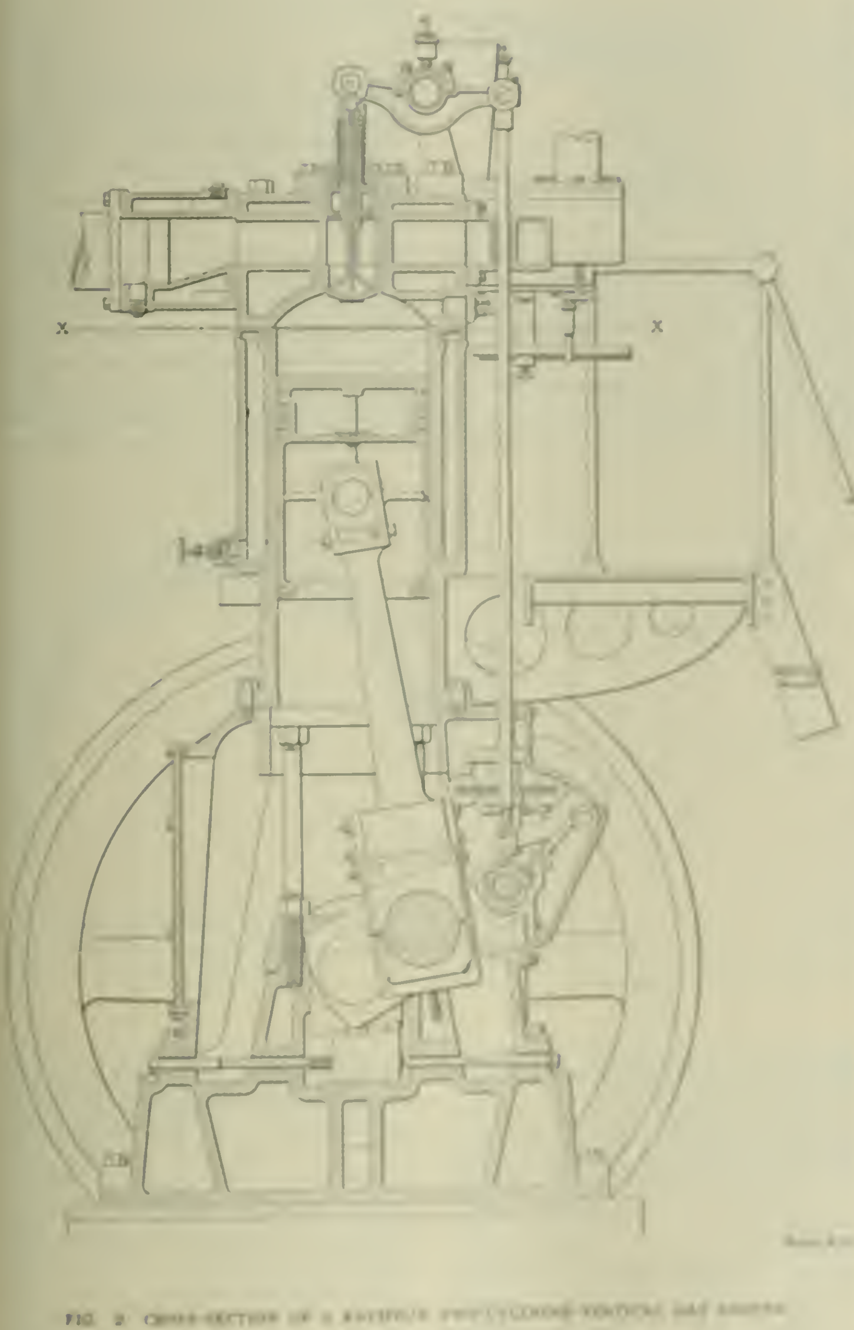

FIG. 2. CROSS-SECTION OF A RATHBUN TWO-CYLINDER VERTICAL GAS ENGINE

This and the automatic adjustment of the ignition timing combine to prevent back pressure by too early combustion at the high compressions. The exhaust valve is water-cooled, as indicated in the sectional view, Fig. 2, and the cylinder head and barrel are separately jacketed. In the latter drawing the section below the line X — X is taken through the center of the cylinder, while the section above that line is taken through the center of the exhaust valve, which is in a vertical plane a trifle nearer the observer than the center of the cylinder.

An interesting constructional feature of this engine is the fixing of the upper part of the crank case to the main journal housings. Stud or bolts extend from each side of each journal box [illegible] of the crank case, allowing [illegible] the crank case of the [illegible] the thrust of the cylinder [illegible] during the power stroke.

The Chief Engineer and the Ventriloquist

The following is a brief account of the terrible fate of a practical joker:

Sunday—Chief engineer's log book reads: Visit of a stranger. A severe squeak in engine No. 1 was remedied by a liberal application of oil.

Monday—Report shows that stranger again called and stayed some time, during which engine No. 2 developed an annoying squeak.

Tuesday—Stranger proves to be brother-in-law of the assistant engineer. Called again today, but could not pay much attention to him, as engine No. 3 had to be oiled to stop a severe squeak.

Wednesday—Everything O. K. No callers and no squeak.

Thursday—Stranger called. Engine No. 1 had to have all the lubricators speeded up in order to stop squeaking. Stranger seems a loafer.

Friday—That confounded stranger called again and I used up three pints of oil to stop the noise. I wonder why he and the squeaks seem to call at the same time. Looks queer.

Saturday—Last night assistant engineer told me his brother-in-law was a ventriloquist. I guess I was pretty easy.

Saturday afternoon—Stranger called. Squeak at last definitely located. Two quarts of dirty oil were poured upon the squeak. The cause of the squeak walked out of the engine room to buy a new suit of clothes. He said he would fix me. That's what they all say.

Work Begun on the Grand Falls Development

Two carloads of plant, consisting of engines, boilers, steam drills, derricks and other machinery, have arrived at Grand Falls, New Brunswick, and are now being set up for the beginning of operations. William Aitken (formerly of Nova Scotia and afterward of Boston) and Clarence A. Conrad (formerly of St. John), representing the Frank B. Gilbreth organization of New York, have already arrived and taken charge of the preliminary work.

W. B. Lowe, general manager for the Frank B. Gilbreth organization, has already placed large orders for supplies in St. John. All compressors and much of the electrical machinery for the temporary power plant will have to be made to order. The development of hydro-electric power at Grand Falls is of great importance to the Province of New Brunswick.

There is in British Guiana the Kaieteur fall, a waterfall [illegible] feet high [illegible] Niagara [illegible]

Hot Bearings; Some Causes and Remedies

An Old-time Topic in a New Dress, Giving the Reader the Full Benefit of Knowledge Gained by a Veteran of Many Years' Experience

BY H. S. BROWN

There are few troubles in the engine room that give the engineer more anxiety than hot bearings, and particularly the crank pin, as it is difficult of examination while the engine is running. An engine may run for years with no sign of heating, when suddenly without any apparent cause the sense of smell detects hot oil, and the man in charge is on the anxious seat at once. A case of shutdown stares him in the face, the thing of all others he strives to avoid. Where is the engineer who does not take the greatest pride in a year's run without a shutdown during working hours? A shutdown once from hot bearings is likely to be repeated, and perhaps many times. This is particularly the case with large powers, as in railway power houses, steamships, etc.

From many years' practical experience in the drawing room, in the shop and as erector of steam machinery, I am free to say that there are numerous cases of hot bearings for which the engineer is not responsible, even though he may be held liable. Conditions beyond his control or foresight will arise when least expected. On the other hand, there are more cases, even, when he is not guiltless. The man who is continually tinkering with his bearings may expect trouble at any moment.

The cases are legion in which engines have run for months without a wrench or hammer being put near the keys or wedges. This is well illustrated in the long runs of marine engines. Twelve to twenty days has in the past been no uncommon experience.

With proper lead and compression on the valves the extremes of light and heavy pressures on the bearings will be so much relieved that the wear will be reduced accordingly. My opinion is that due credit is not given to the proper amount of compression for the even and minimum wear on both pin and main bearing. If we plot a diagram with one line showing the pressure on these bearings with a good liberal compression and another with no compression, we shall see one cause for the heating of bearings in the no-compression treatment. If we take a cold rod of horseshoe-nail iron and draw it to a point, under a rapid-running trip hammer, the metal will be red with heat at the finish. Or, if we heat a steel billet, say 6 inches square, to a red color, and draw it under the blows of a steam hammer, the color of the billet will brighten under the rapid and severe shocks delivered. This shows how much heat is generated from severe shock applied suddenly to metals.

Poor Oil a Cause of Heating

Poor oil is another cause of heating. A new brand of oil should never be introduced until its quality has been established. With an oil of good quality, with body, the shaft practically rides on it; a thin film covers the surface of the bearing; but it should be fed regularly, and just enough. Not a flood at one time, and then the bearing allowed to run dry. With a poor lubricant, the surface of the shaft or pin comes in close contact with the surface of the boxes, and friction, with heat, is the result.

Clean oil is also a very important element. If an engineer will carefully filter his oil before using he will be surprised at the amount of grit extracted. After filtering, the oil should be kept in a closed can until used. A very small amount of grit will sometimes start a rough surface on a pin or bearing and cause heating.

Keying up is an exceedingly delicate operation at times, as what would be a good running condition of the boxes on one engine would start another to warm up. And if the adjustment of the boxes is close a slight raise in temperature will expand the metal and a rapid increase of heat will follow.

I have known cases where the rod had been keyed up at noon and, after starting up, there was no sign of heat for a time; but suddenly the smell of hot oil was noticed, and a shutdown followed. In such cases the bearings should be run as loosely as permissible without knocking.

Another important feature is a regular inspection of the bearings, at stated intervals, depending on the amount of wear in the boxes. To illustrate, in my early days I was employed in the roundhouse of a railroad company where we met with all sorts of conditions of heating. We found many cases in which the boxes had worn until the bearing had extended over the entire surface, always resulting in heat so intense at times that boxes would turn blue. As a never-failing cure,

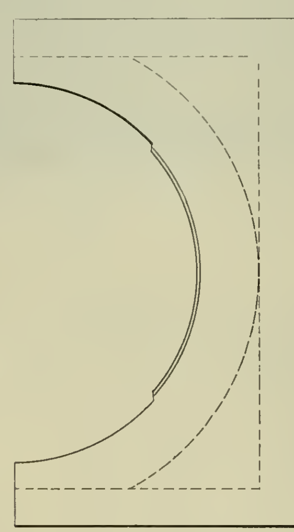

FIG. 1

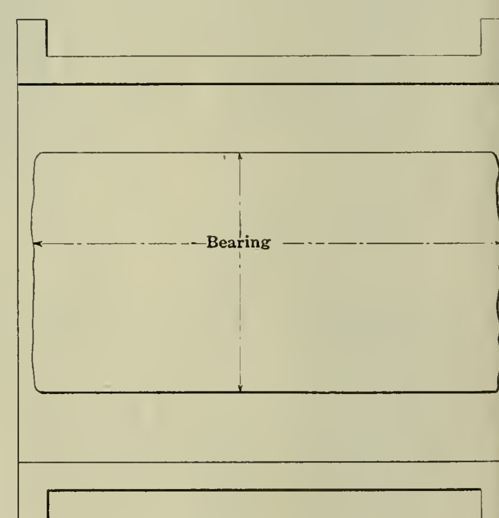

FIG. 2

we would take a half-round coarse file and remove the bearing surface, as shown in Figs. 1 and 2, leaving the bearing in the crown of the box. By this means the oil was carried around on the surface of the pin to the section of bearing where it was required, and the open space that had been formed by filing would form a storage for oil.

When the bearing is extended over the entire box, the oil is not evenly distributed, and the sections not supplied will cause slight friction, with resultant heat. The oil becomes thin and passes off very rapidly. A good result will follow the use of a heavy grease, with just enough oil to keep the grease spread over the entire bearing.

Another evil effect from excessive bearing surfaces with most boxes of hard composition or bronze is that there is a tendency toward a closing-in of the boxes, as shown at *a a*, Fig 3, and even with a slight raise in temperature. Then as the box begins to pinch on the pins heat is generated very fast.

In fitting up new boxes for the connecting rod, it is a good plan to cut away the bearing surface, as shown at *a a*, Figs 4 and 5, to the depth of from 1/16 to ⅛ inch, according to the size of the box. The narrow sections *b b*, Fig 5, should be filed away so as to clear the pin and leave the bearing from *c* to *d* in the crown of the box.

The tendency to close in as shown in Fig 3 is more likely in the round type of box, and to prevent this liners should be fitted, as shown at *a a*, Fig. 6, with freedom enough in the bearing to set up tight on the adjusting bolts. This holds the boxes firmly against the rod and cap, a practice that I think should be followed on all crank-pin boxes.

The liners should be cut as follows: Eight from 1/64-inch sheet brass, four from 1/32-inch, two from 1/16-inch and one from ⅛-inch. This allows of adjustment of the boxes for a long time without filing.

Defects in Crank-pin Box Design

One of the defects in crank-pin box design is in having too little metal at the edges X, Fig 4. The metal is so thin that they will not hold their shape and soon become loose in the strap. Thus, at the first increase of temperature heat will develop very rapidly, as there is no body of metal to carry it off. Also, as the boxes are a loose fit in the strap, that tends to destroy the conduction of heat, which throws a larger portion of it onto the pin. It is also a mistake to cut away the metal from the corner of the box, as shown at *b c d*, Fig. 4. It breaks up the path for heat travel, with very little saving in the cost of metal.

While the designer will cut out the post, he will core chambers in the body of main bearings and circulate water to carry off heat in the second case. The circulation of water in the bearings has been the practice for many years on marine engines, and latterly on heavy stationary engines.

I have seen cases in which a bearing would start to run hot, with a [illegible] supply of cold water, would cut a path in the bearing and go on (with a good supply of oil). On the other hand, I have seen a main bearing (composition) start to cut and, with a free hand for the time that the engine down, the metal of the box cutting and scoring the shaft. There have been cases where no [illegible] [illegible] [illegible] forged on a connecting rod with additional metal and water for larger [illegible] at these points as soon as the [illegible] boxes to absorb heat, and it has proved a success.

On account of a small bearing, a new pin has often been put in, and in some cases an entire new shaft, with increased surface on the bearings to overcome the troublesome heating. I recall cases in which I have been on watch for weeks beside hot bearings, applying every remedy that was suggested, without reducing the heat, a change of metal being the only remedy. In one case the entire shaft was changed. After analyzing the metal in the pin, which was found too low in carbon. It contained only [illegible] per cent. A new pin was fitted with [illegible] per cent. carbon and there was no more trouble. The following will give good results:

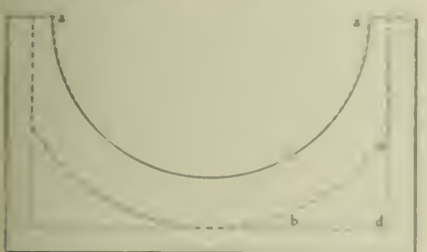

FIG. 3

0.049 " phosphorus
1.03 " manganese.

CARE IN SELECTION OF MATERIALS REQUISITE

Too much care cannot be taken in the selection of material for pins and shafts. The analysis should always be specified in ordering and tested after receiving. With poor material in the pin and shaft, after long service the metal will wear away and uncover the open grain and streaks of gritty matter, which will often start heating, the cause of which seems a mystery. In cases where the bearing of the pin

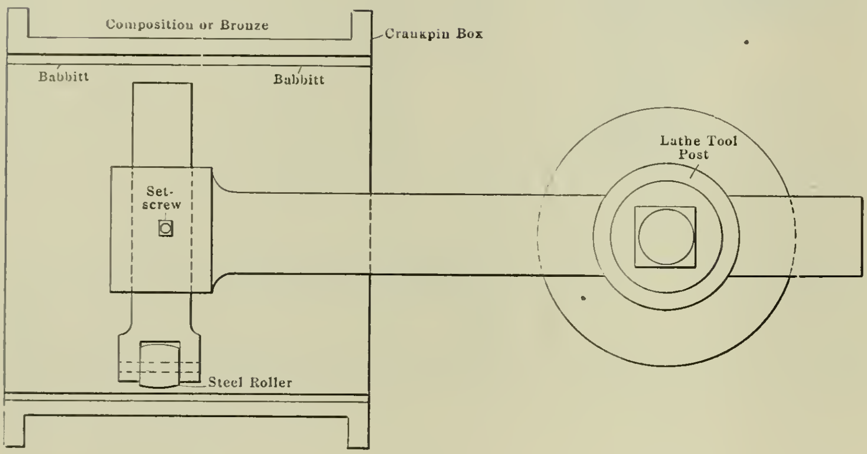

FIG. 8

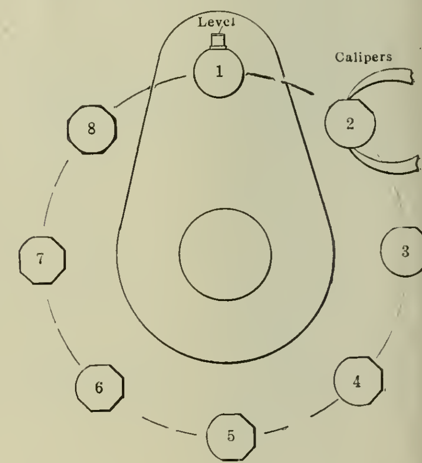

FIG. 9

This gives a hard surface and will wear well in the stuffing box.

All of these are taken from practice and have proved very successful.

A case of crank-pin wear and cutting away is shown in Fig. 7. The engine had run about four weeks and was pounding on the pin so that it could be run no

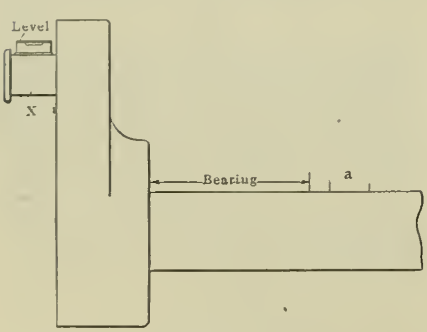

FIG. 10

longer. The wear on the boxes (composition) was about 1/16 inch, while on the pin it was ½ inch, on one side only. The steel in the pin was of poor quality, and there were streaks of dark grit on the surface. This came from the amount of metal removed, as the pin was made from a bar. Crank pins should be forged in dies under a hammer, if the collar is to be solid with the pin. This densifies the surface metal, closing all openness of grain. Not over ⅛ inch should be turned off the bearing in finishing, as the deeper the cut in the bar the more open it shows.

heats, and the boxes are of hard composition, or bronze, with a soft-steel pin, babbitt of a good quality will prove effective. But great care should be taken in putting the babbitt in. Bore about ¼ to ⅜ inch out of the box, leaving a rough surface from the cutting of the tool, then heat the boxes, and thoroughly tin them on this rough surface. Put in the babbitt, leaving about 3/16 inch to bore out. Take a rough cut, leaving 1/16 inch for finish. Then with a small roller in a bar, as shown in Fig. 8, roll the babbitt out against the composition, run the roller back and forth a number of times in the lathe, and then with the boring tool take the finish cut to size, which should be about 1/64 inch larger than the pin. *Never hammer babbitt in the boxes*; rolling is far better.

The following mixture of babbitt has proved very satisfactory for crank pins: Tin, 88; copper, 5; lead, 10. For heavy main bearings: Tin, 85; copper, 4; antimony, 9.5. For light, slow-running main bearings: Tin, 5; lead, 80; antimony, 15.

The different metals should be melted separately and mixed while in the fluid state. This is very important and should be strictly adhered to.

Crank pins that are out of line with the shaft, or when worn out of round, are often very troublesome in heating, and to true them up is a very delicate job. The writer has found the following very successful: Place the pin in position *1*, Fig. 9, and file a flat section true to a very sensitive level, the same level as the shaft but not the main bearing on the shaft, as that may have worn taper. Place the level at *a*, Fig. 10, but caliper the shaft at that point to be sure it is parallel.

After the flat place is filed at *1*, turn the pin to position *2* and file another section. Repeat the operation until all of the flats have been filed as shown, around to *8*. But after the position *2* is reached, caliper the pin (at one point only, preferably in the center as at *X* Fig. 10), to be sure that when *8* is reached it will be round. After all of the flats have been filed, take a cast-iron box, Fig. 11, and bore it to the small diameter of the flats as at position *8*. The casting should be thick enough so as not to spring out of true. Then with lampblack or red lead in the bore of this box to mark the high spots on the pin, finish filing. The last of the filing should be with a dead smooth file, with the corners ground off so as not to mark the pin. If care is used in this operation the pin will be perfectly true and round.

It is often stated that a crank pin out of line with the cylinder will heat, but such is not always the case. In overhauling a large horizontal engine some years ago, it was found that a line through the cylinder was nearly ¼ inch one side of the center of the pin; still, that engine had run for years with no sign of heating.

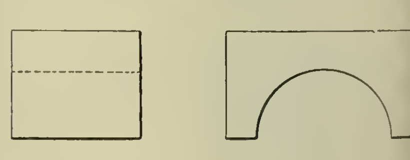

FIG. 11

It is stated that the oil used on railways in the United States as fuel amounted in 1907 to 18,855,691 barrels. It is estimated that 13,593 miles of railway were operated by oil-fired locomotives making some 74,000,000 engine-miles in the year.

Belting Compared with Chain Transmission *

By Harrington Emerson

"For power transmissions, as met with in ordinary shop practice, no means has as yet been devised which can compare in economy of first cost and ease of handling with belting, especially with regard to unskilled labor."—"Power Transmission by Chain," *Cassier's Magazine*, May, 1908.

The writer of the article, Edward J. Flax, is a recognized authority on chain transmissions and was supplied with fullest information by leading European chain manufacturers.

Chain transmission is not thought of for general shop use, although for advertising purposes a shop has in one instance been so equipped. There are, however, installations where chains are best, in spite of their many drawbacks. Chains are, mechanically, merely a form of gearing, and as such are suitable for positive transmissions of very heavy power at slow speed. They are widely and properly used for conveying ashes, sand, chemicals and liquids which would corrode or destroy belting. Chains of this kind are generally made of malleable iron. Even for conveyers for clean substances, flour, wheat and other grains, belts are preferable, and in the best installations leather is preferred to cotton or rubber, being more durable. Transmission chains have to be carefully made. If the chain is to run smoothly, noiselessly, and without considerable friction, both the links and the sprockets must be mathematically correct. This perfection of design is found only in the highest and best makes of steel chain.

The Ordinary Chain

The makers of the best chains are those who know most about the troubles with chains. The American manufacturer of the Renold silent chain thus describes the ordinary chain: "As soon as the chain is started up, it stretches and immediately all the strain falls on one tooth. This condition gets worse as the strain increases. As the wheel turns the working tooth goes out of mesh, then the wheel slips back until the next tooth comes into contact with the next link in the chain. Obviously this jar brings an abnormal strain on the chain and sprockets. Consider how many times a minute this jar occurs at even moderate speeds. It is no large that all ordinary chains stretch rapidly."

This deterioration starts in with the beginning of service. Even in such light and flexible duty as bicycle transmission, a chain is subjected to sudden, severe strains, which either stretch the chain or distort the bearing surfaces. Either mishap is fatal to smooth frictionless running service.

If the transmission is positive, as from motor or shaft to a machine tool, sudden variations in strain become hammer blows, sledge-hammer blows, and the chain must either break or the parts yield. To avoid the evils arising from the stretching of the chain, self-adjusting forms of teeth have been invented, of which the Renold silent chain gear is one of the best.

Distortion

The adjustment of the teeth to wear, however, does not obviate the distortion on the bearing and meshing surface due to blows. The chain being a positive transmitter there is no slip or give under a sudden increase in load, as when a tool sticks in a casting, and even if the tool breaks, the chain has sustained a severe and hammer-like blow. Chains even of the best make are often hopelessly distorted in as little as three months' time. To palliate this evil, spring sprocket wheels are not rigidly mounted on their shafts, but a spring is interposed between rim and hub, so that when the shock or blow comes it is softened by the spring. This added complication and expense has proved a very great betterment, prolonging the useful life of the chain, but wear and jar still exist and the date of renewal is merely postponed. There comes a time when chain and sprocket wheel must both be replaced.

The makers of the Renold silent chain claim that it is superior to leather belting because:

(1) It cannot slip.

(2) It can be used in a hot or damp place.

(3) It can be run on shorter centers than belting.

In all the above respects the chain is good, especially where the work must register exactly, as in the color-printing process. It is very useful for dishwashers, etc., or for other forms of transmission where there is oil or high heat.

The short-center claim is perhaps not quite so sound. The big tools of a planing mill have not found anything to replace belting, yet the centers are very close, the pulleys very small. This is one of the most severe of shaft-transmission problems, and experience has proved that only the finest quality of single leather belting will run these machines successfully.

Short Centers

[illegible] Smith, [illegible] president of the American Society of Mechanical Engineers, at a recent meeting of the society spoke as follows on the subject of short centers:

"In driving the new and extra powerful tools for using high-speed steel, much attention has been paid to trains of gearing and sprocket chains for getting sufficient torque, the good old-fashioned belt being neglected as being too weak and of no account. The trouble with the old-time belt drive was that the belts were run much too slow. Some did not have the capacity to transmit much power. I have found, however, that the cheapest and most practical method to drive a shaft from a motor is with a short belt running at high speed and endless. A small belt running at [illegible] feet a minute will transmit an enormous amount of power and can be kept so loose as not to be strained up to its working limit, thus being very durable. Because it runs loosely the shafts are not pulled together, so that there is very little journal friction and wear. There need not be any fear of its being too short between pulley centers if it is strong, thin, endless and runs at high speed."

The makers of the Morse rocker chain, also a very excellent chain, recommend it for use under the following conditions:

(1) Where room is lacking for the proper sized pulleys for belts.

(2) Where the centers between shafts are too short for belts.

(3) Where a positive speed ratio is needed.

(4) Where there is moisture, heat or dust that would prevent a belt working properly.

(5) Where a maximum power per inch of width is desired.

The Renold silent chain and the Morse rocker chain need springs [illegible] in the sprocket wheel. [illegible] the belt naturally possesses, and where transmitting power is [illegible] of a low speed under the severe conditions of moisture and dirt, as in automobile transmission, the belt will be cheaper to install, cheaper to maintain, cheaper to repair in case of breakdown and more efficient than any chain. A leather belt will run on very short centers and transmit very high powers, but it should be run on [illegible] than a long belt.

[illegible]

One of the most difficult transmissions in engineering practice is from the axle of a moving train to the dynamo which charges a storage battery for train lighting. The transmission must run without attention over a distance of many miles; must stand up under excessive heat and exposure, cold, rain or snow; it must run covered with the sand and grit from the roadway [illegible]. For this very difficult service belts are used because other forms of transmission have failed.

A good belt and a good pulley [illegible]

---

*Paper presented to Leather Belting Manufacturers Association, February 3, 1909.

Selection of Coal for Boiler Furnaces

General Consideration of Types of Furnace and the Selection of Coals, with Recommendations as to Most Desirable Specifications

BY D. T. RANDALL*

It is well known that certain coals are especially suited for locomotive use, others for metallurgical use, for illuminating gas, or for the manufacture of coke, etc., but all coals are considered as possible fuel for boiler plants. This being so, it is important to know about the design of furnaces and the influence of certain characteristics of coal in order that the best results may be obtained.

Furnaces

An ideal furnace would, of course, be one in which all coals, no matter what the character of their composition, could be burned with equal efficiency. Furnaces may be generally classified as follows:

(1) The hand-fired grate set in a chamber inclosed by the iron surfaces of the boiler, as in the internally fired boilers of marine type, in the locomotive type used for stationary purposes, house boilers and small vertical boilers. These boilers cool the gases from the coal and are not suited for use with coals containing more than a small percentage of volatile matter. Where bituminous coal is burned in such boilers there is a considerable loss of unburned gases as is evidenced by the smoke given off.

(2) Hand-fired grates set in a chamber partially inclosed by brick and with the boiler surfaces just above or near the surface of the fire. This includes the usual setting for horizontal return-tubular and water-tube boilers. These are not suited for burning bituminous coal.

(3) Hand-fired grates set in a brick chamber with a considerable space for combustion to take place before the gases reach the surfaces of the boiler. This may be accomplished by brick arches, tiles, etc., and, in addition, piers, baffle walls and other devices are used to assist in mixing the gases and air while within the combustion space. With these may be included down-draft furnaces and coking furnaces fired by hand.

Many of the foregoing, when carefully fired, give good results and with certain sizes and kinds of coal they may be operated without dense black smoke, but usually not without some smoke. Often a special coal is required to secure good results. This creates a demand for coals low in ash and of large size. Screenings are seldom burned in such furnaces with good results.

(4) Automatic stokers partially inclosed in brick, with a small combustion chamber and a short distance from the grates to the boiler furnace. Such settings usually give good results except at high capacities, or when the load is changed suddenly. They give off more or less smoke, depending on the size and character of coal used. Coals high in fixed carbon may be used with good results.

(5) Automatic stokers inclosed in brick settings, with a large combustion chamber and a considerable distance from the grates to the boiler surfaces. Such settings will burn almost any size or kind of coal with economy and without smoke within reasonable ranges of load.

Time is required for the air and gases to burn and any means that will facilitate the ultimate mixture of the air and gases will reduce the size of the combustion chamber necessary for good results. In general, then, for most coals, and especially for those which have high percentage of volatile matter, it has been found more satisfactory to install some kind of device which will feed the coal regularly in small quantities, allowing it to become heated gradually, driving off a practically uniform amount of gas to which a proper amount of air can be admitted and burned in a combustion chamber which is sufficiently large to allow of complete combustion in the furnace.

Draft

In considering any type of furnace, one should keep in mind the necessity of having a strong draft available. This may be provided by a stack or a fan. A stack may be supplemented by a forced-draft fan, or an induced-draft fan may be used alone or in connection with a forced-draft fan. Most plants do not have sufficient draft at times when boilers are overloaded.

The amount of draft required depends upon the kind of coal used, the size of the coal and on the load to be carried. Stacks should seldom be less than 120 feet high. In many cases they must be higher, or a fan used with them. For most bituminous coals a draft or difference of pressure of 1/4 inch of water between the top and the bottom of the fuel bed will be sufficient. For small sizes of bituminous coals and for the various small sizes of anthracite, the draft required is greater. For buckwheat sizes of anthracite, a draft of 1 inch of water is frequently necessary.

Choice of Coals

Because a coal is sold at a low price per ton does not of necessity make it the cheapest coal to buy. In choosing a coal when the furnace equipment and other conditions are favorable, the one giving one million heat units for the lowest cost will prove to be the most economical to purchase. As a rule, coals mined near the point of consumption and bearing only a small freight charge will be the cheapest coals to purchase and, in most cases, it will pay to install a suitable furnace to burn them. An engineer having full information before him may then decide whether his furnaces are suitable for burning the cheapest coal, or whether it will be profitable to change the furnaces.

It often happens that, for some good reason, it is impossible to change the equipment and in this case it is, of course, necessary to choose a grade of coal which will make it possible to generate the steam required, even though it be more expensive. These conditions arise especially in plants belonging to Government or State institutions and in plants which are rented.

In considering coals for boiler plants, one must be familiar with the kinds and grades of coal available, their chemical characteristics and the prices, together with the furnace equipment to be used.

Certain characteristics of coal determine the method of firing or the design of furnace required to burn them most efficiently. Among these are the tendency to clinker and to cake in burning. The amount and character of the volatile matter, ash and moisture are also important.

How to Select Coal

In choosing coal for a boiler plant, it is probable that the chemical comparison is the more reliable, if based upon a representative sample of the coal, than a boiler test. The possibility of doing accurate work in a laboratory is greater than in a boiler room, where the fireman may unintentionally influence results by his method of handling a fire. Usually it requires a few days for a fireman to become accustomed to a new coal, and even an expert fireman has difficulty to burn the same coal two days in succession and supply the same amount of air per pound of coal each time. A boiler test is only a rough

*Engineer in charge of tests at the United States Geological Survey Experimental Station, Pittsburg, Penn. Paper read at Illinois Coal Conference, March 10, 11 and 12.

determination, and two tests, one on each of two coals, are seldom sufficient for comparison. If several tests can be run and the averages of the results of these taken, they will compare pretty closely with the chemical valuation of the coal, provided the coals are of the same general character. Coals high in fixed carbon and low in moisture give better results than those high in volatile matter and moisture. This is true in nearly all furnaces and especially true of those not provided with firebrick furnaces.

Size

In the perfect furnace which has been mentioned, the value of the coal should depend entirely upon the *heat units which are available* in the coal. This being so, the heat value would be the true basis for the purchase of coal. Unfortunately, as has just been mentioned, the size of the coal, even though it is otherwise equally high in B.t.u., is an important element in burning the coal on most kinds of equipment. Usually the smaller sizes are more difficult to burn on account of the difficulty of drawing air through the fuel bed and in many kinds of coal the smaller sizes contain a greater percentage of ash than do the larger sizes.

Owing to the difficulty of burning the smaller sizes of coal, they are usually much cheaper than the larger coals. Improved furnaces with strong drafts have been provided in so many plants that very little coal is being wasted today on account of its size. The culm banks of the anthracite region are being put through washeries and the good portion sold for fuel. Many coals break up badly in handling. This is especially true of some of the high grade Eastern coals. Some of them are delivered with 20 per cent. fine coal which will pass through a screen with round holes ¼ inch in diameter. If the coals cake in burning, this is not as serious as with noncaking coals. With fine coal a much stronger draft is required which, in some cases, carries a considerable quantity of the very fine fuel off the grate before it is burned, and in case it does not cake there is also a considerable loss due to sifting through the ashpit.

Chemical Characteristics

The results of more than 600 steaming tests conducted at the fuel-testing plant of the United States Geological Survey show that with the equipment used coals from Illinois, Indiana, Kentucky, Iowa, Missouri and Kansas may all be burned with practically the same efficiency, even though the heating value varies from 6000 to 13,000 B.t.u. per pound of coal, the ash varies from 8 to 25 per cent., the moisture varies from 3 to 20 per cent. and the volatile matter varies from 30 to more than 40 per cent. in these coals.

Influence of Heating Value

The results of these tests indicate that for coals of the same general character the performance of a boiler depends, for the most part, upon the B.t.u. available in the coal; that moisture, volatile matter, sulphur and ash have more or less influence on the capacity and efficiency. It is difficult to separate the effects due to any one of these items, except when they occur in large percentages. Coals of the same character may be compared directly on the basis of the B.t.u. in the coal *as delivered* without serious error. It is important to note that the heating value should be considered on the basis of the moist coal "as delivered" and not on the dry coal (see Table 2). Coals of different character may be compared on the basis of their B.t.u. values, but account must also be taken of the percentage and character of volatile matter, the percentage of ash and the percentage of moisture. An allowance for these must be made, depending on the conditions under which the coal will be used.

Influence of Moisture

The loss due to moisture in the coal when present in small percentages is comparatively small. Stated roughly, this loss amounts to about 1 per cent. for each [illegible] per cent. of moisture based on the "combustible" in the coal. It will, therefore, be seen that an increase of 1 or 2 per cent. of moisture in the coal has but little effect on the efficiency of the boiler. However, when moisture occurs in large amounts, as it does in some coals, there is a serious loss due to the heat required to evaporate this moisture from the coal and to the reduction in temperature of the furnace gases. This loss is not accounted for in chemical reports on B.t.u. in coal, and an allowance should be made if a coal is high in moisture. This would correspond to the so-called low B.t.u. value of gas and liquid fuels used in internal-combustion engines (see last column, Table 2).

In order to make clear the relation between the different forms of reporting coal analyses and to show the influence of moisture in coal when both moisture and ash are present in varying amounts, the accompanying tables have been prepared.

Influence of Ash

It is difficult to determine just what effect the presence of ash may have on the efficiency of the boiler. Apparently it is small. Ash has, however, a decided influence on the capacity at which a given equipment may be operated. It reduces the effective grate area and introduces an added resistance to the flow of air through the fuel bed. There are also losses of efficiency and capacity due to the necessity of cleaning fires more frequently. This becomes of less importance in types of furnaces where the ash is discharged by dumping or other automatic discharging devices.

Influence of Volatile Matter

The volatile matter in the coal is also an important element, as it is more difficult to burn than the fixed carbon. The percentage of volatile matter as shown by the proximate analysis is not a direct measure of the difficulty of burning the coal with good efficiency and without smoke. Different coals having practically the same percentage of volatile matter vary in the amount of tarry and heavy hydrocarbon gases [illegible] which they are heated.

TABLE 1

PROXIMATE ANALYSES OF COALS FROM DIFFERENT PARTS OF THE UNITED STATES
(See Prof. Paper 48, U. S. Geological Survey.)

Coal		Proximate Analyses of Coal as Fired				
		Fixed Carbon	Volatile Matter	Moisture	Ash	B.t.u.
West Virginia	8	60.68	31.19	1.26	6.87	13,877
Illinois	1	38.21	38.91	9.69	13.19	10,708
Missouri	3	29.08	26.18	18.43	26.31	7,738
North Dakota	1	25.40	28.13	35.84	10.63	6,874

TABLE 2

THE INFLUENCE OF MOISTURE AND ASH IN COAL ON THE B.T.U. VALUES AND ON THE HEAT UNITS AVAILABLE TO THE BOILER. SAME COALS AS IN TABLE 1

Coal		Comparison of B.t.u. Values			Comparison of Ash			Moisture		
		[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
West Virginia	8	13,677	14,408	15,084	6.87	[illegible]	[illegible]	1.26	[illegible]	[illegible]
Illinois	1	10,708	11,862	14,202	13.19	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Missouri	3	7,738	9,593	13,847	26.31	[illegible]	[illegible]	18.43	[illegible]	[illegible]
North Dakota	1	6,874	10,442	12,666	10.63	[illegible]	[illegible]	35.84	[illegible]	[illegible]

In addition to the foregoing, it must be remembered that the volatile matter is not all combustible material and the variation in this respect is very great when all the coals in the country are compared. Coals having a high percentage of volatile matter which is nearly all combustible are found to be the most difficult to burn properly. The results obtained from tests on an iron inclosed furnace show a drop in efficiency as great as 10 or 12 per cent. in burning coals ranging from 18 down to 45 per cent. of volatile matter in the "combustible." A well-designed furnace reduced this loss in efficiency when burning such coals to about 5 per cent. A perfect furnace would, of course, obtain the same efficiency from all coals.

Influence of Sulphur

Sulphur is considered an undesirable element in coal. It usually gives trouble from clinker and is sometimes destructive to the grate bars. Its effect depends upon the form in which it occurs in the coal; on the percentage of ash in the coal. Coals having sulphur varying from ½ to 6 per cent. or more are successfully burned under boilers and, in many cases, no difficulty is experienced.

Purchase of Coal for the Government

The United States Government is a large user of coal. Its fuel bill amounts to nearly ten million dollars annually. Much of the coal purchased is tested and analyzed. One single contract for this year was for 400,000 tons of coal to contain 14,600 B.t.u. per pound.

In order to compare the cost of coals used by the Government in the larger cities of the country, it has been customary to calculate the cost on the basis of the number of cents per 1,000,000 B.t.u. It is interesting to note that for last year's contracts the cheapest coal was delivered in Louisville, costing only 7.1 cents per million B.t.u. The cost in Boston for similar coal was 16.3 cents and in St. Paul the price was 17.1 cents. Anthracite was delivered in Eastern cities at prices ranging from 8½ cents per million B.t.u. for buckwheat coal to 14 cents for pea coal, and as much as 20 cents in some cases for egg and broken coal.

Specifications

Having decided upon a kind of coal to be used for a plant, the purchaser naturally desires to have some assurance that he may be able to secure the coal in question, or one of practically the same composition, for a given period. This has led to the use of specifications for the purchase of coal. If the size of the contract and other conditions warrant the use of a specification, then the proposal for coal to be of value should contain at least two general statements regarding the kind and character of coal:

Proposals for Coal

The bidder should state in his proposal (1) the commercial name and size of the coal to be furnished, the size to be specified within certain limits in order to avoid disputes when coal is delivered, and (2) the character of the coal to be furnished, in the following form:

PROXIMATE ANALYSIS.

	As Received.	Dry Coal.	Free from Moisture and Ash.
Moisture....	....		
Volatile matter.......	....		....
Fixed carbon	....		
Ash........	....	....	
	....		

Sulphur separately determined................ %.
B.t.u. in coal as received (not dry)...

The price per ton should be stated for coal of the specified quality. The price to be paid on coal delivered should vary directly with the B.t.u. in the coal "as delivered;" this value to be modified further, if advisable, by corrections:

(1) For more or less ash in the dry coal;

(2) For more or less volatile matter in the "combustible," allowing in all cases 2 or 3 per cent. variation without premium or penalty. A limiting value may be placed on the percentage of sulphur in the coal which will be accepted. Corrections for ash and volatile matter are best expressed in the form of a table. In making corrections for variations in the quality of the coal delivered, it may in some cases be more convenient to make all changes in the price on the basis of change of the B.t.u.

The reasons for basing the contract on the items mentioned are as follows:

(1) "B.t.u. in coal as received" corrects for changes in heating value due to changes in both ash and moisture.

The B.t.u. in the coal as delivered being the most direct measure of its value to the consumer, it is reasonable that the contract should be based principally upon this value. This value may be determined and reported directly by the chemist. This results in a premium for better coal and a penalty for coal not up to the standard.

As has been shown, as far as is now known the presence of small amounts of moisture in the coal has but little effect on the efficiency of the boiler, and as coals from the same mine or group of mines do not usually vary more than 3 or 4 per cent. in moisture, it hardly seems worth while to correct for the small amount of heat lost in evaporating it. By basing the value of coal on the B.t.u. as received (moist), the variations in heating value as otherwise affected by the moisture are provided for.

(2) "Ash in the dry coal" is independent of changes in moisture in the coal, this figure always being the same no matter what the moisture content may be. Coal delivered from the same mines may vary considerably in the percentage of ash. A reasonable allowance, such as 1 or 2 per cent. from the average, would seem to be desirable, as such a variation is almost unavoidable in commercial products. Inasmuch as the heating value is taken care of by the B.t.u. determinations, the only remaining correction to be made for the ash is the extra trouble in handling the coal and ashes and the possible reduction of the capacity of the equipment. When the ash greatly exceeds the amount for which the furnace was designed the reduction in capacity may become a serious matter and would justify a rapidly increasing penalty. For the first 3 or 4 per cent. increase or decrease in the ash it is only necessary to provide for the difference in the cost of the handling, which is between ½ cent to 1 cent per ton for each 1 per cent. of ash in the coal. If corrections other than for B.t.u. are to be made, and the ash is a factor, the specifications should be based upon the percentage of ash in the dry coal for reasons which are explained elsewhere.

(3) If volatile matter is to be corrected for, then "volatile matter in 'combustible'" is preferable to "volatile matter in coal." It should be the same, or nearly the same, regardless of variations in moisture and ash in the coal, and it is more properly a measure of the difficulty to be experienced in burning coal, as it is the direct ratio of the volatile matter to that part of the coal which is actually burned. It is reasonable to have a penalty for great variations in the volatile matter from the standard specified, for the reason that furnaces are not all equally well designed to burn coals high in volatile matter. This should not in any way affect the dealer or operator, provided the coal is furnished from the same mine, as the volatile matter should remain practically constant and a reasonable limit should be established within which no change in the price would be made. This variation could well be 3 per cent. either way from the standard established. The value for volatile matter should be based on volatile matter in the "combustible" (coal free from moisture and ash), as this value remains nearly constant in the same coal. Premiums or penalties for lower or higher volatile matter may properly vary according to local conditions.

(4) *Sulphur.* Sufficient information is not available on which to base a reasonable rate for correction for this element.

A forest products' laboratory is to be established at the University of Wisconsin, at Madison, by the United States Forest Service, where all lines of the experimental investigations of the Government looking to closer and better utilization of timber and the checking of wood waste will be concentrated in the near future.

Practical Letters from Practical Men

Don't Bother About the Style, but Write Just What You Think, Know or Want to Know About Your Work, and Help Each Other

WE PAY FOR USEFUL IDEAS

Air Receivers

The uses of compressed air are so varied that no definite rules can be laid down to cover all requirements of the receiver. That a receiver is desirable seems to be generally conceded, but the reasons for its use seem to be rather confused.

The most important functions of a receiver can be divided under four heads: To act as a temporary reservoir; to collect the water and grease and insure dry air; to reduce the loss caused by friction in the pipes, and to equalize the pulsations and steady the flow of air to the place of use.

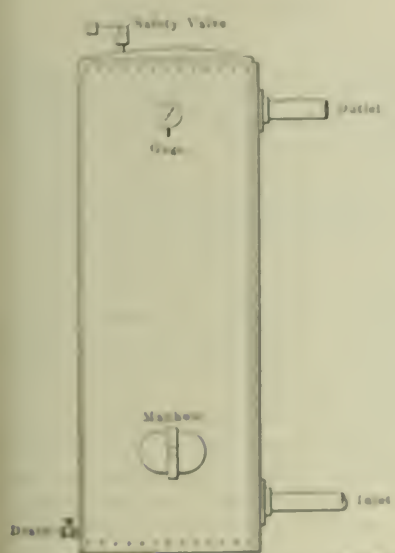

FIG. 1. VERTICAL RECEIVER

The first function of a receiver that occurs to most people is that it will act as a reservoir of power. This is true, to a certain extent, if the receiver is made large enough, but in most cases this would require a receiver so large as to be prohibitory. For this reason the plan of using the receiver as a reservoir will never be satisfactory, and the extra money spent for the reservoir would be better used if expended in the purchase of a compressor of sufficient capacity to supply the greatest demand put upon it.

An idea of the size of receiver necessary to act as a reservoir can be had from the following example of a [illegible] compressor, running at [illegible] revolutions per minute at a working pressure of 100 pounds. It would require a receiver 5 feet in diameter and 60 feet long to keep up the work of the compressor one minute after it had been stopped and not allow the pressure to drop more than 15 pounds. While if the compressor was at work and the demand for air was 25 per cent. greater than the capacity of the compressor in four minutes it would lower the pressure 15 pounds. The real value of the receiver is when the demand for air is very irregular, the advantage being due to the fact that the compressor stores energy in the receiver without any great change in pressure when the demand for air is less. This saves the compressor from the hard usage caused by a varying change in the load, and avoids the loss caused by free expansion, which would result if no receiver were used. When the variation in the quantity of air used is very great, and a uniform pressure is required, an unloader is often used.

FIG. 2. HORIZONTAL RECEIVER

The receiver when properly connected serves as a means for removing the water and grease from the air. The inlet to the receiver should be at the bottom, and the outlet at the top. This applies to both the vertical and horizontal types. See Figs. 1 and 2. To each receiver should be fitted a pressure gage, safety valve and drain. The water and grease are drained from the air by allowing it to pause in its flow, to cool and to drop the water and grease which would otherwise be carried along by the current of air. If the receiver is too close to the compressor the air will not have time to cool sufficiently. The general practice is to place the receiver about 50 feet from the compressor. If the air is not sufficiently dry to prevent freezing after having passed through the receiver, it can be further dried by placing a separator in the pipe line, made as shown in Fig. 3. The shell is made from a [illegible] pipe nipple, according to the size of the line, with caps screwed over the ends. The bottom cap is drilled and tapped for the drain and the top cap for the inlet and outlet pipes. This separator should be placed at the end of the air line, and at the lowest point in the pipe system.

The air may also be dried by placing a second receiver at the end of the air line. This also is useful in reducing the loss by friction of the air in the pipe system. When air is quickly withdrawn from the pipe the pressure will momentarily drop below the average. If a receiver is placed as near the point of action as possible the loss of pressure and momentary fluctuations will, to a large extent, be prevented. Also, by keeping a uniform pressure at each end of the air line, the flow of air will be more uniform, and the pipe friction will then become a constant quantity, due to the average consumption of air and the difference in pressure at the two ends of each end of the pipe. Since the friction loss varies as the square of the velocity, it is [illegible] [illegible] than the loss [illegible] when the velocity is [illegible] due to the [illegible] air consumption.

The fourth function, the equalizing of the pulsations and steadying the flow of air at the place of use, is [illegible] [illegible] the [illegible] [illegible]

FIG. 3. SEPARATOR OR TRAP

comes from the compressor into the pipe, the pressure will run up momentarily far in excess of the average pressure used, unless there is sufficient space for its immediate accommodation. This will throw unnecessary strain on the compressor, and also consume power. By placing a receiver in the air line this difficulty is relieved and a steady flow of air is sent into the pipe leading to the work.

The size of receiver required depends upon the rapidity at which the air is drawn from it, and the drop in pressure permissible. The size also depends upon the working pressure, and in general it can be said that the greater the working pressure, the smaller the size of receiver that can be used for a given number of cubic feet of free air per minute. Fig. 4 is a diagram showing the general practice in selecting the size of receiver under ordinary conditions. For example, to find the size of receiver necessary for an 1100 cubic-foot machine at 110 pounds working pressure, project across to the 110-pound curve, and then down to the lower margin, where the size is found to be 140 cubic feet. From this the dimensions of the receiver can be computed.

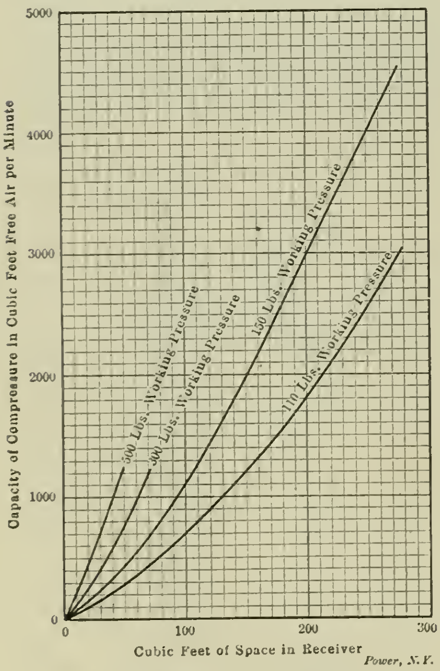

FIG. 4. CAPACITY OF AIR RECEIVERS

Receivers should be made of the best 60,000-tensile-strength steel. The side seams should be double-riveted, and strongly made with dished heads, and tested at a pressure 50 per cent. greater than the maximum pressure used. The larger sizes should be provided with manholes. To prevent too great an accumulation of water and grease, the drains of the receiver should be opened frequently.

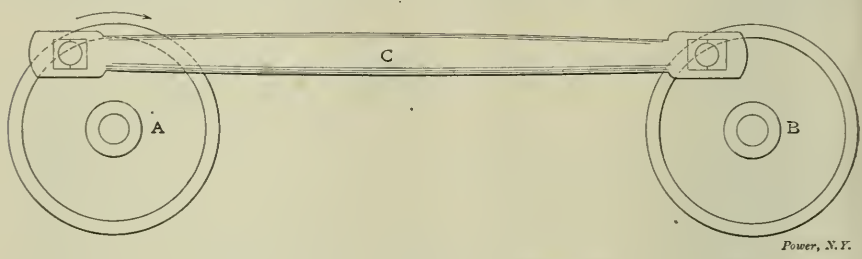
A Problem in Power Transmission

The accompanying sketch represents an end view of two countershafts connected, as shown, by means of two crank disks and a rod C. The countershaft A is belt-driven from the main shaft and runs at from 40 to 50 revolutions per minute, while B is supposed to drive a belt conveyer.



CRANK CIRCLE, 12 INCHES IN DIAMETER; R.P.M., 40 TO 50

The problem is to drive B by means of the rod C, without the use of gears, belt, friction, flywheel or counterbalance. Or, to state it another way, the transmission of power must be made through the two crank pins.

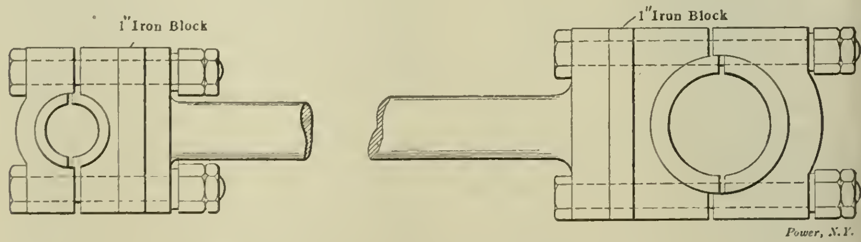
Bankhead, Alberta.

Curing a Balky Gasolene Engine

A short time ago the writer received a commission from a mining company to move a gasolene engine from an old working to a new shaft, and erect and belt it to an air compressor for supplying compressed air to rock drills. A machinist was sent to do the job, with instructions to get everything in first-class order and see that the engine and compressor had at least five days' work under full-load conditions before leaving them.

Within a few days a communication was received from the machinist saying that the gasolene engine would not pull the load, and he could not get more than 30 pounds pressure in the air receiver before the engine began to slow down and finally stop, when the pressure reached 40 pounds; it would work all right when running light, but could not be made to carry the load, and it was impossible to get an explosion oftener than once in every four revolutions.

All of the usual remedies for balky gasolene engines were tried without avail, and it was finally decided that the engine needed more compression, which was given it by inserting an iron block, 1 inch thick, at each end of the connecting rod, between the end of the rod and the brass box (see sketch), thus lengthening the connecting rod 2 inches, which gave about 33⅓ per cent. more compression, with the result that no more trouble was experienced in getting the engine to carry its full load with ease. The 1-inch blocks were only put in as a temporary makeshift until a new piston could be made.



WHERE BLOCKS WERE INSERTED IN CONNECTING ROD

Transformer Connections

Concerning the transformer problem presented by R. S. Carroll, it makes no difference which way the connections are made. Since the motors are not in use when the lights are on, and *vice versa*, the unbalancing of the system, due to the load on the lighting transformer, will not affect the motors. Even if both were in use at the same time it would make no difference, assuming the motor load to balance as the lighting load unbalanced the system, regardless of the phase it might be on.

Such an arrangement for lights is bad, especially if many lights are to be supplied, as the unbalanced condition will cause uneven voltages across the phases.

A two-phase system is much better where both lights and power are to be supplied, as a reasonable unbalancing of the two phases does not make so much difference as in the three-phase system.

Where lights are supplied from a three-phase system, part of the light load should be on each phase, keeping the system as nearly balanced as possible.

Drainage of Steam Piping

From time to time there have appeared communications relating to the erection and drainage of high-pressure steam piping. I have, however, never seen this subject fully and adequately treated, although I have long looked for such an article. What brings this to my attention now is the letter by T. J. Bloss in the issue of February 9.

Mr. Bloss is undoubtedly correct in stating that steam piping should drain in the direction of the flow of steam, and that the steam should enter the engine through a steam separator of ample proportions from which the water of condensation is led away through a trap. A good separator is a valuable addition to the steam line under these conditions, but like every other piece of apparatus, it has its limitations.

I have in mind a 75-horsepower Corliss engine belted from the flywheel to an electric generator. The flywheel is far too light for the service that is expected of the engine, and consequently the regulation is very poor. The steam line is 200 feet long, or more, but is well planned and erected with ample small drip pipes tapped in at intervals, and the water thus removed from the main header is taken off through a trap. Just above the throttle is a large separator of undisputed excellence. Apparently very adequate means of preventing water in the cylinder have been employed, but in several instances water has passed all of these safeguards in such quantities that the engine was stalled. The lightness of the flywheel is, undoubtedly, all that saved the engine from being wrecked on these occasions and no effect more serious than forcing the engine out of alinement was apparent.

I have often wondered whether small pipes tapped into the bottom of a main steam line, as explained, were really of much action as water removers. A jet of steam will not only carry a stream of water over a wide opening in the bottom of the pipe, but it will carry considerable water with it up a long vertical pipe as well. It is reasonable to suppose that, under some conditions at least, the drip pipe may become a more or less perfect condenser, thus supplying considerable water for the trap to remove, and making the engineer in charge think that his drainage system was doing excellent work, when, in fact, little or none of the water came from the steam header.

Meyer, in his "Steam Power Plants," suggests that the steam main be made large enough for the velocity of steam flow to be low, to permit this system of drainage to be used, but the first cost would have been too high in the present case, so the question remains: what is the best and surest way to get the water out of the main?

A Piston Made of Junk

The steam piston head of one of our small pumps became broken in two, the rod was badly bent. We had no casting for the piston and, therefore, set about to devise some means of making a temporary repair. There were found on the scrap pile, however, the following materials from which the piston was built up: Two disks, each 12 1/4 inches, and a piece of an old cast iron bushing 1 5/8x3 1/4 inches. First the bushing was chucked and bored for a 4-inch pipe thread, next the disks were turned down as per sketch, leaving a flange, and both were screwed up tight. Then the whole was chucked and the taper hole bored to take the piston rod. The rod was then turned and fitted to the taper hole and the head was turned and grooved out for the rings.

A PISTON MADE OF JUNK

This piston has run for 3 months, [illegible] without trouble, although it was [illegible].

J. E. [illegible]

[illegible]

Armature Clearance

In all plants, large or small, measuring the armature clearance of the dynamos and motors once every month will prevent a great deal of future trouble. A very convenient method is to turn out on a lathe a set of steel rods of 1/8 inch to 3/8 inch diameter and make smaller sizes of drawn wire from 1/64 inch up to 1/8 inch; a little brass tag should be secured to the end of each, and the diameter of the rod stamped on the tag. These steel rods are to be used in watching the clearance, by passing them between the armature and face of each field-magnet pole, keeping a record of the largest size that passes freely each time. It will be found advisable to test the clearance also after a machine has run on a hot bearing for any length of time.

Motors are operated with smaller clearances than generators, as a rule, because of the difference in size, the smallest generator used in any ordinary plant being considerably larger than the largest motor in the plant.

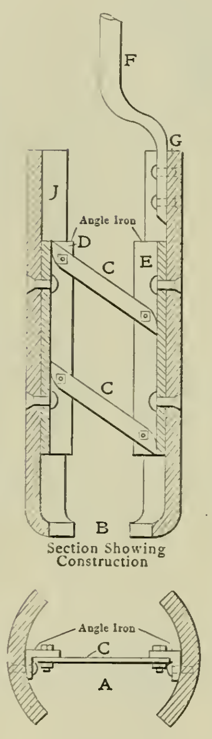
New York City.

Device for Removing Well Pipe

Sometimes when taking out or putting in pipe for an artesian or other small-bore well the pipe slips and falls to the bottom of the bore. This occasions great delay and a new well may have to be dug. By using the device herewith described, pipe can easily be pulled out. Take a piece of pipe the size of the piece in the well, and cut off a piece about twice as long as its diameter. That is, for a 6-inch pipe use a piece 12 inches long. Cut this piece into halves lengthwise and then halve one of the halves lengthwise, making two quarters, as shown in the sketch at *A*. Turn in the lower ends, as at *B*. Take two pieces of angle iron, of suitable size, about two-thirds the length of the pieces of pipe and rivet one piece to the inside of each quarter, in the positions shown at *C C*. Drill two holes in the upright of each angle iron for bolts to go through to hold the links. Drill the holes in the piece *D*, making the upper one one-fifth the length of the piece from its upper end and the lower hole three-fifths the length of the piece from the upper end.

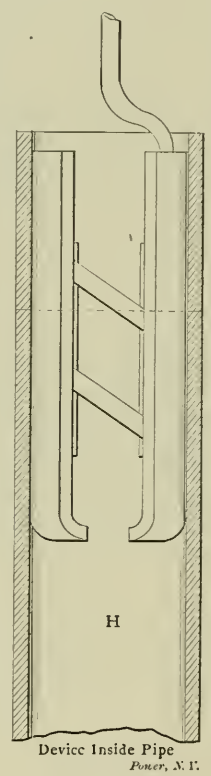
In the angle iron *E* make the upper hole two-fifths the length of the piece from its upper end and the lower hole four-fifths the length of the piece from its upper end. Then make the two links of such length that when they are held straight across at right angles from the angle iron *D* to the angle iron *E* they will hold the two pieces of pipe apart to the original diameter. Forge the ends of these pieces to the shape shown and drill a hole in each end the same size as those drilled in uprights of the angle irons, and at such a distance from the ends that when the bolts are passed through them and through the holes in the angle irons the pieces will not be prevented from coming to position.

After these holes are drilled the links can be bolted to the angle irons with machine bolts, the bolts being loose enough to allow the pieces to swing upward easily. A piece of square iron *F*, of suitable size, is then obtained and one end flattened and riveted to the upper end of the quarter *G*. Then it is bent in and up as shown. To the upper end a rod or rope can be fastened. If these instructions have been followed the device will look like the sectional view. When it is held up by *F*, gripping a pipe, the outside will look like *H*.



Section Showing Construction

FIG. I



Device Inside Pipe

FIG. 2

Secure a rod or rope to the upper end of *F*, and lower the device into the well in which the pipe is. When it touches the pipe the piece *J* will swing in toward *E*, and allow the device to slip into the pipe. When an attempt is made to pull the device out of the pipe it will cause the side *E* to slide up in the pipe, while the side *J* remains stationary, thus causing the links to approach a position at right angles to the angle irons, consequently spreading the two sides of the device and gripping the side of the pipe to be raised. By continuing to pull up on the rope or rod the pipe can soon be raised to the surface.

Receiver Pressure

The relation between cylinder ratio and point of cutoff, in the low-pressure cylinder, and consequently the receiver pressure, are not well understood by many engineers. It is self-evident that if the cutoff in the low-pressure cylinder corresponds to the cylinder ratio, the receiver pressure at all times will be at the point of efficiency; that is, the receiver pressure will follow the high-pressure terminal, giving as nearly perfect expansion as it is possible to secure in a reciprocating engine, the low-pressure cylinder taking steam at approximate pressure and temperature corresponding to the high-pressure terminal.

To make this clear, we will assume a case with a cylinder ratio of 1 to 4. It is perfectly clear that one cylinderful of steam from the high-pressure cylinder will fill the low-pressure cylinder one-quarter full, neglecting the influence of the clearance at the same pressure, and the loss due to condensation and without reheat in the receiver.

With engines where the low-pressure cutoff is controlled by the governor, it is not possible to secure a cutoff that will correspond to the cylinder ratios for all loads. In such, the low-pressure cutoff should be so adjusted as to give a cutoff corresponding to the cylinder ratio for the average load.

If the cutoff in the low-pressure cylinder of a compound engine with a ratio of 1 to 4 takes place before one-quarter stroke, it will cause a negative load on the high-pressure diagram, the size of the load being in proportion to the shortness of the low-pressure cutoff; that is, the shorter the cutoff the larger the load. Also, if cutoff takes place later than one-quarter stroke, it will cause a drop in pressure between the high-pressure terminal and the receiver, the amount of the drop being proportioned to the length of the cutoff, i.e., the longer the cutoff the greater the drop.

This drop represents a loss due to free expansion, all of which goes to show, I believe, that there is just one proper joint of cutoff in the low-pressure cylinder for maximum efficiency, as explained above. A further conclusion would be that the cutoff on the low-pressure cylinder should be hand-controlled for the best results.

It is understood that with a low-pressure cutoff set corresponding to the cylinder ratios the greater the load the larger proportion of load carried by the low-pressure cylinder and, in event of an overlooked engine, it might be necessary to lengthen the cutoff on the low-pressure cylinder in order to distribute the load between the cylinders, and also to prevent injury to the low-pressure cylinder by reason of excess pressure.

The point at which it would be necessary to lengthen cutoff would be when the receiver pressure reached the highest allowable point consistent with safety.

It is not possible to say what should be the highest allowable receiver pressure, as that would be owing to the design of the cylinder and receiver and engine as a whole; but as a general thing, builders place relief valves on receivers set for what, I suppose, they calculate is the safe maximum pressure, and engineers, by adjusting the cutoff so as to keep just under pressure for which the relief valves are set, may feel perfectly safe.

Compound Engines

Having noticed a great difference of opinion in regard to the economy and the amount of power obtainable from compound engines, as compared with simple engines, the following discussion may be of some interest.

It is a fact, determined by tests and experiments, that the best economy in an engine is obtained by a moderately short cutoff, so restricted that it shall not come earlier than one-third stroke. This is due to the fact that the condensation of steam and the amount of heat absorbed by the walls of the cylinder during admission, increase as the cutoff is lengthened, and as this water of condensation is revaporized during the exhaust, the heat is removed from the walls and must be again supplied by the incoming steam at the next admission. This action of the cylinder walls is thus seen to place a limit on the number of expansions that can be profitably used for a simple engine, and while increasing the steam pressure will give greater power, there is no gain in economy by raising the steam pressure beyond a very moderate limit unless the expansion can also be increased at the same time.

This leads at once to the compound and multiple-expansion engines, as they have proved to be the best means for increasing the expansion of steam and at the same time avoiding excessive cylinder condensation. It should be borne in mind, however, that compounding is not always advisable, and it is necessary to determine the conditions under which it should be resorted to and the gain in economy to be expected. In the first place it is obviously unfair to compare a simple engine and a compound engine running under the same steam pressure, for the primary object of compounding is to use high pressures and a large number of expansions. The only true comparison would seem to be between two engines each of which is working under its best conditions of operation.

Experience seems to indicate that for simple condensing engines 80 pounds steam pressure is about the maximum point for best economy, while compound engines may profitably employ from 150 to 170 pounds. With a steady full load the latter engines will show from 20 to 30 per cent. better economy than the former, but it must not be forgotten that when running under a reduced load a compound engine will generally suffer more loss of economy than a simple engine. This is evident when we consider that as the power of a compound engine is reduced by shortening the cutoff on the high-pressure cylinder, the load is in general thrown more and more onto that cylinder, this being universally true if the cutoff on the low-pressure side is fixed. At light loads the low-pressure cylinder may even act as a drag, the high-pressure cylinder performing all of the work and being subjected to the greater temperature fluctuations which the engine was designed to eliminate.

Under maximum load and with the cutoff of the many determined by the ratio of the cylinders, a compound engine will show a good gain in economy over a simple engine of the same power, and has the additional advantages of a more even distribution of work on the crank shaft and smaller strains on the pins.

However, the actual power developed by a compound engine is the same as that of a simple engine which has a cylinder the same size as the low-pressure cylinder of the compound engine, and which takes at each stroke the same volume of steam as the high-pressure cylinder and at the same pressure.

Hyde Park, Mass.

Cleaning Water Tube Boilers

I am pleased to note that during the past year some space has been devoted to the subject of cleaning water-tube boilers. Many a boiler has been entirely ruined by neglect of cleaning, although I appreciate that many forms of water-tube boiler are so inaccessible as to require considerable time for cleaning, which has caused them to be neglected. The types which cannot be quickly cleaned necessitate the investment of considerable money in extra idle boilers, which are not even earning the interest on the money invested in them, because they are in operation but a few days at a time.

I have charge of four [illegible] water-tube boilers and run three of them continually every day in the year for twenty-four hours per day to carry our load, and most of the time the four boilers are required. Therefore, only one boiler can be cut out for cleaning at a time, and it must be cleaned when the load will permit, and sometimes it must be cleaned quickly and cut in for service again.

Our water is quite bad, carrying several grains of impurities per gallon, and I clean each boiler after fourteen days' running. We can clean one boiler in one day, thus cutting out each boiler twenty-six days each year.

My plan for cleaning is as follows: At 8 p.m. after the peak load has dropped off, I cut out the boiler I wish to clean, draw the fires and blow the soot from the tubes. The boiler and setting is then allowed to cool down, the draft doors being opened slightly to allow a little air to flow over heating surfaces. After the boiler has stood two or three hours the steam pressure is allowed to reduce through a valve and pipe suitably arranged for the purpose. As soon as the pressure gets down very the manhead in the steam drum is taken out. At about 4 a.m. the night engineer has a hose placed with its nozzle just inside the manhole, and starts feeding cold water into the steam drum, and at the same time opens the blowoff cock slightly so that the water will flow from the boiler at the same rate at which it is entering. This plan gradually cools the water in the boiler, rapidly draws the heat from the brickwork and safely hurries cooling. When the boiler is drained it is ready for internal inspection and cleaning, the furnace, ashpit and combustion chamber being cleaned while the boiler is draining.

Before starting internal cleaning I send a man into the mud drum with an incandescent lamp on an extension cord. He holds this light at every tube and I, from inside the steam drum, examine the condition of every tube and direct the passing of the turbine through them, if need be.

Scraping and washing complete, I again inspect the tubes and if satisfactory, the two manheads are put in, and the blowoff cock is taken apart and examined for signs of leaks or cutting. If in order, it is put back, packed and adjusted with the set screw until freely working and then locked with a jam nut. If it is leaking it is ground and made tight, after which it is put back and adjusted as described.

The total time required in following out my plan of cleaning this boiler is, using two men, 7 hours and 15 minutes. Therefore, starting to clean at 7 a.m., the boiler is being filled with water again at 3:15 p.m. The filling of the boiler requires approximately ½ hour, and as soon as water appears in the glass a fire is kindled and fired slowly for 1¼ hours, and the pressure brought up to the working pressure. The boiler is then cut into the header at 5 p.m., just in time to help with the peak load. At 8 p.m. the next boiler in turn is cut out and cleaned, so that all four boilers can be cleaned in four days' time, if necessary.

South Bend, Ind.

Results of a Pump Test

As there has been considerable controversy about the power required to operate a centrifugal pump with the discharge valve closed or partly so, I submit the following data of a test made with a No. 6 centrifugal pump, driven by a 35-horsepower induction motor:

Conditions.	Power Required.
Valve closed	12.6 kilowatts per hour.
Valve quarter open	15.0 kilowatts per hour.
Valve half open	16.4 kilowatts per hour.
Valve wide open	16.6 kilowatts per hour.

All other conditions were the same throughout the test.

W. N. GULICK.

Tustin, Cal.

Valve Stem Broke

The man in charge of a large cross-compound engine noticed that the high-pressure cylinder was not developing its share of power. He removed the valve and found the stem broken close to the valve. The engine ran as it did because there was a piece broken out of the valve and steam was blowing through the hole, thus supplying some steam for that end of the cylinder.

J. M. SEWELL.

Hyde Park, Mass.

Reducing Fuel Expenses

Some time ago an engineer took charge of a certain plant which was in bad shape. It had been permitted to run down to such a degree that the fuel expenses were exorbitant. In an attempt to reduce the amount of coal used, the first things the engineer tackled were the valves located on top of the boilers. These valves had been allowed to run so long without packing that the stems were badly grooved and it was almost impossible to make them tight with new packing. As new valve stems could not be readily obtained, it was decided to pack the old stuffing boxes, as the valves were seldom used. In doing the work the valves were left wide open and some heavy lead washers were driven into the stuffing boxes and were calked around the fluted stems. The remainder of the box was filled with a good fibrous packing.

As the safety valves leaked badly, they were ground in and properly adjusted. It was then decided to clean the tubes,

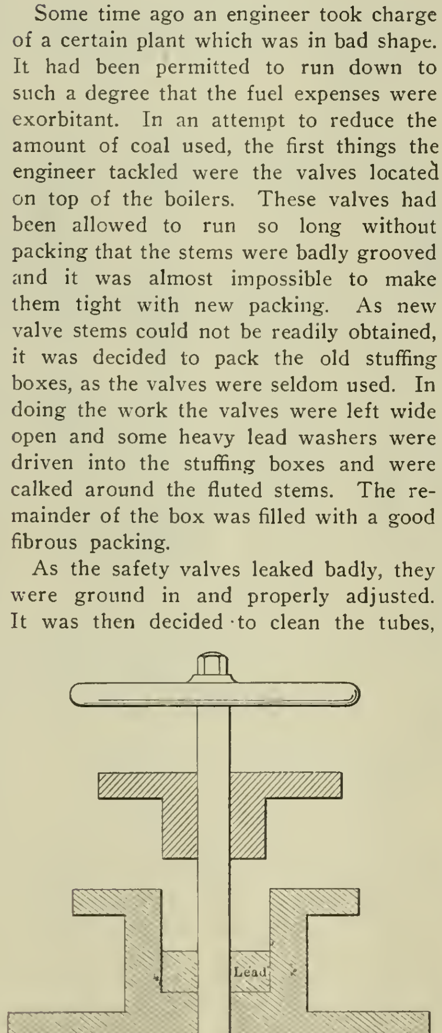

FIG. 1. REPACKING VALVE

and at the first opportunity it was found that it was impossible to force a flue brush through any of the tubes. A length of steam pipe having the largest possible outside diameter that would enter the boiler tubes was secured and forced through each tube by means of a sledge hammer. The flue brush was then used, and after steam was raised, it no longer required the forced-draft fan to hold the steam at the required pressure.

Upon investigation, the feed-water heater appeared as though it had never been blown or opened up for cleaning since it was erected. The amount of scale taken from the heater filled more than three ash cans. During the cleaning of the heater the fire linings of the furnaces

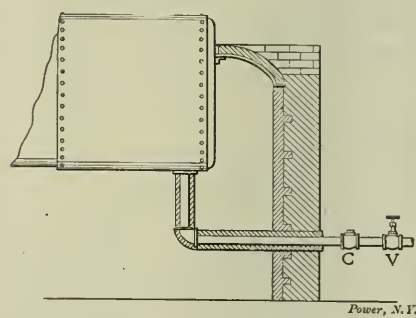

FIG. 2. INSTALLING BLOWOFF VALVE

were put in good shape, and next day when the plant was running the fireman was jubilant, and naturally so, as his work had been greatly reduced.

Next in order to receive attention was the blowoff valve. The asbestos-packed cock at *C*, Fig. 2, received a new lining, and an auxiliary blowoff valve was connected in the line at *V*, the improvement being that valve *V* could always be repaired without shutting down or interfering with the regular operation of the plant.

The engineer noticed that the fireman had to run the boiler-feed pump very fast in order to keep the water at the proper level. The pump was opened for inspection and found to need some packing around the water plungers and a few discharge valves. The packing and valves were promptly inserted, and when the pump was started, it was found that about one-quarter of the original speed was sufficient. All leaking flanges received new gaskets, and the pipe covering was either repaired or renewed wherever it was found necessary.

The next thing to receive attention was the engine. It being found that steam blew past the packing rings rather freely, it was decided to expand them and insure a steam-tight piston. When the rings were adjusted with the piston at the end of the cylinder, great difficulty was experienced in trying to get the piston to pass the center of the cylinder. Hence, the engineer lessened the labor by expanding the packing rings to fit the smallest part of the cylinder. After the rings were adjusted and the piston tested for tightness, the cylinder was closed and the engine started doing its regular work. The application of the indicator showed the valves needed adjustment, which was promptly made.

An account was kept of the amount of coal burned after these repairs were made, and when compared with the amount of coal burned previous to the repairs and the horsepower developed in both cases, the amount of coal saved was nearly 30 per cent.

WILLIAM KAVANAGH.

New York City.

Interesting Indicator Diagrams

The two sets of diagrams herewith were taken from the same engine under the same conditions of working, but with different valve setting. The engine was

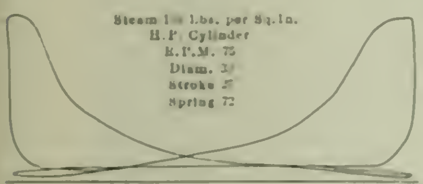

FIG. 1

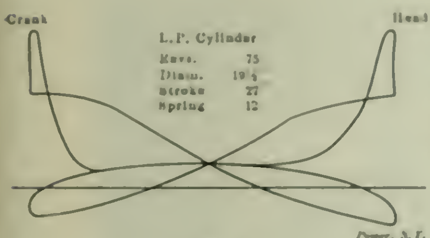

FIG. 2

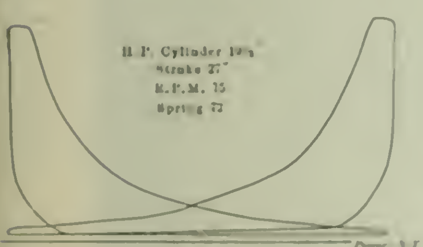

FIG. 3

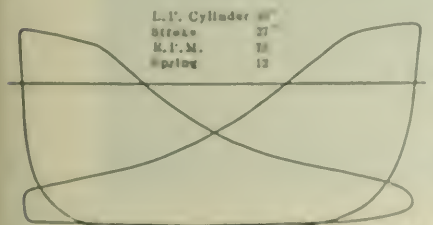

FIG. 4

a 250-horsepower, and was supposed to run condensing.

The first set was taken from the engine as it had been running for two years. The setting had been done by one of the graduates of a continental polytechnic, and represented three weeks work for a man who had done well in his term. On taking over the works the writer was convinced that the engine was not running evenly, and considerable heat was being developed and running on the oil hill.

After indicating, the trouble was shown by diagrams Nos. 1 and 2. There were several men interested in the running of the engine, and in spite of the diagrams they were as convinced as ever that the result was all that could be desired. The condenser was not in use, and the weight of opinion was that it was not worth while, although there was a lake of some miles in area at the engine-room door. It was thought that the pumping of the water would more than balance the gain, so the engine ran noncondensing on a condensing valve setting.

The condenser was dug out and in three weeks was ready for a trial run, and the result of this is shown in Figs. 3 and 4. The pressure at the boiler house was 140 pounds steam superheated to 250 degrees Fahrenheit.

Sheffield, England.

Wants Hydraulic Information

We have a stream of water delivering 360 inches under a 12-inch pressure. By going 500 feet from the estimated location of the plant a fall of 1.40 feet can be obtained. What size and grade of pipe, and what class and size of wheel would be most applicable, and how many 16-candlepower lamps can be carried?

WILLIAM F. P[illegible]

Stine, Nev.

Foot Valves and Suction Pipe Repairs

My first experience was with pumping out ditches for laying sewer pipe. The ditches were narrow and the strainers gave considerable trouble, as splinters, etc., would close up the holes and stop the flow of water. To remedy this, I made a drum of 3/16-inch iron, about 13 inches in diameter by 10 inches long, and drilled the circumference full of ½-inch holes. The bottom, however, was not drilled. This was attached to the top of the old foot valve, as shown in Fig. 1, and was a success as a strainer, as it would rest on the bottom of the ditch and sink no deeper, and the sand could not get through the bottom.

Another experience was with a salt-water pump used to fill a tank for flushing purposes. A cast-iron strainer on a 3-inch suction pipe was originally used but, due to corrosion, barnacles, [illegible] and seaweed, it was soon "down and out." As the lift was not very great, the foot valve was discarded and a large strainer made from a piece of [illegible] sheet brass, bent to form a cylinder [illegible] inches in diameter and drilled with [illegible]-inch holes, as shown in Fig. 2.

The suction pipe of 3 pump began to leak at an underground joint which [illegible] pulled apart and was repaired as shown in Fig. 3. Two half rings were cut out of 1-inch boards, about 10 inches outside diameter, the inside hole being cut to fit the pipe. Over these rings tin was nailed, making a half cylinder about 18 inches long. Then an open box without a bottom or top was made to fit on top of the cylinder. A piece of thin tin was wrapped around the pipe and wired in place. The half cylinder was worked under the pipe and all the sand cleaned out. The box was put on top and the whole filled with portland-cement mortar. This stopped

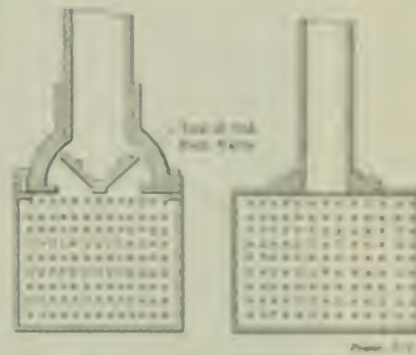

FIG. 1 FIG. 2

the sand from getting in and as there is no pressure on the pipe it gives satisfactory results. I think, however, it would have been better to have wrapped the pipe with cloth first, instead of tin.

The discharge pipe on our salt-water system began to leak. To cut out the piece, cut threads with a ratchet stock and put in a new piece would have been the proper way to do, but the pipe was badly corroded and too thin to cut threads. We

FIG. 3

FIG. 4

therefore adopted the following plan: We [illegible] the pipe each with a pipe [illegible]. Then a piece of [illegible]-inch pipe, about [illegible] inches long, was [illegible]. Cement was then [illegible] as shown in Fig. 4.

Vandergrift Low-Pressure Turbine Plant

A Rateau Regenerator, and a Rateau-Smoot 600-Kilowatt Direct-current 250-Volt Turbo-generator Set Said to be the First of Its Type Here

The Ball & Wood Company, of Elizabethport, N. J., recently built a low-pressure turbo-generator outfit which is in successful operation at the Vandergrift plant of the American Sheet and Tin Plate Company, Vandergrift, Penn. The outfit consists of a Rateau steam regenerator, a Rateau-Smoot low-pressure turbine and a Smoot generator. It utilizes the exhaust steam from reversible blooming-mill engines, which work intermittently and at widely varying loads, thus having a supply constantly differing in volume. In order to overcome this variation and to supply the turbine with a steady flow of steam the regenerator was installed. The Rateau Steam Regenerator Company, of New York City, received the contract for this plant, and the turbine was built in the Ball & Wood Company's shops.

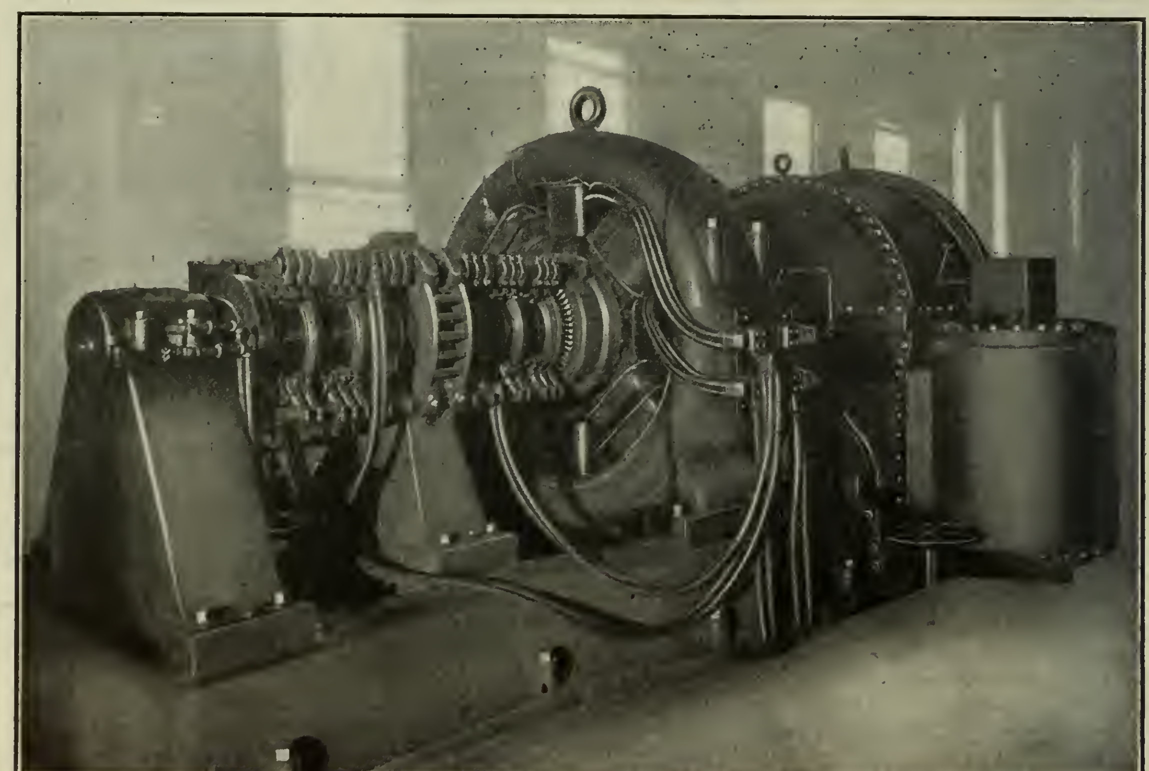

FIG. 1. SIDE VIEW OF LOW-PRESSURE TURBO-GENERATOR INSTALLATION AT VANDERGRIFT, PENN.

The Regenerator

The regenerator in this instance is a cylinder 40 feet long by 8 feet in diameter and contains about 45 tons of water. This water is kept in constant circulation by the steam from the mill engine, which is passed through it in pipes arranged for the purpose. Two results are obtained from this circulation, a practically uniform temperature throughout the water and as thorough an exchange of heat as possible between the steam and the water. The temperature of the water is thus made to correspond to the pressure of the steam in the pipes, so that when the steam pressure falls, owing to the closing down of the engines, the water liberates part of its heat in the form of steam, and when there is an excess of steam the temperature of the water is raised accordingly.

The Vandergrift regenerator is of such size that the mill engines may be completely shut down for periods of two minutes and during this time the regenerator will supply steam to the turbine at the rate of 25,000 pounds per hour. A 24-inch relief valve is set for 3 pounds above atmospheric pressure, so that the pressure of the steam in the regenerator is constantly maintained between 14.7 pounds and 17.7 pounds, absolute, and the back pressure of the engine never exceeds 3 pounds.

If the mill engines are shut down for periods longer than two minutes, or if the exhaust steam is insufficient for the turbine, a connection between the regenerator and the boilers is automatically opened, admitting live steam for the continued operation of the turbine. The action of the live steam, which enters the regenerator through a pressure-controlled reducing valve, is exactly similar to that of the exhaust steam, an equilibrium between the pressure of the steam and the temperature of the water being maintained which gives a very exact control over the amount of steam admitted and absolutely prevents the steam escaping to the atmosphere.

It will be seen from the foregoing that just as the flywheel of an engine is for the storage of energy so the water in the regenerator may be termed a flywheel for the storage of heat, taking this heat from the steam when the latter is in excess, and giving it up when the steam supply diminishes or ceases.

The Low-pressure Turbine

The Vandergrift low-pressure turbine is of 600 kilowatts capacity, operating at

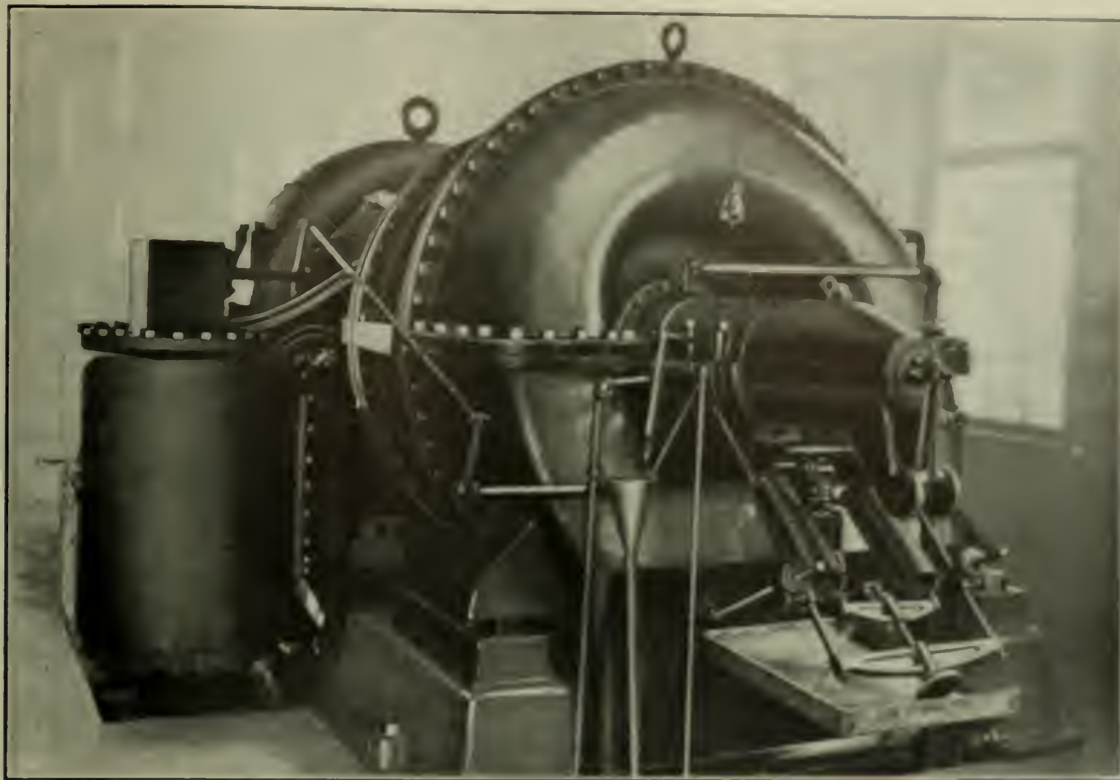

FIG. 2. END VIEW OF LOW-PRESSURE TURBO-GENERATOR INSTALLATION AT CAMBRIDGE

1500 revolutions per minute. It is of the impulse type originated by Professor Rateau, but the installation under discussion was redesigned by C. H. Smoot, of the Rateau Steam Regenerator Company, to meet the requirements of standard American shop practice. The turbine receives the steam from the regenerator and makes use of it between the limits of the pressure of the atmosphere and the vacuum obtained from a condenser, the entire expansion of the steam taking place in the fixed diaphragms.

Due to this fact that there is no expansion of the steam in the moving vanes of the turbine, there is no difference of pressure between the inlet and outlet sides of each rotor, and consequently there is no tendency for the steam to leak past the tips of the blades. On this account the clearances in this turbine are extremely large, running up to ten times the amount possible in a turbine of the type where the expansion takes place in the rotors, and giving absolute immunity from blade stripping.

The rotating element has an extremely high factor of safety, such in fact that the turbine can be operated at speeds greatly in excess of its rated speed without causing any strains in the different parts which will exceed the elastic limits of the materials used.

The Hyllien governor controls the steam admission directly through a positive connection between the flyballs and the steam valve. It is located on an extension of the main shaft with its thrust opposed to the steam thrust and always twice as great. As will be seen from Fig. 3, the flyballs work on knife edges against a spring and are positively connected to the throttle valve. The regulation is controlled from the outside by means of springs mounted on a frame and connected to the governor links. These springs are so arranged that they can be adjusted while the turbine is running, which also enables the engineer to alter the speed of the unit without interfering with its continuous operation. The speed variation is less than 2 per cent. between no load and full load.

The turbine has six rotors, each a [illegible] of [illegible] and [illegible] provided by a [illegible] diaphragm. Nozzles are [illegible] in the [illegible] and [illegible] [illegible] which [illegible] [illegible] the [illegible], are mounted on the diaphragms. Fig. 3 is a vertical section through the turbine and

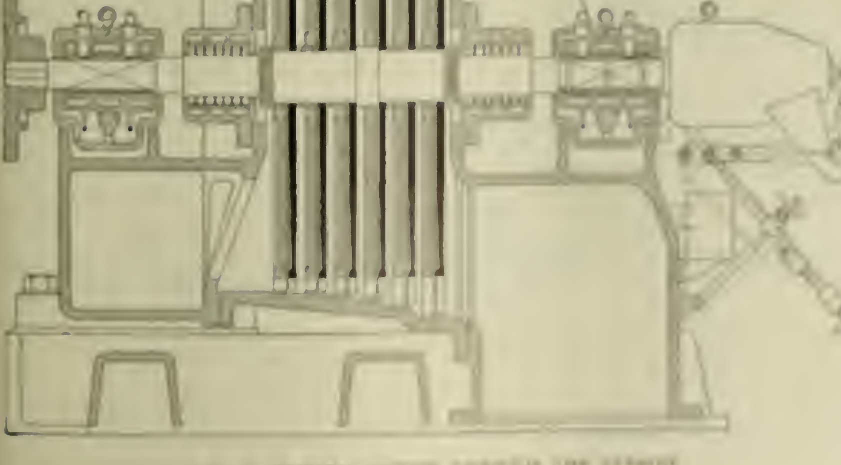

FIG. 3. VERTICAL SECTION THROUGH THE TURBINE

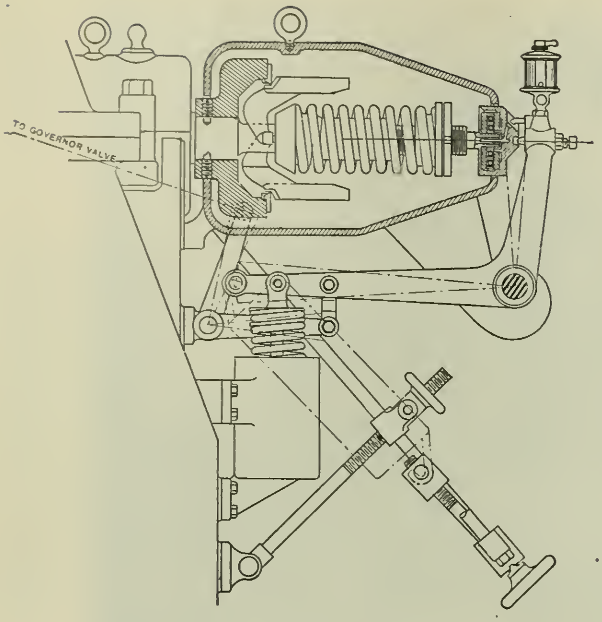

FIG. 4. SECTION THROUGH THE GOVERNOR

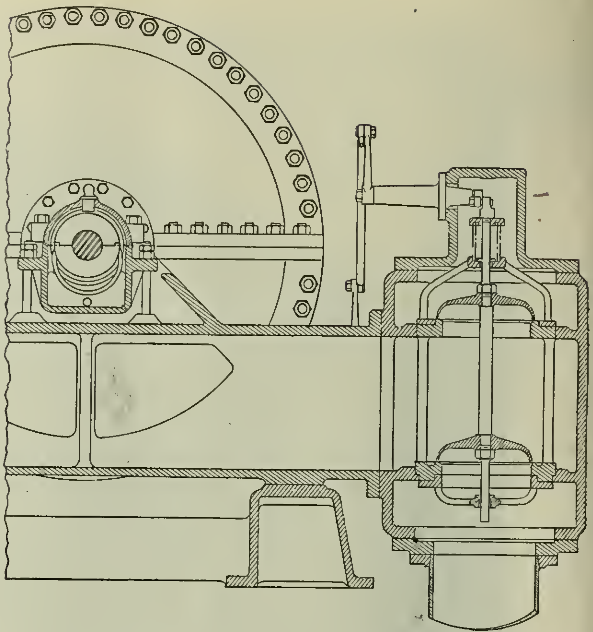

FIG. 5. SECTION THROUGH THE THROTTLE VALVE

shows the general construction, while Fig. 5 shows a section through the throttle valve.

The turbine is connected to the generator by a coupling which consists of two hubs mounted one on each shaft. The torsional movement is transmitted by means of pins so used as to permit smooth operation even though the shafts should become materially out of line.

The Generator

The generator is a 600-kilowatt machine running at 1500 revolutions per minute, and delivers continuous current at 250 volts. It is of the open-frame type with no forced-air circulation, but the design is such that the temperature rise above the surrounding atmosphere is extremely low. The machine has four poles and four intermediary poles. The commutator is in two sections, held together against centrifugal force by nickel-steel retaining rings shrunk in place. No sparking whatever occurs at the brushes, and these do not have to be shifted for any load up to full load. The commutation is first class and the fact that the commutator does not have to be lubricated removes a serious objection to the use of direct-current dynamos in plants such as at Vandergrift, where the metallic dust in the air might settle on the oily surface and cause short-circuits which would seriously injure the machine.

This generator is believed to be the first of its size that runs at that speed to be built in this country, and great credit is due to Mr. Smoot for the successful design. In 1906 two 250-kilowatt 250-volt direct-current generators were installed in the plant of the International Harvester Company, at South Chicago,* both direct-

*See Power for June, 1907.

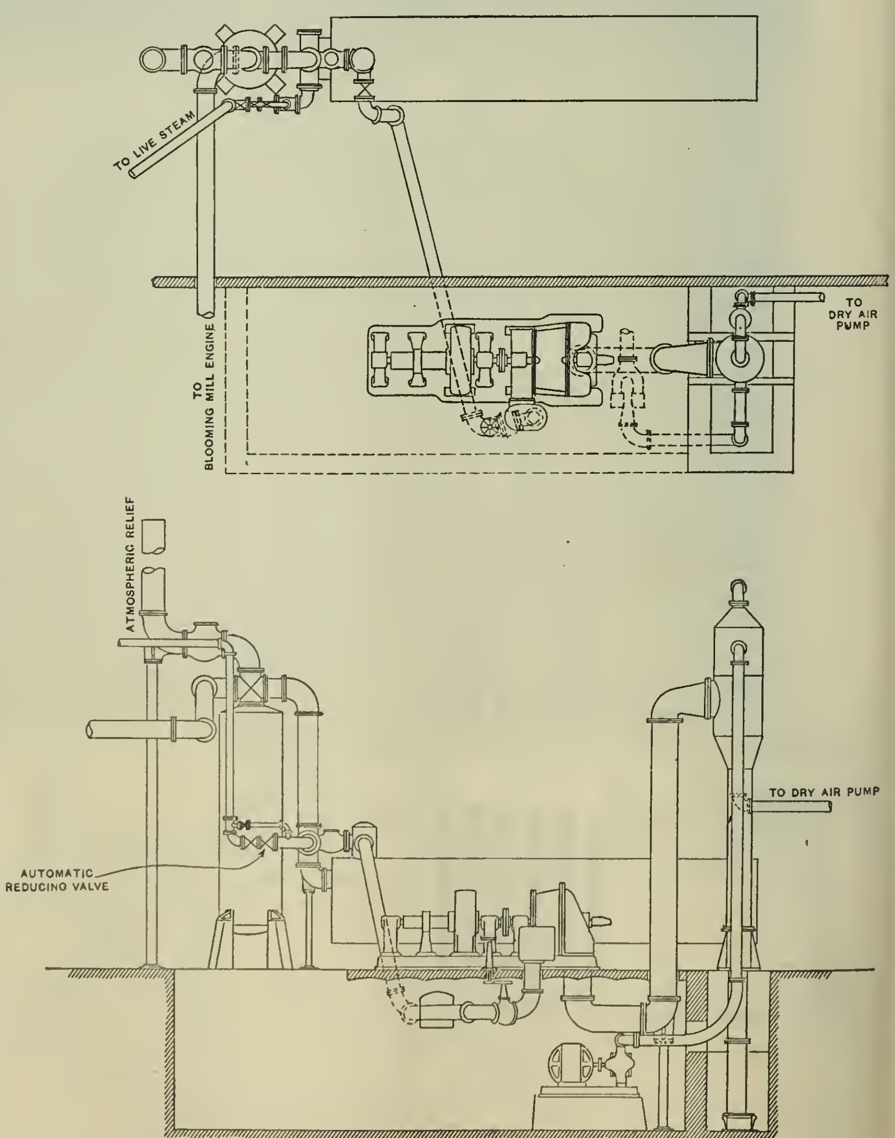

FIG. 6. PLAN AND ELEVATION OF LOW-PRESSURE TURBINE INSTALLATION

connected to a 500-kilowatt low-pressure turbine operating at 1500 revolutions per minute. This was the first low-pressure turbine plant of the Rateau type installed in the United States and it has been in successful operation ever since. All three of these generators are from Mr Smoot's design.

Operating Conditions

The mill engine at Vandergrift, when working under normal conditions, uses about 70,000 pounds of steam per hour, and the turbine when operating at 500 kilowatts uses less than 40 pounds of steam per kilowatt-hour, or less than 20,000 pounds of steam per hour. There is thus some 50,000 pounds of steam per hour still available for future low-pressure turbine installations, and this with practically no increase of operating expenses.

The Rateau-Smoot turbo-generator unit is an extremely simple one to operate, and ordinarily the regular engine-room force required to run the reciprocating engines is fully able to take care of the turbine. When it is desired to place the unit in service, it is merely necessary for the engineer to start up the condensing apparatus, then open the throttle valve gradually, bringing the turbine slowly up to speed. He should, of course, first make sure that there is plenty of oil for the different wearing surfaces.

Power Station Economies at Baltimore

At the Franklin Institute, in Philadelphia, Thursday evening, March 25, Horatio A. Foster, well known to the public as the author of Foster's "Electrical Engineers' Pocketbook," delivered a lecture, illustrated with lantern slides, on the subject of "Power Station Economies at Baltimore." Mr Foster sketched rapidly the situation of the United Railways Company, of Baltimore, at the time of the fire in 1905, which nearly destroyed its main generating station at Pratt street. This station contained about half of the generating capacity of the system, the other half being scattered about the city in eight smaller plants which were mainly noncondensing. He told of the studies which led to the dismantling of all but three of these smaller plants, now held in reserve, the building of the three modern substations, the reinforced-concrete steam station built near the amusement park not far from the bay shore, 11 miles from the city, and the rehabilitation of the partially burned Pratt street station. At present the Pratt street station contains three 1800-kilowatt units, five 2000-kilowatt units and two 5000-kilowatt units, all driven by McIntosh & Seymour engines, and one 5000-kilowatt Curtis turbine, a total of 30,400 kilowatts of rated capacity.

In 1905 the Pratt street station carried 50 per cent. of the load, in 1908 it carried 95 per cent. In the meantime the yearly output had grown from 60,000,000 kilowatt-hours to more than 100,000,000 kilowatt-hours, and the coal consumption per kilowatt-hour had dropped from 4.25 pounds in 1905 to 3.23 pounds in 1908.

The lantern slides showed in a very marked way the difficulties to be surmounted in the reconstruction of even such a modern power house as this, and included the work on the foundations to prevent vibration, which was rather severe in the old engine room, the cable ducts, manholes and switchboard, and numerous changes in location of the smaller engines. The new construction of dock wall was described but not shown. The reinforced-concrete work of the Bay Shore power plant was shown in detail.

The entire work was done, for the United Railways Company, under the direction of Stillwell & Van Vleck, consulting engineers, with the author, Mr Foster, in charge of the work at Baltimore.

To Honor Charles T. Porter

There will be a special meeting of the four national engineering societies, at the Engineering Societies building, 29 West Thirty-ninth street, New York, at 8:30 p.m., Tuesday, April 13, for the purpose of awarding the John Fritz medal for 1909 to Charles T. Porter, for his work in advancing the knowledge of steam engineering and in improvements in engine construction.

The presence is requested of members of all branches of the profession, and particularly of those represented in the four national organizations of engineers participating in the creation of the medal fund. Besides the simple ritual of the presentation of the medal, in the presence of invited guests and distinguished representatives of engineering, there will be addresses by representatives of the four groups of the profession most concerned as follows:

"The Debt of Modern Industrial Civilization to the Steam Engine as a Source of Power," Dean W. F. M. Goss, of the University of Illinois.

"The Debt of the Modern Steam Engine to Mr Charles T. Porter," Prof. F. R. Hutton, of Columbia University.

"The Debt of the Era of Steel to the High-Speed Steam Engine," Robert W. Hunt, of Chicago.

"The Debt of the Era of Electricity to the High-Speed Steam Engine," Frank J. Sprague, of New York.

The board of award will be gratified by a large and representative gathering to do honor to the donor, to the recipient and to the great achievement which the John Fritz medal is intended to commemorate. While evening dress is not imperative, its use is encouraged and requested. Ladies are invited and check rooms will be provided for their use.

Birmingham Won First Test

At Newport, R. I., March 26, the scout cruiser "Birmingham" won first place in the 100-mile endurance and coal-consumption test at 10 knots speed over her sister ships, the "Chester" and the "Salem."

The "Birmingham" is fitted with reciprocating engines, and according to official data the coal consumption for each hour was only 30 tons.

The "Chester," fitted with Parsons turbines, took second place, the consumption being 40 tons, while the "Salem," with Curtis turbines, used [illegible] tons.

No. 27's Housewarming

John Ericsson Association No. 27, N. A. S. E., of Brooklyn, held a smoker and "housewarming" Friday evening, March 26, to celebrate its removal to more spacious quarters in the Masonic Temple on Manhattan avenue. A large majority of the members and many friends attended. President W. T. [illegible] and John M. Lockwood, chairman of the arrangement committee, made the addresses of welcome. A pleasing entertainment was given by Frank Corbett, William Murray, Henry Elder, John Richards and John Armour. Frank Martin officiated as master of ceremonies. There were refreshments of all kinds. The committee is to be congratulated.

Progressive Council, U. C., Reception

Progressive Council No. 12, Universal Craftsmen, Council of Engineers, of Newark, N. J., held its annual reception and ladies' night Friday evening, March 19. There was an enjoyable entertainment and an address by Brother Whitehead. A number of distinguished guests were present. Walter Pratt was presented a [illegible] and Mrs. Pratt a handsome bouquet of flowers. Refreshments were served. J. Gallow was the chairman of the committee.

On Tuesday evening, March 23, H. J. [illegible] spoke before the Modern Science Club of Brooklyn, on the subject of "Steam Engine Governors." The speaker spent some time in the beginning in definitions of terms to be used in the discussion. He then went into the mathematics of the [illegible] governor, both of the Watt and the weighted types. The subject was exhaustively treated and was followed by an interesting discussion by members of the club.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for March, 1909, was (weekly and monthly) 190,000.

April 6................ 42,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents

The Manufacturer's Responsibility

When a man buys an automobile the selling agent turns it over to him and is through. If the purchaser wants to get his money's worth out of it in transportation and pleasure he must learn to run it or hire a man who knows how; and if he punctures tires, strips transmission gears, cracks his water jacket, etc., he expects to pay for replacements and repairs. Only when obvious imperfections in workmanship or material are responsible for the trouble can he expect the builder to see him out of his difficulty. But when a man buys an engine or a boiler, or a stoker, or a condenser, or a water-heating or purifying outfit, or even a little appliance like an injector or an indicator, he often appears to think that he has paid for all the benefits and advantages which it promised when he settles the bill, and that all he has to do is to turn on the steam and gather in the profits. One cannot become a mechanical engineer simply by buying an indicator. He must have the intelligence and the patience, and the skill to apply it so as to get correct and intelligible diagrams, and he must have the ingenuity and intelligence and knowledge of the subject necessary to interpret his diagrams after he has taken them.

A man buys an engine and puts it so far away from the boiler that the steam is full of water and has lost twenty-five per cent. of its pressure; he exhausts it through a back-pressure valve and because it does not come up to his requirements, because the water washes the lubricant off and lets the cylinder cut, because a slug of water makes a wreck of it, he writes indignant letters and condemns the engine and its builder. A man buys a condenser and connects it up with a job of cheap pipe fitting, or runs a lot of leaky engines and pumps into it, and telegraphs the maker to "send man at once," because he gets twenty inches of vacuum instead of twenty-six or twenty-eight. A man buys a grease-extracting and water-softening system, and because he fails to take away the grease after it has been extracted, or because he uses too much or too little lime or soda, and gets priming or scale, he either condemns the system out of hand or expects the manufacturer to keep an expensive man on the job for several weeks to demonstrate that the plant will do its work.

There is a growing tendency on the part of manufacturers of steam machinery and apparatus to resent these impositions; to take the ground that they will furnish apparatus adapted to the conditions as they are represented and guarantee that apparatus to be free from defects of material and workmanship; that they will set it up and operate it for a time if desired, the price to include the expense thereof; that they will bring to bear upon the execution of the order the results of their experience and special knowledge of the subject; but when they have provided the means the purchaser must work out his own salvation, and pay for the benefits which he receives in ordinary vigilance and intelligent use, as well as by his signature on a check.

Look for the Cause

Oil salesmen are generally supposed to be slick artists in every sense of the word, and they usually live up to their reputation. Rare instances crop out here and there, however, to indicate that, after all, they are human and not infallible in escaping every trap that may be set for them. The following is a true instance of how one was snared, and the pleasing feature was that it left no bad feeling on the part of engineer or salesman:

The salesman in question was endeavoring to make a sale in a plant which was purchasing its lubricant from a rival. He was a good salesman and thoroughly understood the art of how to present the merits of his own goods without denouncing those of his competitor, and for this reason his frequent visits were tolerated with good grace. Finally he suggested, as a clincher to his statements regarding the merits of his goods, that if there were a bearing around the plant that ran warm or hot, he would furnish a five-gallon sample, so the quality of his oil could be put to practical test. The engineer thought awhile, and then said that he had an excellent place for such a test, and took the salesman to the engine room, where he was requested to feel the bearing on a belt-driven dynamo. This bearing was always so warm that it could barely be touched. The engineer stated that this was a chronic case and he would certainly welcome any relief.

The salesman extracted a thermometer from his grip and proceeded to take the temperature of the oil in the bearing, at the open end next to the commutator, and made a note of it in his little red book, for comparison with the temperature-to-be of a real lubricant. The next day, while the dynamo was idle, he came with his sample of oil, and to gain the respect of the engineer he insisted that he should prepare the bearing for his sample. He thoroughly cleaned out the old oil and went about the job as if he had obtained his diploma from "Professor Time" in the "School of Experience." After finishing the job, he inquired the starting time and said he would return about two hours later, so as to give the bearing time to warm up. When he returned at the appointed time, the temperature of the bearing was found not to vary more than a degree from the previous reading he had obtained with the old lubricant. The salesman was somewhat crestfallen, but game, and requested that he be allowed to test another sample. The engineer told him to go as far as he liked, so the performance was repeated the following day, with the same result.

Now, this oil man was no "quitter;" he felt he was duty-bound to cool that bearing if it became necessary to try every grade of lubricant his company made, so he brought a fresh sample every day, first using the best grades and finally, in desperation, trying the cheaper ones, but with practically unvarying results. When sample cans began to get so thick in the engine room that walking was difficult, the engineer had a fatherly talk with the oil man. He said:

"Young man, you evidently have great faith in your goods, and I am beginning to have faith in them on that account, but this trial has been going on long enough. I don't want you to waste any more time or oil on that bearing. You could put different oils in that bearing from now until doomsday and never lower the temperature but very slightly. The lubrication of the bearing with the oil you first found in it had practically nothing to do with its temperature. The heat in this bearing is transmitted to it from the armature through the shaft, and the only thing that produces a perceptible change in it is a variation in the load."

The salesman looked at the situation like a man, and insisted that all of the samples be accepted gratis, as "the experience was worth the money."

What Is Trouble?

Different persons have different ideas as to what constitutes trouble. To some it means an aggregation of petty annoyances; to others, it means the difficulties encountered when apparatus fails to operate, or when an accident occurs; while to still others, whose characteristic is to take everything as it comes and make the best of it, there is no such thing as trouble.

What is trouble to one is merely an incident to another. For instance, an engineer, after putting in a somewhat lengthy suction pipe, had considerable trouble with air getting into the pump, which would eventually cause it to lose its water. This caused trouble galore—for him—but when another engineer assumed charge of the plant, he had a steam siphon, fitted with a check valve, tapped to the top side of the suction pipe, which allowed the air accumulation to be drawn out of the suction pipe before entering the pump, and obviated all semblance of trouble for that engineer. This would seem to show that what is frequently termed trouble is the result of ignorance as to what should be done to relieve or counteract certain conditions.

It often happens that conditions are such that the regular work of the plant cannot be carried on without unnecessary manipulation of various devices, which work could be greatly simplified if the devices were in proper condition. This extra work, necessary to obtain a given result, is sometimes taken as a matter of course and not looked upon as trouble. To illustrate: A certain engineer, when asked if he had any trouble with superheated steam with reference to valves, gaskets, etc., replied that he had not, although at the same time his men, in order to do some work on a leaky flange on the turbine steam line, after closing all the valves they could, found it necessary to run the turbine on a vacuum in order to clear the pipe of steam which leaked past the valves. The leakage past the valves was due to distortion of the seats by superheated steam, but the engineer did not think such a little thing as that of moment, or that work necessary to clear the pipe so the men could work was a matter of trouble.

What is trouble, anyway?

Robbing Peter

"Robbing Peter to pay Paul" is an expression that admirably fits a great many conditions that arise when so-called improvements are made in a power plant on the word of the zealous salesman, who is chiefly concerned in having you register on the last page of a formidable contract.

This does not mean that the salesman is not thoroughly honest, for reputable firms cannot afford to have any but reliable representatives. Salesmen are not always posted on the change in effect that may result in the performance of their apparatus from the varying conditions met in each installation, which, although entirely external to the added equipment, may be vitally necessary to its satisfactory operation. If the salesman is thoroughly experienced he should not be expected to serve you gratis as a consulting engineer and, after spending his time investigating the conditions of your plant, tell you that if you wish to gain the maximum return for the limited amount of money you intend investing his apparatus should be omitted from the scheme. This, however, is frequently done.

In this connection there comes to mind a place where the limit to steaming capacity was finally felt. The proprietors began to discuss how the shortage was to be met, but it never occurred to them to call in a reliable engineer to advise them how they could best spend the amount of money available to accomplish the desired increase in the capacity of their boiler plant. While the owners were in this very receptive mood for the advent of the [illegible] salesman, one came along who represented a [illegible] firm [illegible] economizers. The salesman drew a [illegible] coal economizers working up over what the apparatus could do for an overburdened steam plant, took them over the Marathon route of high economies and financial effort to carry over the peak of the load. Now, this salesman was perfectly honest, and every claim he made was justly his, with the apparatus installed under proper conditions, and his argument was so convincing that an order was given at once, and the economizer installed. After installation, which was accomplished in a light-load season, everything ran smoothly and there was an apparent economy in the coal consumed, and if there had not been the engineer would have been satisfied after consulting the stack and feed-water temperatures. When the normal load was restored to the plant, strange to say the total output was apparently less than before the change in the equipment, but this was accounted for by the supposed increase in load due to some new machinery, for the low stack temperatures [illegible] convinced the owners that they had trapped every B.t.u. that could be coaxed from coal to water.

At this stage an experienced engineer, who was familiar with the equipment of the plant before the economizer was installed, was called in to give information as to what was required to meet the demands made upon the steam-generating apparatus. After casually looking over the improvements he went back to the office and, getting comfortably well established on the right end of the proffered cigar, said:

"I understand that your wish to increase the capacity of your plant was the reason for the changes you have made; if so, why did you cut the capacity down about twenty per cent. by installing an economizer?"

The senior member of the firm gripped the arms of his office chair, to make certain that everything was real, and mentally running back through the flywheel effects and low stack temperatures, finally managed to say:

"What do you mean?"

"Exactly what I have said. Your plant has always lacked draft capacity, and what you have been needed to increase its steaming capacity was ability to burn coal; and instead of your first installing a stack of reasonable size, you have diminished the capacity of your already overburdened one with the result of reducing the capacity of your plant as I have stated. Your only salvation is ample stack capacity to care for your economizer and boilers, and then you will begin to realize on your [illegible] investment."

The owners were so astonished at the engineer's statements that they proceeded to test the plant with and without the economizer in service, and found the figures the engineer had given them were not far from the truth.

Some Useful Lessons of Limewater

An Excursion into the Realm of Hydrogen, Made Exceptionally Interesting and Instructive by Means of Several Simple Experiments

BY CHARLES S. PALMER

In the last two parts we studied the making of oxygen, because oxygen is the active part of the air insofar as burning is concerned. But, more than that, oxygen is one of the great "oxidizers," and as such it is contrasted with the opposite sort of chemical agents called "reducers." The relation between the oxidizers and the reducers is a very broad and fundamental matter in chemical study. The oxidizers include not only oxygen and a great many of its compounds which give off oxygen under certain conditions, but also such things as chlorine, bromine and iodine. Later we will give a list of some of the more important oxidizers, and I will also show how there may be such a thing as "moist combustion;" that is, burning in solution without any flame, but with all the results of real burning or combustion.

The reducers include such things as hydrogen, and many other compounds which act like hydrogen, in being opposed to oxygen and the oxidizers in their action and results. That is why it is necessary about this time to study hydrogen, although it is not found "free" in the air as oxygen is. You will want to read these first paragraphs over several times to emphasize in your mind the fact of the natural distinction between the "oxidizers" as a class and the "reducers" as a class; for theoretically any of the oxidizers can play proxy for each other in their opposition to the reducers; and similarly any of the reducers can play proxy to each other in the similarity of their action and in their opposition to the oxidizers.

An illustration of all this might be found in business accounting; thus, one might have all sorts of debts or debit accounts which would resemble each other insofar as they represent a balance of loss; and, on the other hand, one might have all sorts of credit accounts, represented by coin, paper money, bank checks, credit on real or personal property, etc. Thus we might liken the oxidizers to the debit or debt account, all the debts of whatever character or amount being entered in the same column and being opposed to the credit items of whatever character or amount, represented by the reducers.

This metaphor (of likening the contrast between the oxidizers and the reducers, to the contrast between debit and credit) is no mere childish fancy, but refers to a very real condition in all chemical reactions; and Mother Nature never neglects to keep a perfect account of the exact balance between the oxidizers and the reducers. Indeed, this balancing of accounts in nature concerns not only the kind and weight of the material substances which act on each other, but it also concerns the balance account of the amounts of *energy*. This also you will want to read over several times; and you will want to impress on your attention the fact that when the various chemical reactions go on, nature is at the same time using these reactions with a severity and rigor, in accounting for every particle of matter and every unit of energy, and to a degree of perfection which are simply astonishing. All this means that we must lose no time in getting acquainted with a typical reducer, hydrogen.

Hydrogen

Hydrogen is a light gas, invisible, colorless, tasteless, odorless, but very inflammable. Hydrogen is a metallic gas; that is, in its *physical* properties it is like any common gas, such as nitrogen, oxygen, carbonic-acid gas or the like, but in its *chemical* properties hydrogen is just as metallic as iron, copper, lead, zinc, sodium, potassium, calcium or the like. By this we mean that chemically hydrogen plays proxy with the metals, and the metals with hydrogen, in that they are all reducers. Also, hydrogen and the metals can replace each other in hundreds and thousands of salts. And, further, as when the electric current acts on soluble salts all of the metals proper go with the positive current, from the anode to the cathode, hydrogen does the same thing. Thus hydrogen, in an electrolytic cell, appears at the same pole where copper comes down; and this is practically a perfect demonstration of the fact that hydrogen is a chemical metal; but we will take up that side of hydrogen later. Just now you want to make some hydrogen and study it, just as you made carbonic-acid gas and oxygen, because if you have made a thing and handled it you have something that books alone can never give you.

Making Hydrogen

The first thing to do is to make a simple apparatus like that shown in Fig. 1. This has the same wash-dish pneumatic trough, with the same fruit jar filled with water and inverted in the trough, as you used in preparing oxygen. You have the same glass delivery tube and the same glass leader or conducting tube connected with a perforated cork; only, instead of having a glass flask containing a dry mixture, you will have a small bottle like an ordinary horseradish bottle or small pickle jar, and in this jar you will have some metallic zinc covered with some dilute acid, like sulphuric or hydrochloric (muriatic) acid. Get a strip of sheet zinc (not galvanized iron) and, with ordinary metal-cutting shears, cut off a dozen strips or so, 4 to 8 inches long and ½ or ¾ inch wide. Roll each of these strips up as though it were a ribbon, making a circular roll like that shown in Fig. 2. Then drop a handful of these zinc rolls into the bottle.

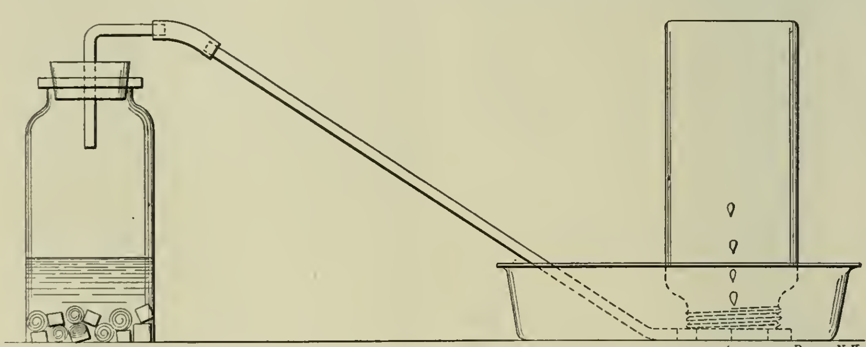

FIG. 1

You will see that the object is to get a supply of the metal in compact form, which will yet have a large amount of exposed surface. The inside and the outside surfaces of the various coils will amount to several square inches. You will see that the acid will have a chance to act on the zinc much better than as if you should cut it into flat strips and throw them into the bottle where they might lie so closely together that they would choke each other and hinder the action of the acid. The next thing is to cover the handful of rolls of zinc in the bottle with an inch or two of water, and then to pour in carefully two or three tablespoonfuls of sulphuric acid. If your sulphuric acid is already diluted, you will have to add more of it; if of the heavy concentrated "oil-of-vitriol" variety, of course you will add less of it; and in this case and always *when working with concentrated sulphuric acid remember to pour it carefully into the water*—never

FIG. 2

the water into the acid. The reason is that a great deal of heat is developed when sulphuric acid is mixed with water, and if you make one or two little breaks in mixing it with water never mind. But look out for any spattering, and look out for your eyes. In case you are using the strong sulphuric acid, as you pour it into the water and zinc, it being a heavy liquid—almost twice as heavy as water—the acid may settle to the bottom in a sluggish layer, but you can mix it with the water by shaking the bottle a little; pretty

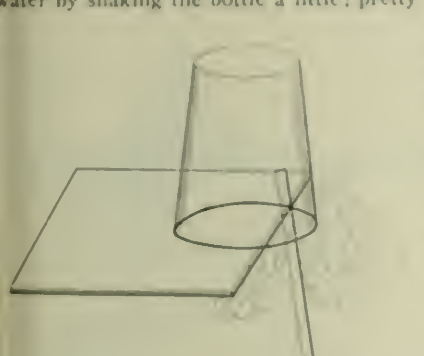

FIG. 3

soon the diluted acid ("diluted" means mixed with water) will begin to act on the zinc, and then the current of hydrogen bubbles will keep the liquids well mixed.

Look Out for Explosions

Now there is one thing that you should remember: Hydrogen makes an explosive mixture with the oxygen of the air. Therefore, do not bring a flame near the hydrogen apparatus for some minutes after the action of the acid and the metal has begun. You will see, as you stop to think of it, that the air in the pickle jar above the dilute acid and zinc is being mixed with the hydrogen, and it will take some few minutes for the current of hydrogen in the bottle to flush out the air from the bottle so that it will consist mainly of hydrogen. If you should neglect this caution, you will get a sharp, sharp explosion, the cork will be blown out of your bottle, and the bottle itself might be broken. Consequently, it is always safer to wrap an old towel loosely about the hydrogen-making jar, so that in case of an explosion there will be no flying glass.

The correct thing to do is to fill a tumbler with water, cover it with a cardboard, invert it in the trough and, after a few moments, collect a tumblerful of hydrogen. Then covering the mouth of the tumbler under water with a cardboard, remove the tumbler and cardboard together from the trough and set them on the table with the tumbler mouth downward, because the hydrogen is a light gas, much lighter than the air, and a jar full of hydrogen can be preserved in the air for some minutes if the mouth of the jar is kept downward. Now take a splinter of wood, light it and, holding the jar mouth downward, raise it from the cardboard cover and thrust the lighted splinter up into the jar. If the hydrogen burns quietly, it is a sign that you have driven off all the air from the space in the hydrogen apparatus above the liquid, and you can go on and collect it by filling the jar in the trough; but if there is a sharp explosion, indeed if there is any noticeable explosion, you must let the hydrogen apparatus run a few moments longer, when you will collect another tumbler of hydrogen, testing it in the same way until you get a sample that burns quietly.

When you have got to this stage, then you may get ready to go on and collect several jars of hydrogen. You will want at least four jars, perhaps five; one to test its burning, two or three to test its lightness and one to test what is called the "diffusion" of hydrogen, or what the old books used to call the "osmose" of hydrogen. We will now discuss, in anticipation, each of these tests so that you can be ready to make the experiments quickly, and so that you can understand well in advance something of what is going to happen. It may not be necessary for you to collect all of the jars of hydrogen at once, for you can easily have two or three jars, and you can use one jar while you are waiting for the next to fill, and so on.

Testing the Hydrogen

The first Jar. We will suppose that you have collected a jar of hydrogen from the pneumatic trough. You will remove this jar just as you did the first tumbler, from the water, holding the [illegible] downward, and when you are ready you will raise the jar with one hand, still holding it mouth downward, and thrust the long lighted splinter full way up into the jar. Now keep your eyes "peeled," and notice that the hydrogen is burning with a soft and almost colorless bluish or yellowish flame, but the end of the taper up in the jar is itself extinguished. That is, the hydrogen burns at the mouth of the jar with the oxygen of the air, but the hydrogen does not support the combustion of the splinter up in the inside of the jar; although that part of the splinter near the mouth of the jar will probably be re-ignited by the hot hydrogen flame.

The set of experiments concerning the lightness of the hydrogen, and the pouring it upward in the air from one jar to

FIG. 4

FIG. 5

another, we will leave until the next lesson.

The next experiment is something which will take a little more time in preparation, but it is well worth the trouble. You want to hunt around and find a small cup of unglazed earthenware, about [illegible] inches wide and 2 or 3 inches long. You can get such a cup [illegible] called a "porous cup" from the [illegible] in the February number; but perhaps you can use a [illegible] if you [illegible] one small enough, although the trouble with [illegible] is that they usually are too wide at the bottom. A [illegible] will do [illegible] as shown in Fig. 5. Fit a cork [illegible] the mouth [illegible] and [illegible] the cork make a hole [illegible] for a tightly fitting glass tube, several inches long.

If you use the tobacco pipe, cover the stem but not the bowl with glue to give it an air-tight layer. The mouth of the pipe bowl must also be closed with a tight, flat cork. The lower end of the glass tube leading up into the tiny jar, or the lower end of the stem of the tobacco pipe, should be connected with a bit of rubber tubing to a straight delivery tube of glass, 10 or 15 inches long. In the case of the tobacco pipe you can lengthen the stem by connecting it with bits of rubber tubing to several pieces of stem broken off from other clay pipes and varnished. The point is to have a closed porous jar, with a straight air-tight tube, 10 or 15 inches long, leading to its interior. If you use a baby flowerpot, you will have to be careful to plug up the small hole usually found in the bottom of such pots with a tight cork; and also be careful to get a wide, flat cork thick enough to close the mouth air-tight.

Another point: If you use a tobacco pipe in this "osmose" experiment your fruit jars will serve very well; but if you use a baby flowerpot, you will have to find a larger-mouthed jar, something like a wide-mouthed candy jar. The point is (as shown in Fig. 5 in triplicate to suit various conditions of our readers), you are going to place a jar of hydrogen, the mouth of which is open to the air, down over the pipe bowl, or the porous jar, or the tiny flowerpot, each of which is connected, by a well fitting cork and air-tight tube, with a tumbler of water some 10 or 15 inches below, as shown. If you are successful, you will see this simple but very remarkable result: some bubbles of air will be forced down through the long straight tube and will bubble up through the tumbler of water. This is all the more remarkable because the jar of hydrogen, which is open to the air, acts on the closed pipe bowl, or porous jar, or tiny flowerpot, as though it were blowing in gas through the unglazed and porous walls of the pipe bowl, or porous cup, or tiny flowerpot, down through the long tube into the water.

The "Kinetic Theory of Gases"

When you get this apparatus ready, you can test it in anticipation by lowering, mouth downward, a jar of common air over the pipe bowl, or porous cup, or tiny flowerpot; and with no bubbles, because air will not act on air, while a jar of hydrogen will act on air. I will not stop now to explain just what happens, but you will note that it is quite remarkable to have an open jar of hydrogen act on the air within the pipe bowl, or porous cup, or tiny flowerpot, as though the hydrogen could blow through into it and down the air-tight tube with considerable pressure. It will be worth your while to try to get this experiment and to make it work, because it will prove to you something which the books call the "kinetic theory of gases."

The explanation of this experiment, which is one of the most remarkable in all chemical physics, is that the nitrogen, oxygen and hydrogen of the air are made up of little parts called "molecules." Now these molecules are jostling each other about in a very rapid and rude way, and the walls of the porous jar mark the "rush line" in this hand-to-hand battle of the molecules. But the hydrogen fellows, although much lighter, are much more active, and they easily get away with the heavier and more sluggish molecules of the nitrogen and oxygen of common air in the fine passageways of the walls of the porous jar. Therefore, the hydrogen fellows force back the nitrogen-and-oxygen team, "rush" them down the long tube, and force them out bodily as bubbles through the water in the tumbler, as shown in Fig. 5.

Scientists have figured that the molecules of the nitrogen and oxygen of the air are moving around, swinging and bombarding each other, at a rate of some 2000 or 3000 feet a second, and the hydrogen molecules are swinging about at a rate of about 8000 feet a second at ordinary temperatures. This does not mean that either is moving at this rate *as a mass*, but that the small physical units or parts of the gases are moving at this rate. It is almost inconceivable, almost incredible, that such should be the case; but after you have performed the experiment, and especially after you have studied carefully the conditions of the experiment, you will see that you have got something so remarkable in fact that the explanation is not incredible but is in keeping with the fact.

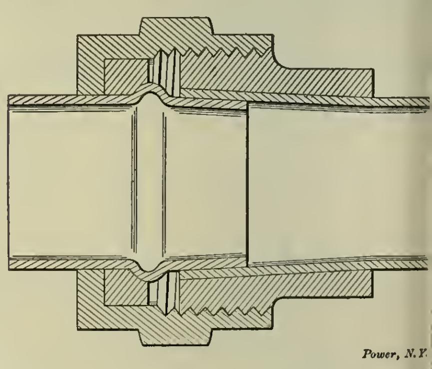
Acids Are Salts of Hydrogen

There is one other point which I want you to notice, and that is that it is not alone the acid that attacks the zinc, but the zinc attacks the acid, forming sulphate of zinc, or "white vitriol," in driving off the hydrogen. You will note that if the zinc can drive off hydrogen from dilute sulphuric acid, then the zinc has taken the place of the hydrogen; that is, the hydrogen is a metal. Further, if the zinc acting on the sulphuric acid makes zinc sulphate, then the acid itself is a sulphate of hydrogen, and this will introduce you to a new way of looking at acids; namely, that all acids are "salts of hydrogen."

Thus, sulphuric acid is hydrogen sulphate, nitric acid is hydrogen nitrate, hydrochloric or muriatic acid is hydrogen chloride, phosphoric acid is hydrogen phosphate, tartaric acid is hydrogen tartrate, acetic acid (acid of vinegar) is hydrogen acetate, citric acid (acid of lemons) is hydrogen citrate, and so on through the long list. From each of these acids, theoretically, any metal will drive off the hydrogen, but practically some metals act better than others and some acids act better than others. The metal commonly used is zinc, although you can use clean iron turnings or filings; the acid commonly used is sulphuric acid, although you can use hydrochloric acid; but you cannot use nitric acid if you want to collect the hydrogen, because nitric acid is itself an "oxidizer" and eats up the hydrogen as fast as it is formed.

New Joint for Copper Pipes

A simple and effective form of joint for copper and brass tubing is being introduced by J. M. Leigh & Son, 67 Deansgate, Manchester. It is illustrated in the accompanying engraving, is known as the "compression" joint, and is made between the ends of the two tubes themselves, one end being forced into the opposite expanded end of the other tube, the coupling being merely intended to keep the tubes together. Two small hand machines are



JOINT FOR COPPER PIPES

used in the making of these joints. The screwed portion of the joint or union is slipped on the end of the tube, which is then put on the expanding machine and the end of the tube expanded until it fits tightly into the union piece and forms a lining for it. The union nut and ring are next slipped on the other tube, which is then beaded as shown. The tubes are afterward placed together, the beaded end inside the large end, and the joint is tightened up with a spanner, no jointing material being required. It will be seen that the connection is complete with only one joint. The amount of force required on the union is small; in fact, a tight joint under pressure can almost be made without the use of a spanner. We are informed that a test of an arrangement of various sorts of fittings attached to a 1¼-inch diameter seamless-copper tube, 20 wire gage, proved perfectly tight at a pressure of 700 pounds per square inch, a tensile stress of 8½ tons being necessary to sever the joint.—*The Engineer.*

Helander Barometric Condenser

In Fig. 1 is shown the manner in which the Helander type A barometric condenser is installed. This type of condenser is used with either a basement or an overhead exhaust main, but is particularly

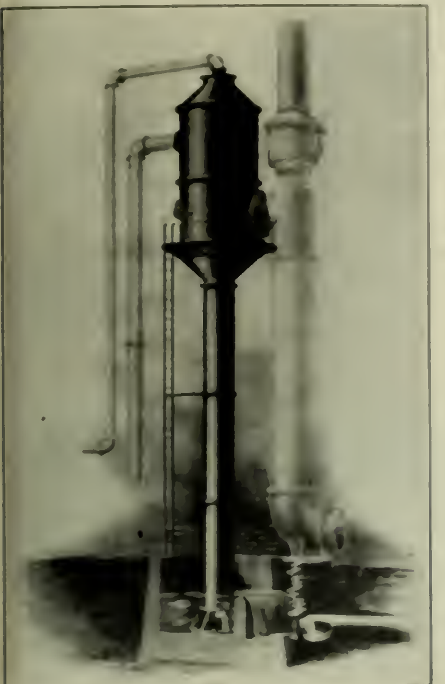


FIG. 1

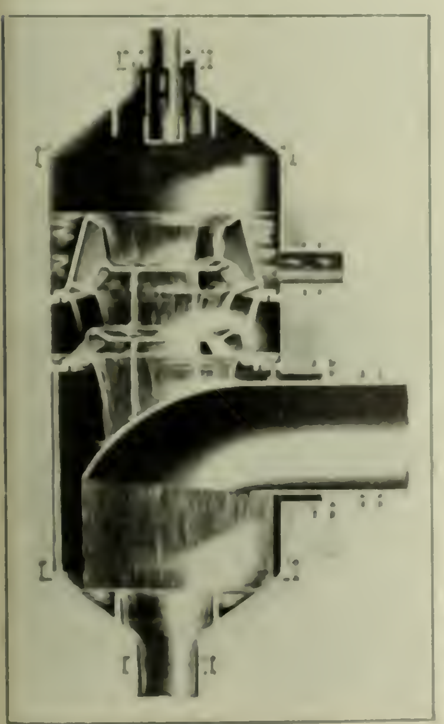

FIG. 2

adapted to the latter. Fig. 2 is an interior view, an examination of which will bring to notice the large number of water pools between the steam inlet and the top of the vessel, where the air is extracted, which keep down the temperature of the cooling water. It also shows that a large surface contact for water and steam is afforded by a series of waterfalls.

This condenser is fitted with a new type of release valve which does not in any way depend upon a mechanically tight joint to seal the vacuum when operating the condenser. This valve is placed at the foot of the barometric column and automatically comes into action whenever the vacuum is lost and the barometric column of water falls to the hotwell level. The steam then passes down the overflow pipes and out through this valve to any convenient point.

Some of the advantages claimed for this type of condenser is the simplicity of construction and erection, and as it is built entirely of cast iron it is said not to be injured by acid or silt water. It is also claimed that it has a large overload capacity without impairing its efficiency, and there are no movable parts and [illegible] adjustments to suit conditions of operation.

Due to the peculiar internal design and construction, the noncondensable gases are removed by the air pump when their temperature is approximately that of the cold injection water. At this point the density of the vapor is a maximum and the volume a minimum, thus permitting the use of a small air pump, which results in less first cost, maintenance and power required, it is said. This condenser is manufactured by the Mesta Machine Company, Pittsburg, Penn.

A Turbine Gasolene Engine

This engine is a gas or hydrocarbon type. As shown in Fig. 1 it has no balance flywheel, set between a pair of cylinders, acting on a turbine rotor. Its operation is as follows: When the first cylinder in a four-cylinder engine is firing, the third cylinder is compressing and, just at the point where the compression or resistance is at the highest, the exhaust [illegible] the [illegible] cylinder [illegible] and the exhaust gases strike the turbine [illegible] before the piston [illegible] the compression stroke. It is claimed that the turbine [illegible] [illegible] a period [illegible] the cylinder [illegible] [illegible] the engine and [illegible] it [illegible].

In Fig. 1 are shown exterior and sectional views of the arrangements of the cylinders and turbine. Fig. 2 shows end views of the engine and turbine. This construction is the invention of [illegible], Elmira, N. Y.

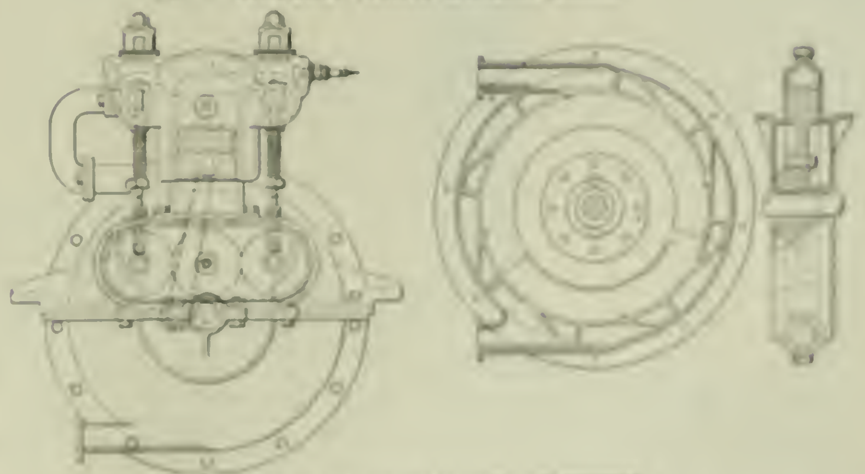

FIG. 2. END VIEWS OF ENGINE AND TURBINE

Business Items

The Quaker City Rubber Company, of Philadelphia, has opened a branch office, in charge of Charles W. Thomson, at 50 Church street, New York City.

The Crocker-Wheeler Company, of Ampere, N. J., recently received an order through its Denver office for a number of small motors for the Cox-Clark Engraving Company, Barclay building, Denver. The motors will be used for individual drive on engraving and electrotyping machinery. They are all 230-volt, direct-current motors of the form L type, which is built in sizes from 1-20 to 7½ horsepower.

Owing to the growing demand for "Komo" steam traps, it has been necessary to increase the manufacturing and sales facilities. Therefore, the business formerly carried on by P. A. Moulton, as sales agent of the "Komo" steam trap, at 92 Liberty street, New York, will hereafter be transacted by the Linton Machine Company, of 26 Cortland street, N. Y., which is in a position to furnish these traps in any desired quantity. The standard of material and workmanship will be maintained, and P. A. Moulton will be associated with this company as manager of the steam-trap department.

The Mesta Machine Company held an "at home" Saturday afternoon, March 27, at its works at West Homestead, Penn. Thither wended a large number of persons interested in works of that character, including many engineers and the Engineers' Society of Western Pennsylvania. It was an afternoon of inspection, followed by a lunch. The fireproof office building, the roll and steel foundry departments, the new foundry and the new pattern shop were duly viewed and appreciated. Among the chief objects of interest were a 36x72-inch Corliss engine, with 100-ton flywheel, which was built in 30 days from receipt of order; a blast-furnace blowing engine, with steam and air cylinders each 84 inches in diameter and with 60-inch stroke; and machinery for a 600-ton metal mixer, which will be double the size of the largest now in use.

One of the largest orders booked by the Crocker-Wheeler Company during a recent week was for 14 three-phase, 60-cycle, squirrel-cage induction motors, aggregating 220-horsepower, for Johnson & Johnson, New Brunswick, N. J. Other induction motor sales of the week were 160-horsepower of the wound-rotor type for the Buffalo Copper and Brass Company, of Buffalo, and a 20-horsepower for the Frick Company, Waynesboro, Penn. The demand for direct-current apparatus still continues. The Eastwood Wire Manufacturing Company, Belleville, N. J., has ordered a 250-kilowatt, engine-type generator, and the Atlantic hotel, Bridgeport, Conn., has purchased a 35-kilowatt machine. A large rolling mill near Pittsburg has placed an order for 244 horsepower of direct-current motors of the rolling-mill type. Other direct-current sales are those of 20 motors for the Lanston Monotype Machine Company, Philadelphia; a 75-horsepower motor for the W. W. Herron Lumber Company, Mobile, and six motors for the F. P. Little Electric Company, Buffalo. There were a large number of smaller orders.

The former American Boiler Economy Company, of Philadelphia, manufacturer of the Copes boiler-feed regulator and the Copes pump governor, has been consolidated with the Northern Equipment Company, Old Colony building, Chicago, which will assume all obligations of the former company, including guarantees to replace free of cost any part of any Copes regulator that may develop a defect within five years from the date of purchase. The branch offices of the American Boiler Economy Company, viz., Tribune building, New York City; Oliver building, Boston; 226 East Pleasant street, Baltimore, and the Frick building annex, Pittsburg, will be continued under the style of the Northern Equipment Company, while the sale of Copes regulators will be handled in Philadelphia by the Adjustable Grate Bar Company, North American building. The Northern Equipment Company announces that it will continue to install the Copes regulators on 60 days' free trial. The following recent sales to prominent concerns are mentioned: Nichols Copper Company, the Delaware & Hudson Railroad Company, the Clark Thread Company, the Consolidated Gas Company, of New York, and the Boston Elevated Railway Company.

Keystone grease, made by the Keystone Lubricating Company, of Philadelphia, is claimed to be especially adapted to shafting lubrication, for the reason that it cannot drip, but remains in the bearing where it belongs. In the silk-ribbon manufactory of Smith & Kaufmann, New York City, and in the silk mills of Pelgran & Meyer, the Harmony Silk Company and Cramer & King Co., of Paterson, N. J., this product is stated to give perfect satisfaction. Other instances of the successful use of Keystone grease are the Botany Worsted Mill, Passaic, N. J.; C. M. Hedden Company, Newark, N. J., manufacturer of fine soft hats; C. B. Rutan, West Orange, N. J., and the No-Name Hat Manufacturing Company, Orange Valley, N. J.

The owners of the "New Belnord" apartment house, at Eighty-sixth street and Broadway, New York City, which is to be one of the largest apartment houses yet built, recently placed an order with the American Engine Company, of Bound Brook, N. J., for three angle-compound engines, one of 500-horsepower, one of 400-horsepower and one of 160-horsepower. This type of engine is adaptable to isolated-plant work because of its relatively small space requirements and the absence of vibration. It gives the advantages of compounding while requiring less floor space than a horizontal simple engine of the same output.

New Equipment

Bids will be received by C. W. Jackson, city clerk, Plymouth, Wis., some time in May for laying about 16,000 feet of 6, 8, 10 and 12 inch vitrified sewer pipe. W. G. Kirchoffer, Madison, Wis., engineer.

The Waukegan, Rockford & Elgin Traction Company has been incorporated with $1,500,000 capital to construct an electric railway. Principal office at Waukegan. Incorporators, R. D. Wynn, C. C. Edwards, Fred Bairstow, etc.

The Pennamaquan Power Company, whose head office is at Providence, R. I., has taken over the property and holdings of the Pembroke Power Company, at Pembroke, Me., and will rebuild plant which was burned some time ago.

The Sioux Falls & Sioux City Electric Railway Co. will commence construction of proposed railway soon. There will be two power stations, one at Sioux Falls, S. D., and one at Sioux City, Ia. G. W. Burnside, Sioux Falls, is general manager.

L. Adler Bros. Company, Rochester, N. Y., has awarded contract for the construction of a new factory building. Equipment will include boilers, engines, generators, motors, blowers, etc. Chas. A. Alexander, Rochester, is consulting engineer.

Sealed bids will be received by P. D. Hendershot, city clerk, Platteville, Wis., until 7:30 p.m., April 2, for furnishing and installing a pumping system. Plans and specifications can be had of W. G. Kirchoffer, consulting engineer, Madison, Wis.

The Central City Refrigerating Company, Syracuse, N. Y., is erecting a cold storage and electric plant. Gas producers, engines, generators, refrigerating machines, etc., will be needed. R. S. M. Mitchell, Kirk building, Syracuse, is consulting engineer.

The Agricultural and Mechanical College of Texas, College Station, Tex., is contemplating installing new equipment in the machine shops and engineering laboratory, including centrifugal pump, air compressor and internal combustion motors.

The Water Power Light Company, Ozark, Mo., contemplates installing additional equipment, including 50-kilowatt alternating-current generator, water turbine, engine. It is said the company also contemplates installing an ice and cold-storage plant.

The finance committee of the Council, Pittsburg, Penn., has approved ordinance providing for bond issue of $1,975,000 to purchase plant of the Monongahela Water Company and $700,000 bonds to purchase machinery for same. N. S. Sprague, city engineer.

The Paris and Mount Pleasant Railroad Company has been incorporated with $75,000 capital to build an electric railway from Paris Texas, to Mount Pleasant. Headquarters at Paris. Incoporators, R. F. Scott, T. J. Record, J. J. Culbertson and others.

The Walsenburg (Colo.) Light, Power and Ice Company is contemplating increasing the capacity of its ice-making plant by the installation of a 12-ton ammonia compressor and the necessary cans, tank, condensers, etc. S. B. Richey is manager and P. A.

W. F. Cooper has purchased the plant of the Winnfield (La.) Light and Power Company and will rebuild same with new and modern machinery, such as dynamo and engine, switchboard and line material. H. W. Wright, Winnfield, is engineer in charge.

Bids will be received by R. Sutton, city clerk, Richland Centre, Wis., for furnishing and laying about 5000 feet of 8 and 10 inch cast-iron pipe. Special castings, valves and hydrants will also be purchased. W. G. Kirchoffer, Madison, Wis., is consulting engineer.

The Portland (Ore.) Water Power and Electric Transmission Company has been incorporated with $1,000,000 capital and will erect a power plant. W. H. Hurlburt, formerly president of the Oregon Water Power and Railway Company, is at the head of the new company.

Power System of Louisville Lighting Co.

Single-phase Engine Installation Remodeled into Two-phase Turbine Plant. Novel Features Are the Water Supply and Removal of Ash

BY OSBORN MONNETT

For some time alterations have been in progress at the Fourteenth street station of the Louisville Lighting Company, during which a great deal has been accomplished in changing the character of the station to one of the most modern kind.

Coal-handling Facilities

The property is adjacent to the main line of the Pennsylvania railroad and together with the coal-storage facilities occupies one entire city block. A spur track from the railroad enters the coal- [illegible] making a total coal-storage capacity of [illegible] tons, neglecting the working capacity of the coal bunkers themselves inside the station, which will hold [illegible] tons [illegible].

Each car of coal is weighed on a plat-

FIG. 1. EXTERIOR OF FOURTEENTH STREET POWER STATION, LOUISVILLE, KY.

The old engine room is now occupied on one side by a row of boilers, leaving the other side available for doubling the boiler capacity when required, and a new turbine room has been built on the west side, giving the completed station the appearance illustrated in Fig. 1.

[illegible] yard, [illegible] the old boiler room, as indicated in the plan, Fig. 2. This storage yard has space on either side of the track where coal may be unloaded, and in addition to this a further emergency supply is stored [illegible] on the other side of the tracks. The [illegible]

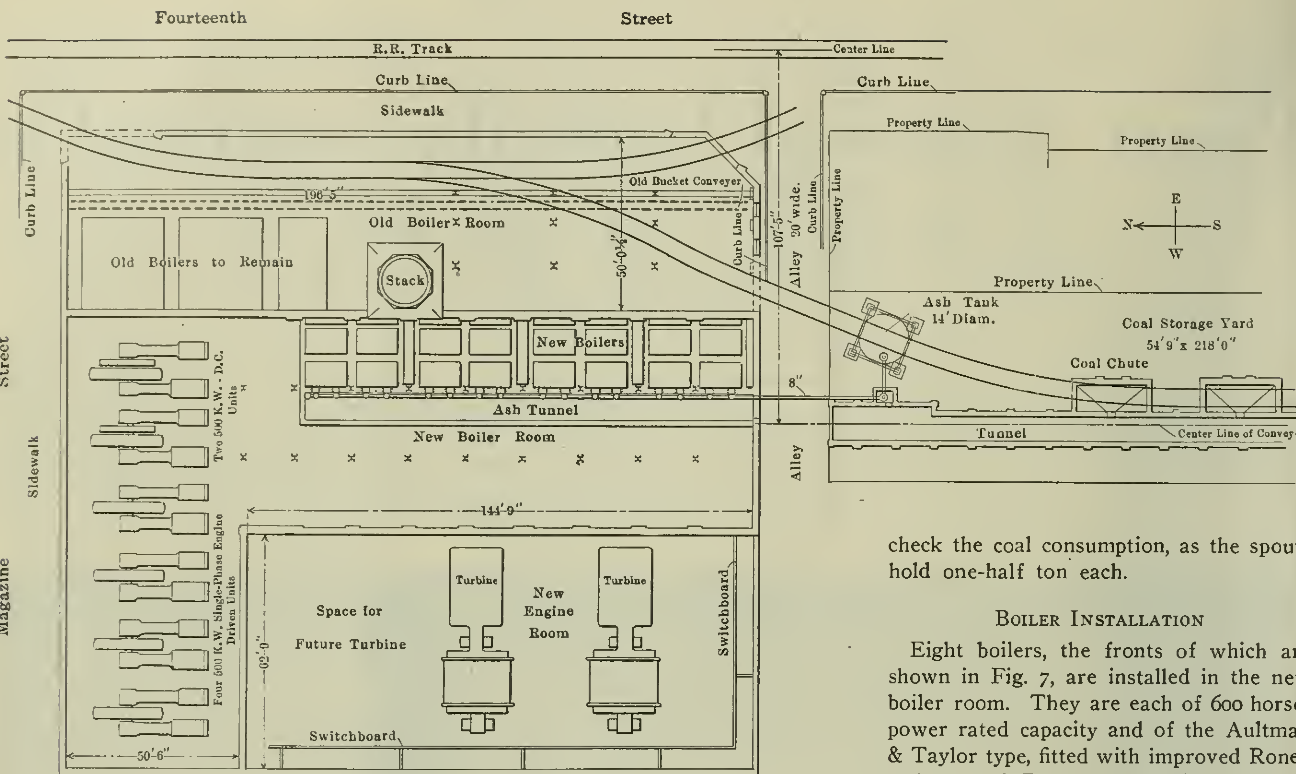

FIG. 2. GENERAL PLAN OF YARDS AND PLANT

to a motor-driven crusher, discharging onto a bucket elevator which raises the coal above the bunkers and it is then distributed automatically on another Robins belt conveyer as shown in Fig. 6. This conveyer is provided with an automatic traveling tripper which distributes the coal uniformly the entire length of the bunkers, reversing itself automatically at the end by means of a lever engaging the trip on the rail. This tripper may also be spotted over any boiler along the line of the coal bunkers. The bunkers are of reinforced-concrete construction and deliver the coal to spouts in which Hunt valves are arranged, making it convenient to check the coal consumption, as the spouts hold one-half ton each.

Boiler Installation

Eight boilers, the fronts of which are shown in Fig. 7, are installed in the new boiler room. They are each of 600 horsepower rated capacity and of the Aultman & Taylor type, fitted with improved Roney stokers and Babcock & Wilcox superheaters. The boilers have vertical headers and are installed with a clearance of only 18 inches between the rear header and wall, the gases passing upward between the drums to the uptake, as shown in the elevation, Fig. 4. This drawing also shows the relative location of the old boilers which have been retained as reserve. Of these there are 1800 horsepower of Babcock & Wilcox make, with

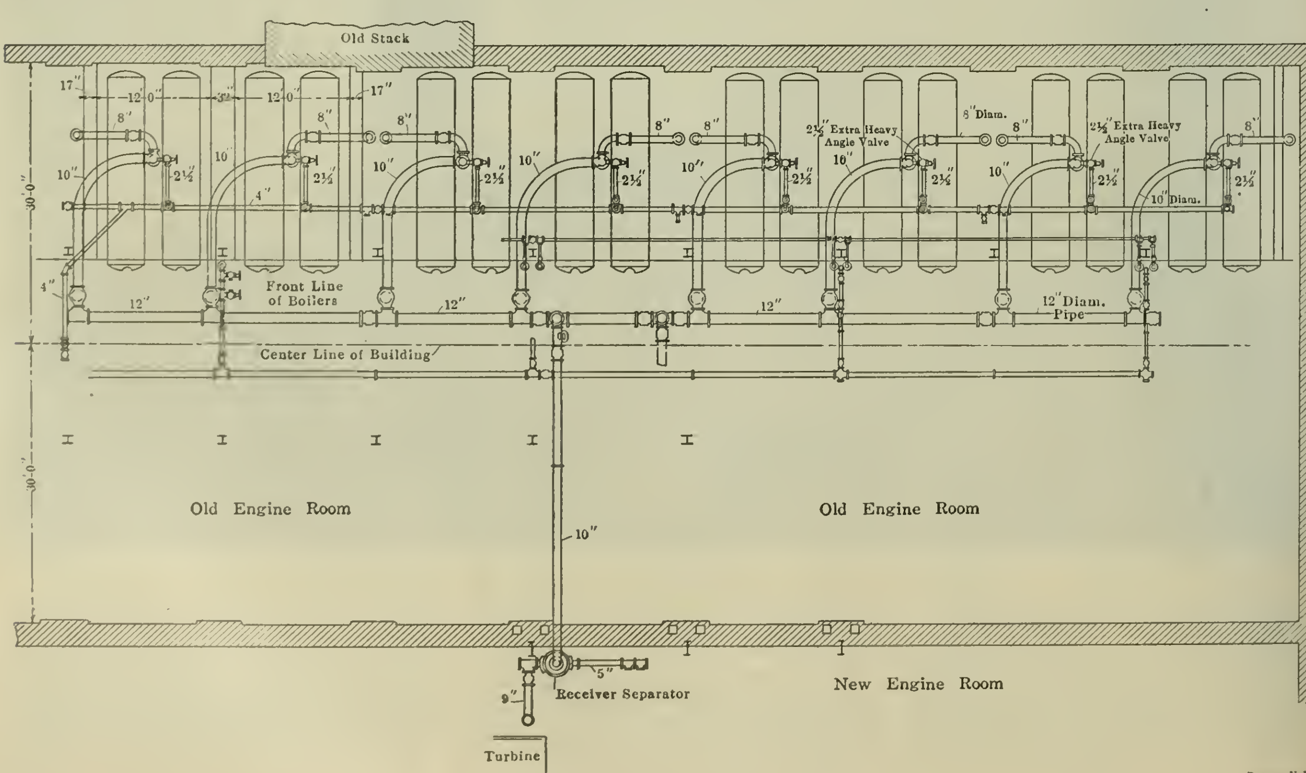

FIG. 3. HIGH-PRESSURE STEAM PIPING

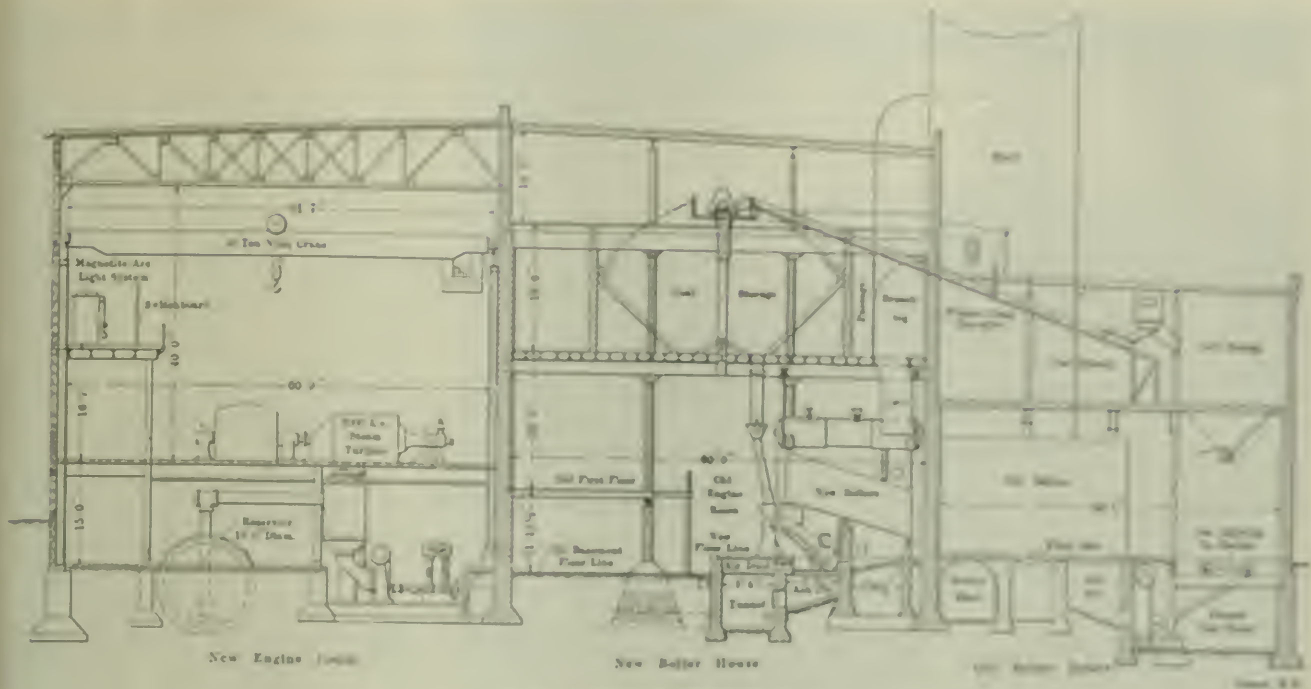

FIG. 4. ELEVATION THROUGH PLANT

Babcock & Wilcox chain-grate stokers. The manner in which the former coal-handling arrangement is utilized as an auxiliary is indicated in Fig. 2. The bucket conveyer has been retained and a Robins belt conveyer is installed to shift the coal into the main hoppers when necessary.

Exceptionally complete facilities are provided for determining conditions in the boiler room. Located at a central point on the firing floor is an Ellison differential-draft gage, and each boiler setting is tapped at the furnace and in the rear gas pass with ¼-inch pipe leading to a manifold, which may be connected at will with the gage. In this way the draft at all important points may be quickly determined. A line extends also to the stack at a point 50 feet above the ground where the main uptake enters; the draft at this point shows 1.4 inches of water. The stack is of brick, 208 feet high, octagonal in shape, with a 13-foot circular flue.

In addition, a board located in the office of the operating engineer is fully equipped with recording and indicating gages, enabling the engineer to determine the steam pressure, vacuum obtained or draft on any unit at any time. An indicator on the switchboard gallery also shows in large numbers the total amount of load that is being carried at all times.

Referring to the sectional elevation of the boiler room, an air duct will be noticed immediately under the boiler-room floor in front of the stokers. This has been put in as an extra precaution, so that the furnaces may be run with closed ash-pits under forced draft, if circumstances should ever require it. Two Buffalo engine-driven fans are installed for this purpose.

Ash Removal

The ash-handling arrangement is simplicity itself. Extending along in front of the ashpit doors is an 8-inch wrought-iron pipe, with a 6-inch opening at each furnace according to the Darley system. The openings are loosely fitted with

FIG. 5. STEAM AND FEED-WATER PIPING

FIG. 6. AUTOMATIC ROBINS DISTRIBUTER OVER COAL BUNKERS

cast-iron plugs, but the farther end of the pipe is open. The pipe extends out through the basement wall and upward into a large elevated steel tank of 50 tons capacity. At the entrance to the tank, the ashes, which are frequently red hot, are sprinkled with water as they drop into the receptacle from which they are loaded into cars. At the top of the tank there is an 18-inch connection which is carried down into the adjacent crusher house and is connected to a Connersville high-pressure blower with a capacity of 200 cubic feet per minute and driven by a 30-horsepower induction motor. This installation maintains the vacuum upon which the operation of the system depends. Fig. 8 shows an elevation of the system as installed, and the tank itself may be seen in Fig. 1.

In operation a plug is removed from one of the tees, a funnel is inserted and the ashes are raked into the pipe, being taken away as fast as introduced. As the suction is always inward, there is no dust nor dirt in the ash tunnel. At the point *X*, Fig. 8, a special elbow with extra thickness of cast iron is used for the reason that the particles of ash in changing their direction from the horizontal to the vertical impinge on the metal at a speed of several thousand feet per minute. This is really the only part of the system subject to severe conditions, but as the elbow can be easily replaced there need be no trouble at this point.

Boiler-room Piping

The high-pressure piping is designed for 100 degrees of superheat. An 8-inch riser leads from each superheater into the end of a 10-inch horizontal bend with a radius of 6 feet 6 inches and terminating in a 12-inch main header from which 10-inch leads pass to the turbines. The only separators in the system are those at the turbine throttles, one being a Cochrane receiver and one a Swartwout receiver-separator.

Kellogg valves and fittings are used and the gate valves all have their stems looking downward, the main boiler stop valves being operated from the boiler-room floor. A 4-inch auxiliary header is also provided to furnish superheated steam to the pumps, etc. All high-pressure flanged joints are packed with Goetze asbestos-copper corrugated gaskets. The feed piping is located overhead in front of the boilers, as shown in Fig. 7, and the main lines are in duplicate, with a 3½-inch branch to each battery of boilers. One Lambert hot-water meter is located in the main feed line, and a Worthington meter is used when making individual tests on boilers. Williams feed-water regulators are installed on the system. Feed water is supplied by two Blake, vertical simplex, outside, center-packed plunger pumps, with cylinders 14x20x12¼x18 inches in size and capable of delivering 300 gallons of water per minute against a boiler pressure of 250 pounds. These pumps take water at an average temperature of 200 degrees under a minimum head of 5 feet 2 inches from a 6000-horsepower Cochrane open feed-water heater and purifier. The heater receives the exhaust from the feed pumps, stoker en-

FIG. 7. BOILER ROOM

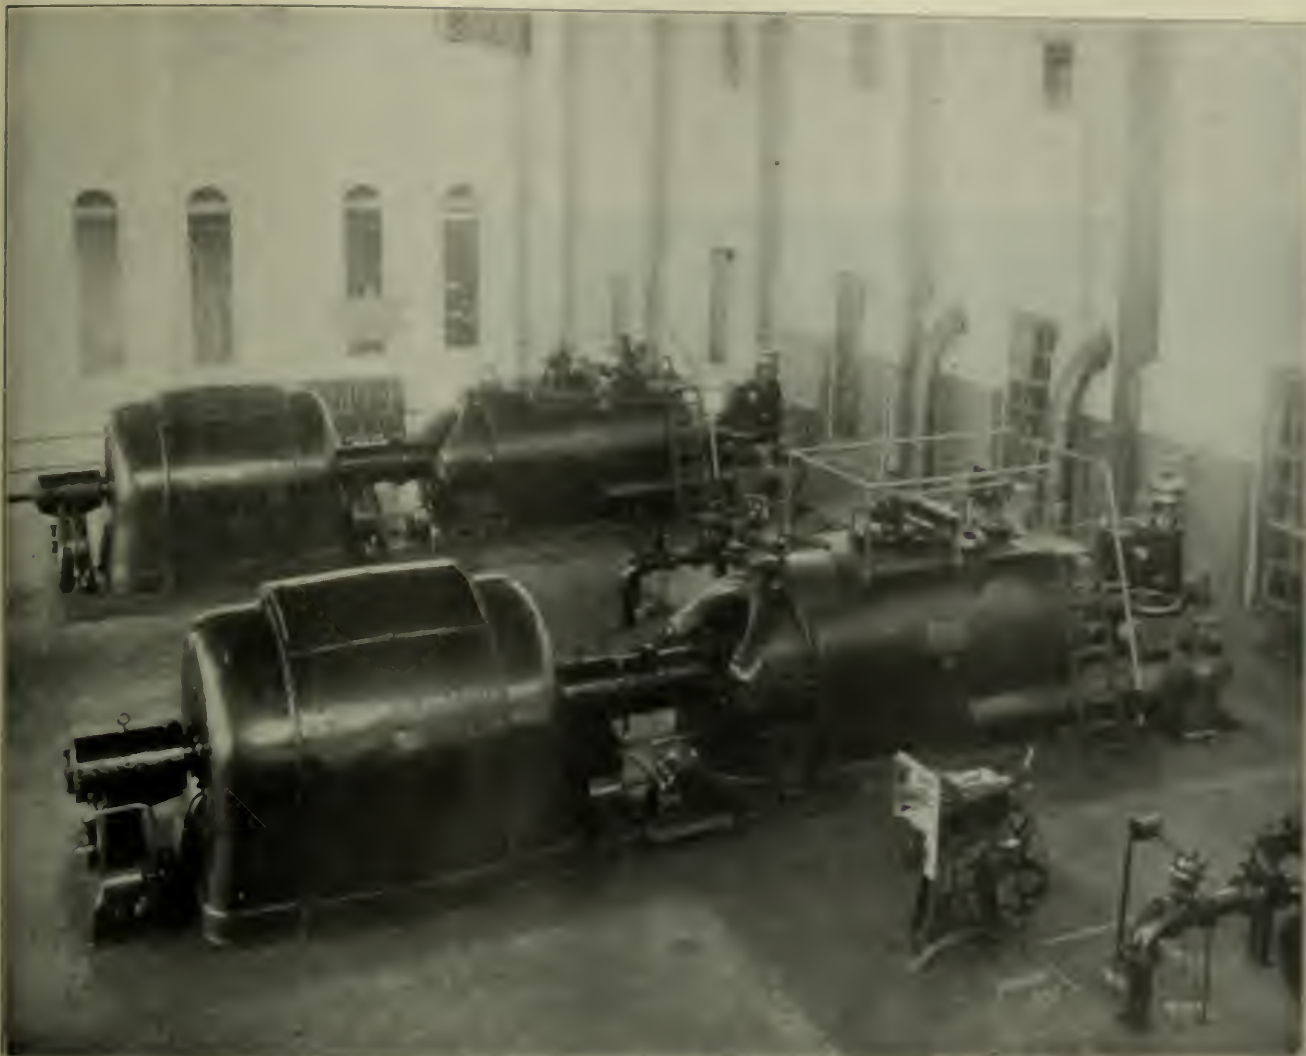

FIG. 9. MAIN GENERATING UNITS

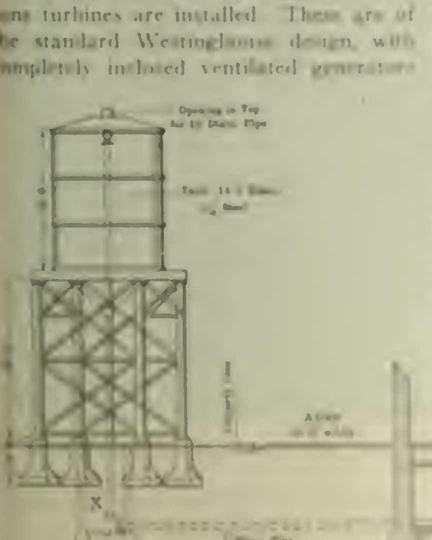
gines, condenser and dry vacuum pumps; all the other auxiliaries are operated by electricity.

Generating Units and Exciters

Two 3000-kilowatt Westinghouse-Parsons turbines are installed. These are of the standard Westinghouse design, with completely inclosed ventilated generators delivering two-phase, 60-cycle current at 2200 volts. The machines run at 1800 revolutions per minute under 200 pounds steam pressure, 100 degrees of superheat and 28 inches of vacuum. The 42-inch gate valve in the connection between each turbine and condenser is operated by a 5-horsepower, 220-volt, direct-current motor geared to the valve stem. This valve is opened or closed by simply throwing a switch up or down, the motor being automatically cut out at the end of the stroke in each case, and a colored signal lamp is automatically lighted to indicate the position. The valve is also arranged with a handwheel in case the electrical apparatus should get out of order.



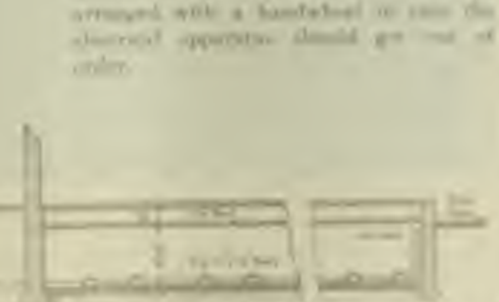


FIG. 8. [illegible] SYSTEM

Fig. 9 is a view in the turbine room, which is spanned by a 30-ton Niles traveling crane. The turbines exhaust into Alberger jet condensers provided with centrifugal steam-driven vacuum pumps which are of single-stage [illegible] make, [illegible] being driven by a [illegible] double engine and the other by a [illegible] and vertical compound. In combination with the Alberger [illegible] dry-vacuum pumps furnished, no difficulty has been experienced in maintaining 28 inches of vacuum at all times.

The Alberger condensers are each fitted with automatic vacuum breakers to insure against water reaching too high a level in the condenser proper. The breaker is essentially a counterbalanced valve connecting to atmosphere and to the exhaust line of the condenser system, the valve being held closed by a trigger. When the water reaches too high a level, it raises a float which releases a trigger and the valve immediately opens. This method of breaking the vacuum is used when shutting down the turbines and is found to be reliable. Fig. 10 is a photograph of one of these breaking valves.

Injection water is obtained from a horizontal concrete reservoir 12 feet in diameter and 140 feet long, located in the basement. The reservoir has a capacity of 400,000 gallons, and as indicated in Fig. 4, the injection pipes terminate in an 18-inch foot valve at the bottom. A 28-inch Crane relief valve is provided on each machine. The exhaust is carried away by a spiral-pipe line which terminates in a riser common to both machines and capped by a Swartwout exhaust head.

FIG. 10. JET CONDENSERS AND CENTRIFUGAL VACUUM PUMP

To the main turbine units the old single-phase equipment of the station is held as a reserve. It will be remembered that at its installation in 1893 this was rated as the largest single-phase generating plant in the world. This notable installation, a view of which is given in Fig. 11, consists of four 500-kilowatt, 2200-volt, single-phase Westinghouse generators, driven by cross-compound Allis-Corliss engines. It has been doing duty ever since installed and works admirably on the two-phase circuits when they are isolated and used in single phase. Two 500-kilowatt, 500-volt direct-current outfits have also been retained. In connection with the generating units there is a complete White Star filtering system installed, with an oil-storage capacity of 3000 gallons.

For regular excitation purposes there is installed a 2200-110-volt, 75-kilowatt motor-generator set taking current from the busbars, or it may take current from the company's Tenth street station. Another smaller 500-110-volt set rated at 25 kilowatts is provided for starting. It is furnished with current from the 500-volt generator in the station or from the Tenth street plant. A third steam-driven set rated at 75 kilowatts is held in reserve. The exciters are all of Westinghouse make, and the engine is a 12x12-inch machine of Chuse design. A 110-volt switchboard is located on the main floor adjacent to the exciter sets. All lighting of the building is at 110 volts from the exciter circuits.

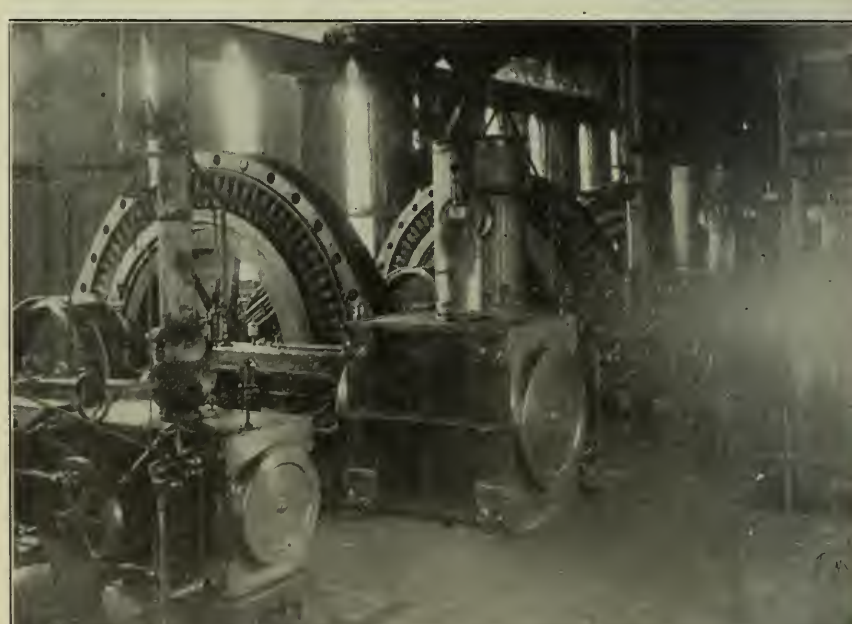

FIG. 11. OLD "WORLD'S FAIR" SINGLE-PHASE INSTALLATION HELD AS RESERVE

Water Supply

One of the most interesting features of the plant is the system of water supply. The station is situated at Fourteenth and Magazine streets at a considerable distance from the Ohio river and does not depend upon this source of water supply, either for condensing or for boiler feeding. As is generally known, the Ohio river is subject to violent fluctuations, the water level varying from 3 to 50 feet, which makes it exceedingly difficult at times to be certain of an uninterrupted supply, either because of low water or on account of the water being so high as to be unmanageable. The river water always contains a certain amount of débris which has to be removed before using in the condensers. Besides, a large amount of mud makes the water undesirable for water-tube boilers. When it was found that the City of Louisville was situated over a natural reservoir containing an almost unlimited supply of clear water not more than 50 feet below the surface, it was decided to take advantage of this and eliminate the many troubles due to a location on the river bank. All the above considerations were gone into years ago when the plant was first built on its present location, and up to the present time the management has seen no reason for making any change. The water is exceptionally fine for condensing purposes, being delivered at a temperature of 55 degrees Fahrenheit the year around. It is, however, quite hard, and for boiler feeding it is treated in a Scaife We-Fu-Go water softener having four setting tanks of 35,000 gallons capacity each.

The principal scale-forming materials

are calcium carbonate and magnesium sulphate, as shown by the following analysis:

	Grains per Gallon
SiO_2	[illegible]
$CaCO_3$	[illegible]
$MgSO_4$	7.44
$MgCl_2$	[illegible]
$NaCl$	2.77
Incrusting solids	[illegible]
Nonincrusting solids	2.77
Total solids	[illegible]

There are at present two deep-well pits in use, the first of which is 500 feet deep, elliptical in shape, with 34 and 48-foot axes, sunk with a steel casing lined with an 18 inch brick wall. At the bottom of the pit around the periphery are 8-inch driven wells, 25 feet deep, with 10-foot well points. Each well is connected by gate and check valves to a 20-inch manifold from which the water is delivered into the large reservoirs in the basement of the engine room by two duplex, tandem-compound pumps, one a Gordon with 12x20x20x24-inch cylinders, and the other a Worthington, 10x20x18x18 inches in size.

The other well is located 200 feet northwest of the first one and consists of a circular concrete-lined steel-shell casing, 25 feet in diameter and 60 feet deep. Fig. 13 is a view looking down into this well. The 24 driven wells here are arranged in a similar manner to those in the first pit, but are alternately 15 and 25 feet deep, with 10-foot well points, the object being to draw from a greater vertical section of the water bed. In this pit a 200-horsepower Westinghouse induction motor drives a vertical single-stage Worthington centrifugal pump having a capacity of 5000 gallons per minute. The motor and pump are connected by a vertical shaft 25 feet long. This outfit operates continuously at full capacity. Sufficient room is available for an additional pumping unit of equal size.

For further water supply the experiment is being made of sinking individual 8-inch wells, fitted with Columbus impeller pumps, driven by vertical induction motors. If this proves successful it will obviate the necessity of sinking the expensive well pits, and will have the further advantage of drawing the supply from a larger area with the consequent decreased liability to failure of supply.

Electrical Control and Distribution

All alternating current from the station is delivered at 60 cycles and is controlled by switchboards in the gallery. The main alternating-current board illustrated in Fig. 14 contains the generator panels, a synchronizing panel, 12 single-phase circuit panels and panels for the motor generators, auxiliaries, arc lights, Highland park and the down-town substation. This board is equipped with a Tirrill regulator for field control and a recording wattmeter. In the Highland park circuit the supply is stepped up to 6600 volts three-phase, is transmitted eight miles and is then stepped down to two-phase 440-volt current. A load of some [illegible] kilowatts is carried. Another notable circuit is that of the 2300-volt single-phase line to Fountain Ferry amusement park, where in addition to upward of [illegible] incandescent lights, there is a load of 150 horsepower in single-phase motors of various sizes.

The feature of the switchboard equipment, however, is the series luminous-arc rectifiers for the magnetite arcs which light the city of Louisville. The board containing the rectifiers occupies the entire length of the switchboard gallery at the western side of the turbine room and consists of 48 panels, each controlling a circuit of 50 lamps, making a total of 2400 lamps for the city. Front and rear views of this board are shown in Fig. 15. It is 144 feet long over all and is the largest board of its kind installed to date.

Each pair of panels operate in conjunction with a General Electric constant-current transformer of 100 lights capacity situated directly behind the board. The rectifier tubes are cooled by an air blast, the openings for which may be seen on the front of the board in Fig. 15. This blast is maintained by two sets in duplicate of motor-driven Sturtevant fans located on the floor of the main engine room below. The life of the rectifier tubes is, of course, uncertain, but it is stated that the record life of a tube on this board has been over 3500 hours.

FIG. 12. EXCITER SETS AND SWITCHBOARD

FIG. 13. LOOKING DOWN INTO WELL PIT

FIG. 14. MAIN ALTERNATING-CURRENT SWITCHBOARD

A vigorous campaign for power business is now being conducted, and on a gallery across the [illegible] switchboard are located some 2300-volt two-phase power panels which control all the alternating-current power circuits in Louisville, except [illegible] the downtown district. The [illegible]

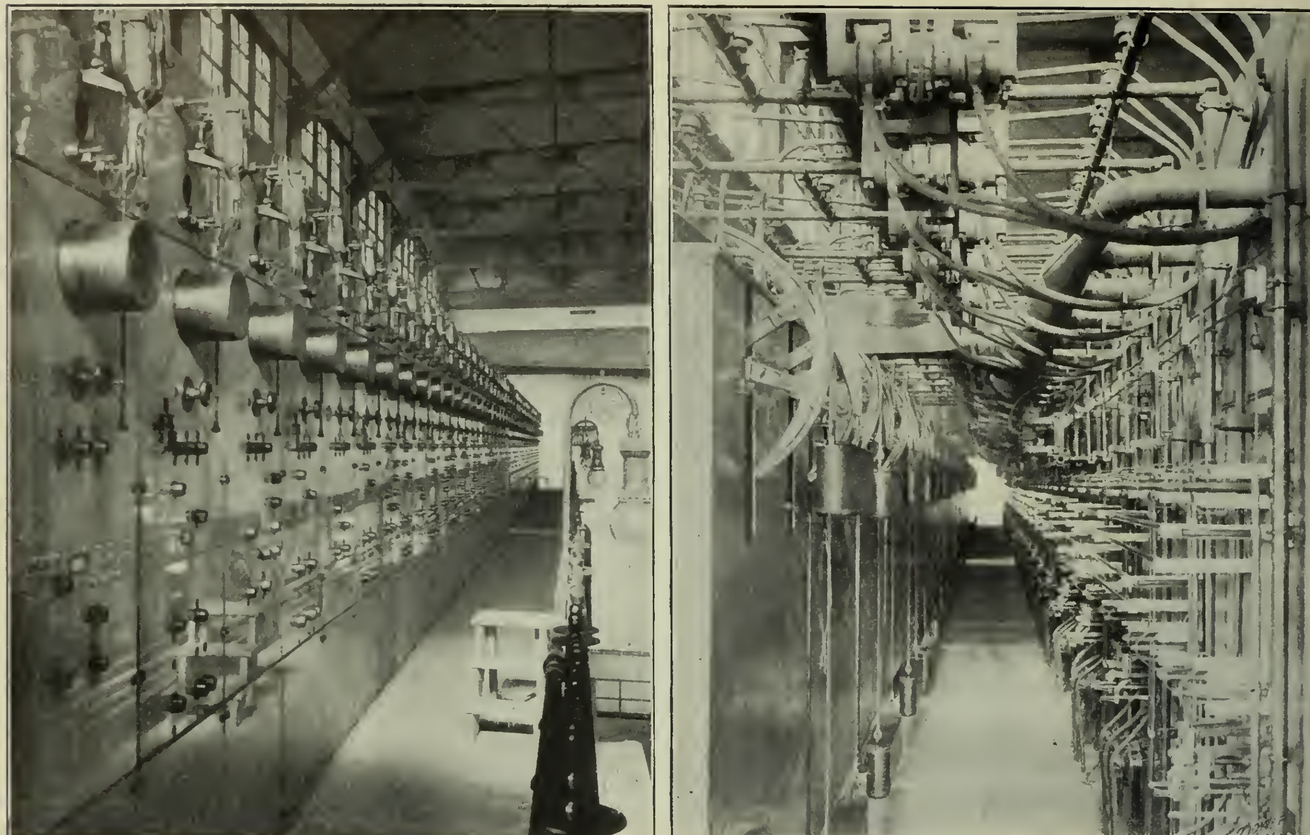

FIG. 15. FRONT AND REAR VIEWS OF LARGE RECTIFIER SWITCHBOARD

the substation and consist of 500-volt direct-current power circuits and 110-volt three-wire alternating-current circuits for incandescent lighting. All circuits are underground.

The substation contains a 1200-kilowatt Westinghouse synchronous motor-generator set supplied with current at 2200 volts through a 300,000-circular mil four-conductor cable. For the alternating-current service there are four sets of two-phase alternating-current static transformers stepping the 2200-volt current down to 240 volts, and at this voltage it is distributed through eighteen single-phase underground circuits to various centers of distribution in manholes. Each circuit has its own regulator on the low-tension side and balance coils in the manholes on the three-wire, 110-220-volt circuits. Fig. 16 is a view of the interior of the substation, which is fitted with a traveling crane and all necessary facilities.

In addition to the synchronous motor-generator set at the substation, there is another of 225 kilowatts capacity at the Fourteenth street station tying the alternating-current and direct-current systems together. These sets have a beneficial effect on the power factor, maintaining it at approximately 95 per cent.

The wiring diagram, Fig. 17, indicates how the load may be handled by the different generators. Ordinarily the machines at Tenth and Fourteenth streets operate in parallel on the turbine busbars, handling the load in general. However, any desired combination may be arranged according to circumstances. Thus the Tenth street station may carry any of the single-phase city-lighting circuits, the magnetite arcs or Highland park, direct. Similarly the old single-phase equipment may serve the magnetite arcs, and any of

FIG. 16. INTERIOR OF SUBSTATION

the city-lighting circuits, including Fountain ferry, but cannot connect with Highland park or the motor-generator at the substation, both of these circuits demanding strictly two-phase current.

TENTH STREET STATION

This station, which has also recently been remodeled, is a brick building, the walls, engine and boiler foundations being built upon a 24-inch concrete slab, which is supported by 12-inch oak piles 35 feet in length. In addition to the 750-kilowatt and 400-kilowatt two-phase generators indicated in Fig. 17, the Tenth street station contains one 750-kilowatt and one 500-kilowatt direct-current 500-volt generator. The two 750-kilowatt units, one alternating and one direct-current, are driven by [illegible]-inch Knowlton & Kelley horizontal Corliss engines, which operate in conjunction with Deane[illegible]-Holyoke flywheel-type jet condensers. Both of the other units are vertical, with McIntosh & Seymour engines, the cylinders in the case of the alternating-current unit being [illegible] inches in size and the direct-current machine [illegible] inches. These engines are equipped with Wheeler surface condensers and motor-driven air pumps.

As this station is located on the river, the precautions taken to maintain a water supply furnish the most interesting feature of the plant. About halfway down on the river bank is located a water-tight pumping station. It consists of a circular cistern about 18 feet in diameter, made of steel boiler plate and having a cone-shaped roof ending in a vertical shaft with entrance at the top. On the up-stream side the structure is protected by a concrete wall.

Inside, the pumping equipment consists of two Worthington single-stage centrifugal pumps, each with a capacity of [illegible] gallons per minute. Each pump is driven by a 60-horsepower General Electric motor taking current from the 500-volt mains. These pumps furnish cooling water directly to the two surface condensers and injection water to the jet condensers. Although normally above the surface of the water, this pumping station operates equally well when entirely submerged. The basement of the Tenth street station would be under water in the spring; [illegible] it is frequently below the water level. The condensing water [illegible] has to be pumped out of the basement, and for this purpose a [illegible] suction pump is held in reserve.

The discharge from all condensers [illegible] into a cistern [illegible] to the sewer. From this cistern feed water is pumped to a Stilwell open heater and thence to the boilers, of which there are three of the Anderson & Taylor type, rated at [illegible] horsepower each and provided with Green traveling-grate stokers.

The work of designing and reconstructing the power stations has been under the direct supervision of G. Wilbur Hubley, superintendent and engineer, Louisville Lighting Company.

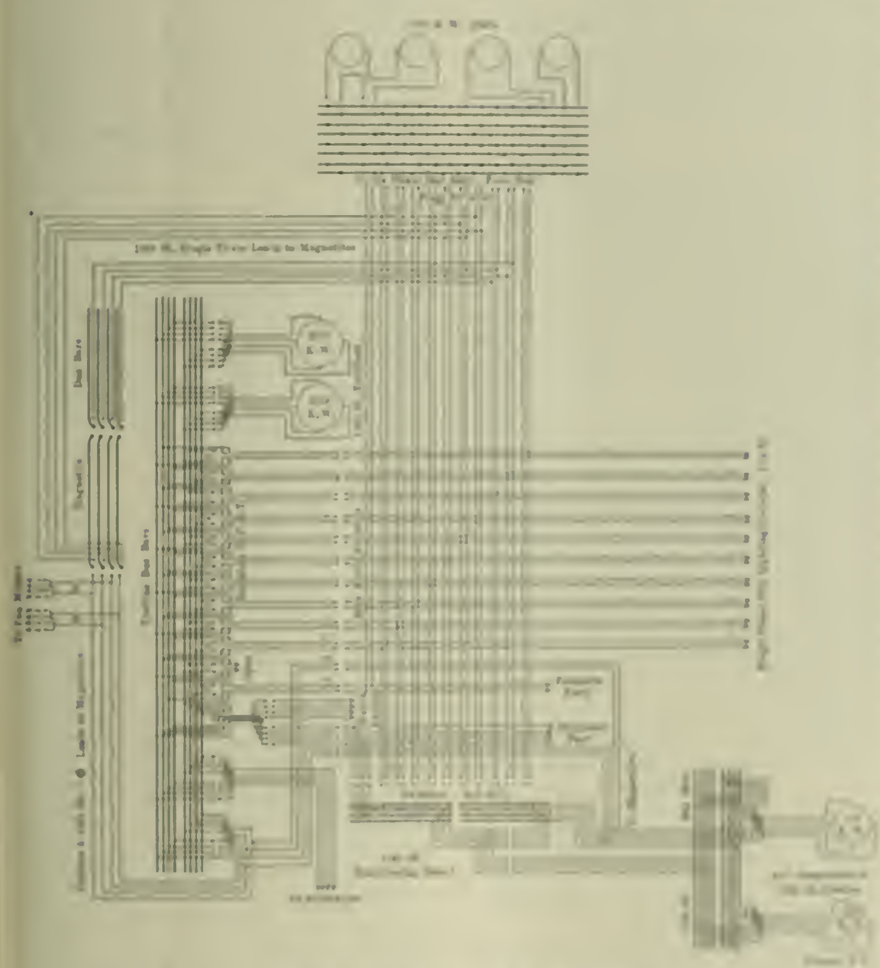

FIG. 17. WIRING DIAGRAM OF STATION

Engineering Societies Discuss Conservation of Natural Resources

Wednesday evening, March 24, a special meeting was held in the Engineering Societies' building on West Thirty-ninth street, New York, under the auspices of the four national engineering societies, American Society of Mechanical Engineers, American Institute of Electrical Engineers, American Society of Civil Engineers and American Institute of Mining Engineers. The conservation of natural resources was the topic under discussion, and four papers by representatives of the societies were presented. Nearly 800 engineers were in attendance and Dr. James Douglas presided.

Before the papers were read, a telegram from President William H. Taft was received with considerable interest. The President was greatly gratified to know of the cooperation of the engineers in the movement for the conservation of natural resources, as the members of the four societies with their technical knowledge were not only better advised as to the necessity for such conservation, but were competent to suggest practical methods by which such conservation could be carried out.

WASTE [illegible]

In a few preliminary remarks, Dr. Douglas expressed his opinion that the waste of coal above and below ground should be regarded more in the light of a relative rather than an absolute waste. Great advancement has been made in chemical and metallurgical engineering, and this advancement means the saving of coal. [illegible] energy in the coal. The efficiency of the Diesel engine is reported as 36 per cent. Improvements along this line should be the aim of the engineer. But the conservation is not being restricted to coal alone. The amount of steel used in buildings and bridges is being cut down, and cheaper materials are being substituted for the rarer ones. All engineers are working with the same end in view, and instead of feeling repentant over the resources that have been wasted, they should rather feel jubilant that there is yet much that they can do toward conserving these resources.

Conservation of Water

The first paper of the evening was presented by John R. Freeman, consulting engineer for the Department of Additional Water Supply for the City of New York. His topic was "The Conservation of Water," and he prefaced his remarks, to the surprise of some of the engineers present, by saying that he did not believe the cutting off of the forests in the Eastern mountains had affected the flow in flood or drought of any important rivers. Land covered with an undergrowth was quite as effective as timber, and the error had been in the failure to differentiate between kinds of soil. It was his opinion that if half the stations of the United States Geological Survey were abandoned and the total appropriation devoted to the remaining half, more precise information on stream flow would be available.

In conclusion, it was his recommendation that each State should collect the facts regarding each of the notable opportunities for power development within its borders. Select the important ones for survey in detail after reconnoissance, prepare an outline plan for each, with all the detail that would be required in the preliminary studies for actual developments, with the full estimates of cost of plant and of the amount of power available in different seasons of the year, and make these matters of permanent public record, printed and widely distributed. In these surveys the conservation idea should have full sway, measuring up the full engineering opportunity, with dams planned at the highest levels and tailraces at the very lowest levels that the topography will reasonably permit, and with the storage reservoirs of the greatest hight and area for which nature has provided a reasonable location, up to the full measure of reasonable flood control. Every noteworthy opportunity for development that will ever exist within the State can thus be soon placed on the map, and there will never be a more advantageous time than the present to take account of stock, so that the public and the promoter can see just what degree of promise there is in each opportunity. The State can perhaps wisely go farther than heretofore, and at some of the great sites itself construct the main works, much as the United States Reclamation Service has built reservoirs and canals, or it can invite private capital, through the removal of the restrictive laws like those now forbidding storage reservoirs in the Adirondacks, or by laws helpful in bringing the full natural opportunity of one proper site under one control, like the mill and the flowage acts of some of the States.

By far the most beneficent policy of conservation of its water power that the State or Nation can adopt is one which will tend toward its being devoted to the founding of industrial communities, and that kind of industry is best which will bring the greatest population per horsepower and the most highly skilled class of operatives. The first step in such a policy of conservation is an accurate inventory and publication regarding each undeveloped or scantily developed opportunity.

Conservation by Legislation Doubtful

"Conservation of Natural Resources by Legislation," the second paper of the evening, was delivered by Dr. Rossiter W. Raymond, secretary of the American Institute of Mining Engineers. As expressed by the speaker, true conservation lies in the diminution, not of use but of waste. The error of our pioneer miners and metallurgists was not that they worked prematurely and imperfectly, but that they too often left their low-grade ores, slags and tailings in such positions as to be unavailable for retreatment by their successors; but no legislation, even if the legislators had been wiser than the engineers, could have remedied this evil half as quickly or thoroughly as it has been remedied without any legislation at all, for the trouble was simply lack of knowledge. The moment the mine operator realized that his tailings were a part of his assets to be turned into money at once, either by himself or by lessee, or by sale to a speculative purchaser with an eye on approaching improved conditions, that moment he began to preserve and protect them. Much the same ruling applies to our timber lands.

The Government had failed to deal competently with the mineral resources of the country, and why should it be trusted to legislate concerning other resources? The progressive education of the people and the steady pressure of economic conditions would do more to prevent waste than any amount of legislation. Of all the extra Governmental functions, the education of the people by the spread of information is the most beneficial, the most potent and the least objectionable. The information presented by the Government should be collected with care and not in a hurry, should be stated without bias or argument in favor of this or that measure or policy; and made accessible to all who desire it, not by the wasteful and inadequate system of giving to members of the Congress so many copies per capita, but by printing in successive editions, if need be, as many copies as individual citizens are ready to buy at cost.

Engineers may render most useful service by freely scrutinizing and criticizing the figures upon which all propositions of reform, private or public, are professedly based. Others will always furnish the motive power of eloquence and enthusiasm. It should be the business of engineers to test the machinery and hold the rudder.

Fireproof Buildings to Reduce Fire Loss

Charles Whiting Baker, editor of *Engineering News,* talked on "The Waste of Our Natural Resources by Fire." The loss by fire in 1907 amounted to $215,000,000, and if all the buildings visited by fire during that year were lined up along a single street, it would reach from New York to Chicago, approximately 1000 miles. In this long line of buildings much of our wood and mineral resources are annually destroyed. An even division of this loss by fire would mean a tax of $2.50 for every inhabitant of the United States, or for every family of six a tax of $15. Similar figures in Europe are much lower and in fact do not even approach one-half this value. A more careful selection of building materials, insuring a fireproof structure, would lessen the annual destruction and to no small extent conserve our natural resources.

Install Water Power to Save Coal

The fourth and last paper of the evening, on "Electricity and Conservation of Energy," was presented by Lewis B. Stillwell. The speaker expressed himself in favor of a much more extended development of water power to develop electrical energy. Excluding locomotives, there are 25,000,000 horsepower of steam engines in the country, 5,000,000 horsepower of water motors and 800,000 horsepower of gas engines. Our water resources are such that 37,000,000 hydraulic horsepower could readily be developed and utilized at a less cost than steam. Every hydraulic horsepower saves from 7½ to 10 pounds of coal, and with the above number of hydraulic horsepower actually installed an enormous saving in our coal resources would result. Centralizing our steam-generating stations into larger plants would also reduce the demand for coal. With this end in view the State should hasten instead of retard our water-power developments.

New York N. A. S. E. Convention

New York State Association No. 34, N. A. S. E., will hold its annual convention this year at Syracuse, June 11 and 12, in the assembly hall of the new court house. The exhibit room will be in the same building.

Analysis of the Subject of Coal Analysis

A Government Expert Discusses the Chief Things Coal Users Wish to Know; Values of the Various Methods Used In Analyzing

BY N. W. LORD*

Within the last few years the subject of coal analysis has become of very great importance to many lines of industry. The demand for the analysis of coal has come from a great variety of sources and largely from those having little acquaintance with chemical methods and the interpretation of chemical results. The chemists, on the other hand, have been compelled to take such methods as were found at hand, and the result of those conditions has been not altogether satisfactory in many ways.

What So-called Coal Analysis Means

If we consider somewhat in detail the various determinations made in the laboratory in connection with coal testing, it will be easy to show how much is commercial and how little what might be called scientific. The so-called analysis of a coal is usually a practical test of purity of the material on a small scale, but it also involves determinations which are supposed in some way to indicate the nature of the coal itself.

To illustrate, suppose we consider an ordinary sample of bituminous coal. It may be assumed to consist, first, of an organic constituent composed of vegetable residues more or less altered but retaining traces of its original woody structure and composite character, and containing as an integral part certain inorganic components. Like its source, woody fiber, it is hydroscopic in its nature, holding mechanically variable amounts of moisture, the equilibrium amount depending upon the moisture percentage of the air; in other words, like a piece of wood it absorbs moisture in damp weather and gives it up in dry weather. The ultimate chemical composition of this material varies with the extent of the alteration, as shown in the peats, lignites and bituminous and anthracite coals, and also, as has been shown, in all probability with the nature of the vegetation from which it has been derived. This extremely complex and indefinite material may be called "coal substance," for want of a better term. Intimately mixed with this are inorganic substances, probably mechanically introduced with the original vegetable debris or else precipitated by secondary reactions from circulating waters. These may be in the nature of clays or fine sand and also intimately mixed iron pyrites. I have examined samples of coal under the microscope in which microscopic crystals of pyrites were scattered through the mass in sufficient amount to give high percentage of sulphur in the total, yet in which a superficial examination of the coal itself practically showed no pyrites to the unaided eye. Other minerals may be present in the same way, even such unusual constituents as zinc blende, and, as Doctor Hillebrand has shown, considerable percentages of vanadium sulphide. The extremely complex nature of the organic constituents themselves may be inferred from the variable but sometimes very large amounts of sulphur they contain, well shown in the case of certain peats. Now in addition to this base, constituting the principal part of the sample submitted to the chemists for analysis, it has, secondly, more or less coarse admixture of slate, clays and other rock-like material occurring in connection with the deposits of coal and not properly separated in mining, bone coal and also streaks of cannel and other associated material, coal-like in character, but differing notably even in the organic material they contain from the coal itself. Add to this enumeration of the constituents of commercial coal the fact that many of these ingredients, on standing or exposure to air, alter by absorption of oxygen, evaporation, etc., and it would appear that the problem is still farther complicated.

Things Coal Users Wish to Know

Now some of the things that the users of coal wish to know and for which they turn to the chemical analysis in the hope of receiving information are the following: The heating power of the coal; the amount of ash or inorganic matter left on burning the coal; the nature of the combustion of the coal, whether flaming, smoky, rapid or slow; the gas-producing quality of the coal, both as to yield and as to the nature of the gas; the nature of the ash yielded by the coal; the coking quality of the coal and the nature of the coke produced; and the possibilities of improving its quality by coal washing.

In addition to these are many questions of special character, such as the demands for scientific investigation as to the nature of the coal substance, the relations of its composition to the geological history of the deposit and the relation of the total heating power to the heating power actually available for technical operations.

Analytical Methods Employed

What are the analytical methods at present used in the laboratory to meet this series of questions and to handle this very complex material? Most of the laboratory work is done upon a sample which represents or is intended to represent the average composition of the material and which in no way recognizes the separate constituents of the very complex mineral aggregate of which it purports to be an average. The methods therefore give results only approximately related to the coal substance and difficult of general application.

We have, as of generally recognized importance, the ultimate analysis as ordinarily made, giving the determination of the hydrogen, the carbon, the nitrogen and the sulphur and the percentage of ash left after burning. This analysis also includes an estimate of the oxygen by difference which is, of course, only approximate, as has been frequently pointed out in discussion on the subject. This ultimate analysis is capable of a high degree of accuracy for certain elements, which I think could be safely stated within [illegible] per cent. in the hydrogen, [illegible] per cent. on carbon, [illegible] per cent. on the nitrogen and [illegible] per cent. on the sulphur. I do not mean that closer results are not obtainable, but ordinary work in the laboratory by competent chemists would, I think, run within these limits. The value of the ultimate analysis in all technical applications of the coal consists of its giving a reasonably accurate basis for the calculation of products of combustion and of comparisons with the heating power of the coal otherwise determined. The weakest point in the ultimate analysis is the uncertainty of its connection with the actual composition of the organic material as distinct from the ash portion. Carbon, hydrogen and sulphur are present respectively as carbonates, as combined water and as sulphates respectively in the slates and other mechanical mixtures and the ultimate analysis does not distinguish between such constituents and those in the coal substance. Ingenious efforts to eliminate these uncertainties in adjusting the heating power by comparing that of various samples of the same coal differing widely in percentage of mechanical impurities have been made by several chemists.

*Chief chemist, technologic branch of the United States Geological Survey. Paper read at the Illinois Fuel Conference, March 11, 12 and 13.

Proximate Analysis

In addition to the ultimate analysis, we have the more commonly made "proximate analysis," consisting of the determination of the moisture, ash, fixed carbon and volatile combustible matter in the coal. Much has been written in regard to these determinations.

On the same sample of coal closely agreeing results can be obtained on the ash and fairly close on the moisture. The variation in the volatile combustible is much larger and can only be kept within reasonable limits by very careful adherence to a definite method of procedure. The term moisture simply means the loss in weight under fixed conditions of treatment. It is intended and does bring the material to a condition which can be duplicated closely and represents a fixed basis for comparison, but in nowise stands for all the water in the coal. The volatile combustible, as has been carefully investigated by Professor Parr, is by no means properly named. Only a fraction, and a variable fraction at that, depending largely on the kind of coal, is combustible, and a considerable fraction, consisting of water vapor, carbon dioxide, nitrogen and other dilutants is inert or noncombustible. It is well to recollect that the proximate analysis of coal was devised many years ago, and primarily as a means of testing the amount of coke left by coal. The volatile combustible has since been the subject of much discussion and many attempts have been made to correlate it with heating value, geological changes and the various questions arising in coal utilization. Some undoubted connections have been shown, but I feel that possibly too little recognition has been given to the empirical and more or less uncertain nature of the determination.

"Float-and-sink" Tests

Of growing importance, particularly in connection with coal washing, and as a tool for the study of coal samples is the application of the separation by gravity or the so-called "float-and-sink" tests, in which the coal crushed to a moderate degree of fineness is separated on solutions of high specific gravity, chloride of calcium for specific gravities up to 1.35 and chloride or sulphate of zinc for higher gravities. Chloride of zinc solution can be made of a specific gravity as high as two and by dilution any of the intermediate gravities obtained. I have used this method in my laboratory for years to separate heavy mineral materials like slate and pyrites, as preliminary to the study of the composition of coal. The method is excellently adapted to tracing out the variations in composition as the intermixed mineral substances are eliminated. It will enable the experimenter to distinguish with considerable accuracy between the inherent intimately mixed ash and the sulphur compounds and the coarser and mechanical contaminations.

In recent years the leading factor in the commercial valuation of coals has become the calorific value or heating power of the coal and today the most important demand on the laboratory is the determination of this. The widely extending use of the bomb calorimeter is leading to new problems for the investigation of the chemists. Here again the heating value of the sample is modified more than by mere dilution by the nature of the mineral aggregate. As Mr. Turner and others have shown, the heating value is not entirely proportional in a given kind of coal to the residue left after deducting the ash and the moisture, but that there are factors depending on the influence of the inorganic material. Work of this kind is of great importance in order that the effect of ash, moisture and pyrites on the commercial value of coals may be more accurately shown.

Calorimetry Requires Skill

Calorimetry is, unfortunately, work demanding considerable training and experimental skill and the recently adopted policy of the Bureau of Standards of furnishing materials of known heating value so that the constants and correction of the calorimeter can be determined is greatly to be commended. The possibility of error in calorimetric determinations due to alteration of samples should be borne in mind. A very finely pulverized coal sample will oxidize in many cases very rapidly and comparative results by different chemists on such a sample are liable to vary unsatisfactorily unless all made approximately the same time on samples that have been sealed in air-tight receptacles. Experiments made by the fuel-testing plant afford ample evidence of the extent to which this alteration may take place.

The determination of the water equivalent of the calorimeter experimentally gives rise to many difficulties and hence except for those having had a great deal of experience in fundamental measurements it is far better to use the calorimeter as a comparative instrument and depend for its constants upon burning substances of known calorific value such as are furnished by the Bureau of Standards. Commercial chemicals are quite variable and different samples of napthalene, benzoic acid, etc., from different dealers will differ notably in their heating value. Recently the writer has obtained very successful results by the method of mixtures, adding hot water to the calorimeter from the Dewar flask or thermos bottle in which it is possible to read with great accuracy the temperature of the added water and to add the water to the calorimeter with a very small correction for radiation loss during the addition. The method has proved successful in the hands of students who have made a number of water equivalent determinations agreeing within a very small limit of error with the calibration of the calorimeter obtained in other ways. Of course, this method has the advantage of being absolute and not relative.

Weakest Point in the Results

The foregoing outline has dealt with the laboratory side of the question. All the analytical work, calorimetric work and everything else in connection with the testing depends for its economic value on the fundamentally representative nature of the sample of coal tested in the laboratory. Here is the weakest point in the commercial application of the results. Coal sampling is a matter now prominent before the technical world. Now that the extending recognition of the value of laboratory work is leading to the purchase of coal on chemical specifications the whole question is under review. The ingredients most affected by sampling are obviously moisture, ash, sulphur, and calorific value. In a recent paper of great interest, E. G. Bailey has presented a large number of results in which he criticizes existing methods and lays down certain general deductions from carefully conducted experiments as to the general principles involved in the securing of correct samples. Mr. Bailey has, in my opinion, done a very valuable piece of work, both in calling attention to the importance of the subject and in the experiment he has brought forward. As having been connected with the Government work in St. Louis, I feel called upon to correct certain misapprehensions in regard to that work which I think unintentionally on his part led him to place it in a somewhat false light as to the accuracy with which the sampling was done. As I followed this paper he makes a fundamental assumption that the variations in the portions of coal taken at the plant from the same car shipment and sent to the boiler-gas producer, briquet and washing plants were identical in composition with the carload sample, and that the variations shown in these different portions were due to variations in sampling of the portions at the various plants. Whereas, the facts of the case are that the different portions taken from the car were not supposed to be sampled from the car, but simply portions unloaded at different points and the reason why analyses were made of the separate portions was because it was recognized that the carload was not uniform as far as contents of ash, sulphur, etc., were concerned, and that the carload analysis could not be taken for the different portions without a preliminary thorough mixing of the whole carload which was not practical. This is clearly stated on page 284 of professional paper 248, part 1, from which I quote:

"It was intended that the car sample should represent the average of the whole car while the other samples stood for different portions of it. These would average about 5 tons each. In some cases the car sample was taken on only part of the car. The large variation in the different samples in a few cases shows the irregularity in the coal in the car."

Experiments were made at St. Louis and published in this same work giving the analysis of duplicate samples, and while the results were not very satisfactory and some errors were found, they were not of the magnitude as given by Mr. Bailey from his comparison of the other samples based on the assumption which I have shown was not warranted and which was contrary to the facts as we stated them at the time. Mr. Barrows has discussed the question of mine samples, but the comparison of those with coal shipped from the mines makes no allowance for the extent of cleaning that the coal underwent in shipping and in taking the mine samples. As stated, several duplicate samples on the carloads were run to check the St. Louis sampling, and the worst result obtained I think was the one given on page 287, in which an extreme variation in ash on a coal averaging about 15 per cent. ash, was a little over 2 per cent. This coal was selected as the worst obtainable from the standpoint of sampling and the variation of the highest and lowest samples from the average of all the experimental samples on this coal was only a little over 1 per cent. Notwithstanding the criticism that I felt compelled to make of Mr. Bailey's representation of the St. Louis work, I feel that his general proposition in regard to the uncertainty of much coal sampling is well sustained. His conclusions as to the amount of sample necessary in order to obtain a representative sample are of great interest. However, I do not feel that the difficulties are quite as great as his experiments would lead one to conclude.

Things Important to Consider

Two things are important to consider. In the first place, in crushing coal a large proportion of fine material is produced so that the average size of particle is but little more than one-half of the maximum size and therefore results on the distribution of the maximum size pieces greatly exaggerate the difficulties. I recently took four samples of screened coal and had them put through a jaw crusher and screened.

In No. 1, 8.8 per cent. was retained by a ½-inch screen and 91.2 per cent. passed a ½-inch screen. This sample of coal was sampled in duplicate at this stage of crushing, portions of coal of about 5 pounds were taken. The two 5-pound portions were each separately pulverized, mixed and analyzed. The first portion gave 13.86 per cent. ash and the second portion 13.56. A similar experiment on a second sample of coal gave 16.3 over a ½-inch screen and 83.7 per cent. through a ½-inch screen. The ash in the first sample, 14.50, in the second sample, 14.41. A third sample of coal gave 7.2 per cent. over a ½-inch screen and 48.1 per cent. through a ½-inch screen. The ash in the first sample was 15.11; in the second sample 15.10. In two of these samples the percentage of ash in the finer portion was considerably greater than the percentage of ash in the coarser portion.

Of course, these results are too few in number to amount to anything, but they show that the finer material is in sufficient proportion to diminish the irregularity introduced by the bad distribution of the coarser lumps in the sample.

A further point in coal sampling which has to be considered is that in the larger sizes there is a natural mixture in the material of the slate and coal, so that a 4-inch lump coal does not represent a mixture of 4-inch lumps of coal and 4-inch lumps of slate to any appreciable percentage of the ash present. In other words, the inspection element must enter coal sampling, and no man would draw a moderate-sized sample of a coal in which he has a large percentage of lumps of slate as large as the lumps of coal, while the occasional presence of even a large lump of slate would have but little influence on the ash percentage of the resulting sample.

Mr. Bailey gives what he names the size-weight ratio or the relation between the maximum sized piece of coal in the sample and the weight of coal necessary to take in order that the sample may be certainly representative within an error of 1 per cent. of ash.

Now his figures lead to very large samples in cases of lump coal, but the foregoing indicates that the size ratio should probably be that of the maximum slate sizes present in the coal lumps, or free, rather than the actual coal lump size. The moderate variations in the ash percentage of the different lumps would have far less influence in disturbing sampling than the presence of equivalent-sized lumps of slate.

Obviously, therefore, careful inspection must precede the sampling in the case of lump coal and the presence of large pieces of slate and pyrites in lumps in the coal allows due consideration in determining the size of sample necessary in order properly to sample the coal.

I have always directed samplers to inspect the coal carefully and break up any small pieces with traces of slate, bone coal or pyrites found, or anything that does not look like coal, before taking or finishing the sample.

Of course, it is well known that no system of sampling which is purely mechanical is satisfactory for materials in which coarse distribution of the constituents exists, unless the whole of the material is crushed to approximately such limits as are defined by Mr. Bailey. This is the principle involved in the sampling of lead and copper, gold and silver ores where the system of sampling involves the crushing of entire lots of material. Such a system of sampling is, of course, out of the question with lump coals where the crushed material would be to a certain extent rendered of small value. The system of sampling adopted in this case must be based on an estimate of the maximum size of slate and pyrites, constituting an important portion of the impurities.

The difficulty of eliminating the personal element in doing such sampling is one of the problems which the committee on specifications will have to contend with. Meanwhile, the sampling problem is before us and must be adequately solved before the laboratory analysis of the coal reaches its full application.

The preparation of the laboratory sample from the field sample is a much easier matter and is easily within the reach of the present methods. One of the principal difficulties involved at this point is the avoiding of changes in the composition of the sample due to loss of moisture and to oxidation. I notice in many experiments the coal is ground to 100 mesh or even 200 before analysis. I think this is a step in the wrong direction. The finer the powder the more prone to oxidation and loss of moisture, and I think the effect of the samples should be to determine a lower limit for Mr. Bailey's "size-weight ratio" as well as a higher, and not to reduce the sample beyond this point before weighing out.

We have considered that a 60-mesh sample will meet the ordinary requirements where 1 gram is taken for the determination, which is within Mr. Bailey's figures as I understand them.

The Status of the Wave Motor

By James T. Barkelew

Now that there is a comparative lull in the production of new designs and ideas for wave motors, it is well, perhaps, to make a resumé of the different forms and their relative effectiveness before taking further steps in the actual reduction to practice of the theories already advanced, and to lay out the probable conditions under which it is possible that the wave motor may become a commercial success.

In general, inventors have approached the problem with the single notion that there is unlimited power in the waves awaiting utilization, and the result has been a motley array of devices which take up the motion of the waves and transform it, in some method or another, into a power of practical utility, generally electrical. All this has been done without any thought of efficiency, but with the sole idea that, as there is unlimited power, a device of any character would take up a sufficient amount to raise the designer to opulence. After numerous trials of various machines it has been found that the results do not come up to expectations, in the majority of cases the market price of the power produced not equaling the interest on the capital invested, and being more than offset by the maintenance cost. It is true that some devices have excelled others in efficiency and are also less susceptible of destruction by storms, but even with these better machines the returns have not seemed to be large enough for the investment demanded.

Maximum Average Energy in Wave Motion

It is the purpose of this article to investigate the basis on which the profit-paying chances of the present motor rest, and to point out, if possible, the line of advancement to the future successful machine. The first step will be to ascertain the maximum average energy in wave motion at accessible and practical localities, where the power produced may be marketed without excessive costs over that of initial production. For this purpose a simple and easily understood formula will be deduced and then maximum average values applied.

Referring to Fig. 1, which represents a greatly exaggerated contour of a wave from crest to crest, we will be able to deduce a simple formula for the total power, sufficiently accurate for the purpose of this paper. Deductions which take into account the theoretically exact trochoidal form of the wave give a resulting equation different in form from the following, but the numerical calculations of the different formulas will check fairly closely. The superiority of the simpler formula is that its derivation can be easily reasoned out and the logic of its being perceived without the aid of higher mathematics.

Let L represent the length of the wave from crest to crest, D the depth from crest to trough, and C a constant depending upon the configuration of the wave. Then the weight of water in a single wave, the shaded portion in Fig. 2, a foot wide, is,

$$W = \frac{62.35\,D\,L}{C}. \qquad (1)$$

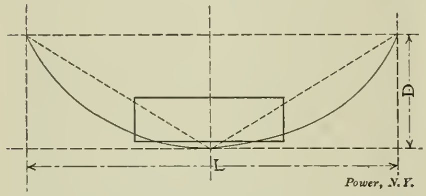

FIG. 1. EXAGGERATED CONTOUR OF WAVE FROM CREST TO CREST

In long waves the contour approaches the dotted lines in Fig. 1 and the value of C approaches 2, the area of the shaded portion on the diagram being nearly that of a triangle whose base is L and altitude D, so that the formula may be written:

$$W = 31.18\,D\,L. \qquad (2)$$

It will readily be observed that every particle of water on the contour of the wave must at one phase of its motion be at the top of the crest, and in the opposite phase be at the bottom of the trough. This is true of the surface water, but the vertical movement of the particles below is not so great, diminishing to zero at a plane just under the surface. The average motion may be taken at $\frac{D}{2}$, and the total energy for a single wave a foot wide may be expressed,

$$E = \frac{31.18\,D^2\,L}{2}\ \textit{foot-pounds}. \qquad (3)$$

Then, if N be the number of waves per minute, the total power of regularly succeeding waves will be:

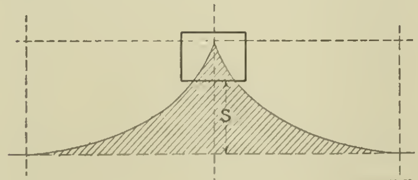

FIG. 2. THE SHORT FLOAT

$$H.P. = \frac{31.18\,D^2\,L\,N}{2 \times 33{,}000}, \qquad (4)$$

all the dimensions being in feet.

To strike a high average the number of waves will be taken at four per minute, the distance between them, 300 feet, and the depth as 6 feet. These are figures well over the average for fair weather. In reality, waves of this size do not succeed regularly, there usually being a short succession of large waves followed by a longer succession of smaller ones. It is not just to take into account the storm figures, as it is impossible to use the energy of the waves at that time to any advantage. With these figures the actual horsepower per foot breast of waves becomes:

$$H.P. = \frac{31.18 \times 36 \times 300 \times 4}{33{,}000 \times 2} = 20.5, \qquad (5)$$

or approximately 20 horsepower per foot of width. In favored localities conditions may be found which will average at the above power, but on the larger part of our coast line this amount of power is not available. As this amount is possible, however, it will be taken as the basis of the following:

Wave Motors Depending on Horizontal Motion

Having determined to fair accuracy the amount of available power, the next step is to ascertain, if possible, the proportion which may be absorbed by the different classes of wave motor. These may be divided broadly into those utilizing the vertical movement of the water and those depending for their motion on the horizontal motion of the surface water or of the breakers on the beach. In regard to the latter class it may be noted that the energy of the horizontal motion is always a small fraction of the total energy. In the case of the movement of the surface water, the layer in which slow movement takes place is very thin and the proportionate amount of energy is consequently very small. This fact reduces the available amount of power to an extremely small per cent., so that a motor built to utilize this form of energy is necessarily inefficient. And there is usually a farther limitation in the motor itself, in that some portion of the power receiving member is always submerged in water which does not partake of the horizontal movement, the free motion of the member being thus greatly impeded and its transmitted power cut down.

This action alone probably reduces the power available from a horizontal-movement motor to the extent of 50 per cent., and it is consequently doubtful whether the output is equal to 5 cent. of the total energy of the waves. The other form of horizontal-movement motor probably gives better results from an efficiency standpoint, but the impulses from the breakers are more spasmodic and the energy therefore more difficult to handle. Moreover the total energy available from a breaker is only a part of the energy of the wave forming the breaker, as a large part of the movement is taken up by the cause of the breaking. the contact with the sloping shore. Also the falling of the water from the crest of the breaker effectually removes a large amount of energy. For these reasons the final efficiency of the horizontal-movement motor is singularly small, being much lower than that possible with the vertical-movement machine.

Motor Utilizing Vertical Movement of Water

Coming now to the vertical-movement type, it may be taken that about 75 per cent. of the total energy is available in the vertical movement of the water. The proportion available in this direction is far above that on any other direction, and consequently motors built to utilize this movement have more chances of success than others. However, there are limiting circumstances which prevent the present devices from utilizing but a diminutive fraction of the energy, these circumstances residing mainly in the inherent principles and construction of the motors. With a device showing a respectable efficiency, it is possible to finally utilize about 50 per cent. of the available power, about 37 per cent. of the total, or about 7½ horsepower per foot of breadth on the basis of the previous calculations. Even this possible figure is high, as there are several distinct losses in transforming the energy into a practical form suitable for transmission. In the usual case electrical energy is the final product and its production involves three transformations. The first is mechanical, being the conversion of the irregular motion of the waves into a reciprocating or a rotary motion. Striking an average, this means the loss of approximately 25 per cent., assuming that all of the energy of the waves is taken up by the floats or other members. The next operation is one of storing the energy in such a manner that it may be used regularly. In the typical instance the operation consists in pumping water into a reservoir under pressure, a loss of another 15 per cent. under the best conditions obtainable. The final step is that of converting the water pressure into electrical energy. On the water-motor side of this step the average loss will be at least 15 per cent. and on the electrical side about 10 per cent. The total loss in such a system would then figure approximately 51 per cent., or say 50 per cent.

The previous figure of 7½ horsepower per foot breast of wave is based on a float or other device which will absorb from the waves their full energy. Even with what might be termed a perfect device, this is not possible, the loss even then being at least 10 per cent. on account of mechanical limitations. If all the power were absorbed it is evident that the waves would be perfectly leveled out and that the last part of the power would be taken on an infinitesimally small movement. Practically, this is impossible and the average efficiency of such a device would be around 90 per cent., or the final horsepower in electrical energy produced would be 6.75. At this figure it would probably be profitable to produce and sell power at the prevailing rates, but this naturally depends to a great extent on the capital required for installing the plant.

Efficiency of the Float

The next point in question is that concerning the efficiency of the float or the device for taking up the energy of the waves. In all of the devices so far produced, these parts have been remarkably inefficient, being merely more or less buoyant objects moved by the waves and absorbing in most cases an inappreciable portion of their power. In some instances, however, a genuine attempt has been made to increase the efficiency by adding special devices to the float, and it is with this class the following will deal.

Referring to Fig. 2, where an exaggerated crest of a wave form is shown, the following will deal with possible and average float efficiencies. In Fig. 2 a comparatively short float is represented

FIG. 3. LONG FLOAT

floating on the crest, while in Fig. 3 a longer float is illustrated. In Fig. 2 the stroke of the float is approximately the distance S, and the power derived depends directly on this distance and the buoyancy of the float, or the weight of water displaced. In Fig. 3 the longer float is shown in full lines as having the same stroke S, and consequently displacing the same amount of water, riding equally high in the water as the smaller float. Its length is therefore useless, unless it is sunk to such a position as shown in dotted lines with a corresponding stroke S'. But the displacement has been increased and this increase has practically been proportional to the square of the decrease of the stroke, so that the energy available from the float increases directly as the stroke diminishes.

If this were the only condition imposed it is evident that by increasing the length of the float to equal that of a complete wave and sinking it so that it had its maximum buoyancy, the maximum power would be obtained. But there are conditions which prevent this being true. Looking again at Fig. 3, where the longer float is shown in the trough of the wave, it is seen that it does not sink to the same depth as the shorter float would, so that by increasing the length of the float we decrease the stroke from below as well as from above. Taking this factor into account for the shortest average wave lengths on which the float is designed to tally, the effectual length of the float will be reduced to approximately one-quarter of the wave length. Other considerations of a purely mechanical nature usually reduce the size farther to a fraction of this quarter length, a float of any considerable size being extremely unmanageable at sea, especially when in working connection with some fixed structure.

Taking the quarter length for the purpose of calculation, it is seen that only one-quarter of the wave energy is possible of absorption, as the float only comes into contact with and is operated by, one-quarter of the water in a single wave. On this basis the final power available is 6.75 ÷ 4 or 1.69 horsepower per foot breast. A float of, say, 20 feet breast would then afford 33.80 horsepower, a float of this size being fairly typical and amply large to be difficult to manage in storm conditions.

Cost of Installation and Upkeep

The cost of installation and upkeep of such a device and the attendant mechanism for transforming the power is variable with the style and nature of the machinery used. Calculating, however, on the formerly outlined plan, an approximate result can be obtained which is instructive. In the first instance the cost of the float and anchorage in the most inexpensive system known to the writer will average a minimum of $1000 per unit, this figure presuming the construction of a large number of units to aggregate about 10,000 horsepower. Reducing this to cost per horsepower, the outlay is $29.59. The next cost is that of running gear for connection with the fluid-pumping machinery. This may be reduced as low as $10 per horsepower, depending upon the design of the float and its relation to the pump. The pumping-machinery cost will average approximately $20 per horsepower, including piping, etc. The reservoir cost is so extremely variable that it is difficult to make a fair estimate. In the majority of cases, and it seems to be the most practical, water is the fluid used to store up the energy and it is pumped to a reservoir on the nearest and most suitable shore. Taking a fair average at a head of 100 feet and under favorable conditions as to location, an estimate might be placed at $20 per horsepower, allowing sufficient [illegible] water for twenty-four hours' run. The cost of electrical installation with water power would average around $60 per horsepower.

The sum of these economic figures gives a total outlay of $139.59 per horsepower, but it must not be assumed that there has been a complete, commercial, [illegible] installation built at a figure at all approaching this. [illegible] horsepower installation, it is [illegible] to presume that the [illegible] would [illegible] and that the [illegible] will be placed at [illegible]. Calculating all these factors, together with a possible return of $35 per horsepower-year, the following totals are obtained:

Interest on $210.50 at 6%	$12.63	
Caretaking, etc.	10.00	
Deterioration	21.05	
Power sale		$35 00
Totals	$43.68	$35.00

This leaves a balance of $9, in round figures, per horsepower-year on the wrong side of the account. Allowances have been made in favor of the motor at every step of its construction and operation, so that, although the above figures probably do not represent a possible installation, they give a fair idea of what the average motor lacks in the direction of making financial returns.

Reverting again to the consideration of a float or other device which will absorb a large proportion of the wave energy, it will be assumed as before that a total of 6.75 horsepower per foot breast may be finally produced in electrical energy. This increase in efficiency over the above-tabulated figures would lead to the following possible results:

Anchorage cost per H.P.	$ 5
Connection to pump per H.P.	5
Pumps per H.P.	75
Reservoir per H.P.	10
Electric installation per H.P.	50
Total	$145

These figures are again minimum, as every previous figure is cut with the exception of the electric installation. This would not be reduced, as it was supposed for the first figures that there would be a single electric plant for a large number of motor units. Again tabulating the expense and income, a small balance is obtained on the profit side of the account:

Interest on $145 at 6%	$ 8.70	
Caretaking, etc.	8.00	
Deterioration	14.50	
Power sale		$35.00
Totals	$31.20	$35.00

This gives a profit of $3.80 over all expenses. Thus, even with everything in its favor, it is doubtful whether the motor in its most highly efficient form would be a dividend-paying investment.

At any rate, until there appears a float or barge device which will absorb a fairly large per cent. of the energy of the waves, it is evidently impossible to deliver enough power to place the motor on a paying basis. Until this device appears it seems that the wave motor must remain undeveloped. If such a device is produced, it will probably be devised by someone who has made a scientific investigation of the facts in the case and has experimented with and tested the actual efficiency of models of machines growing out of his investigations.

Heat Transmission Through Pipes and Tanks

By F. E. Matthews

Given two rooms of the same dimensions and insulation, one cooled by a brine pan of a given cubical capacity and the other by coils of 2-inch pipe of the same capacity. The brine is circulated through the pan and pipes at a temperature of 10 degrees Fahrenheit during the day, but the brine pump is shut down at night and the rooms are refrigerated only by the rise in temperature of the brine (about 200 cubic feet) in the pan or coils, respectively.

Will the cooling devices be equally efficient? Will they both perform the same amount of work in a given time? Will the brine temperature in each be the same in the morning?

Heat transmission per square foot of surface from still air through a given thickness of iron to still brine should be the same in all cases where the temperatures of the air and brine are the same, or where the difference in temperature between the air and the brine is the same. Whether the heat transmission in a given time and subsequently the rise in temperature of the brine in the case in question will be the same, will depend directly on whether or not the two heat-absorbing devices present the same amount of heat-absorbing surface to the air to be cooled. This is on the assumption that all other conditions such as difference in temperature, direction and velocity of the air traveling over the heat-absorbing surfaces, and the resistance to the passage of heat offered by the heat-absorbing surface (which depends on material, thickness and structure) be the same.

In the case in question the kind of material, iron, of which the devices are constructed, is the same; the thickness of the material is slightly different, but this difference probably need not be considered provided the surfaces are not coated with ice, or are coated with ice of the same thickness and density. The velocity of the travel of the air over the heat-absorbing surfaces may be assumed to be about the same if the pipe coils occupy about the same space and same relative position in the room as the pan. The direction of travel of the air as regards the heat-absorbing surfaces will probably be a little more favorable in the case of the pipe coils, but this factor may also be ignored without any great error.

On the assumption, then, that all of the conditions are practically the same except the area of the surface exposed, it may be stated that the heat absorption and rise in temperature of the brine in the two containing vessels of the same volume will be directly proportional to the areas exposed. Except in the case of surfaces of the same shape there is no fixed geometrical relation between the area of the superficial surface and the volume. Of the more common forms the sphere contains the greatest volume within the least surface. Next to the sphere comes the cylinder, of which a pipe is the best practical example. It is farther evident that the ratio of volume to superficial area of the pipe may be varied by varying the shape of the cross-section. The surface of a square pipe would be greater than that of a cylindrical one containing the same volume, and that of a very deep, thin tank greater than that of a square pipe.

It is reasonable to assume in general a form of brine tank that would be commercially practical to construct, will have less heat-absorbing area per unit of volume than a coil of pipe of the same volume, and in the present case that the heat absorbed, the rise in temperature of the brine and subsequently the refrigerating capacity of the devices in question will be directly proportional to the superficial surface exposed. A single example will suffice.

A form of tank more or less commonly used in refrigerating systems in connection with brine circulation, and known as a congealing tank, is usually 10 feet long, 3 feet deep and 3 inches thick. Such a tank would have 66½ square feet of surface, including the open top, and a volume of 7.5 cubic feet.

A cube having the same volume would measure 1.957 feet on a side and would have 23 square feet of surface, or only 34.5 per cent. as much as the congealing tank.

To contain 7.5 cubic feet of brine a 2-inch pipe would have to be 322 feet in length and would have 201 square feet of surface.

The rate of heat absorption by the cubical tank of 7.5 cubic feet capacity, a flat congealing tank of the same cubical capacity, and a coil of 2-inch pipe of sufficient length to contain 7.5 cubic feet will be directly proportional to the 23 square feet, 66.5 square feet and the 201 square feet, respectively, of heat-absorbing surface exposed. This rate of absorption would continue so long as the conditions above defined are kept constant. It is obvious, however, that when the brine pump is shut down the cooling device having the greater area will absorb heat so much more rapidly that the brine contained will soon become much warmer than that in the other vessels, and as there is a lesser difference in temperature between the brine and the outside air, the heat absorption per square foot will be reduced, which would tend, but never allow, the brine temperatures in the other receptacles to become quite the same except in the limiting case in which the brine finally becomes as warm as the room and heat absorption accordingly ceases.

Reversing Direct-Current Machines

The Effect of Reversing the Residual Magnetism of a Generator, and the Change of Connection Necessary When Running as a Motor

BY F. P. M'DERMOTT, JR.

In solving problems concerning the reversal of polarity, or of rotation, of direct-current machines, certain principles can be used to advantage. It is the purpose of this article to show the application of some rules for studying these problems, including the problem of the behavior of the same machine as a motor and as a generator.

Rule 1—If the current through all of

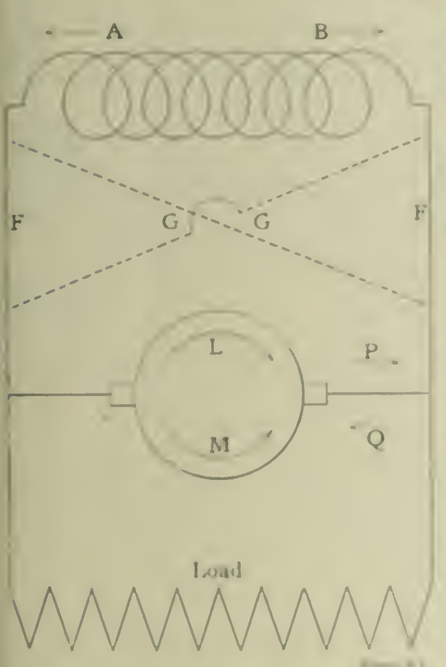

FIG. 1. SHUNT-WOUND GENERATOR

the field windings of a machine is reversed, the field magnetism is reversed. In a machine containing only one field winding, such as a shunt-wound or series-wound machine, reversing the current through this one winding reverses the magnetism, but in a machine with more than one field winding, such as a compound-wound generator, the field magnetism depends on the current in all of the field windings, and reversal of current in one of them may reverse the field magnetism or may merely change its strength.

When there is no current in the field windings there is generally some residual magnetism present. For convenience in discussing such magnetism, its direction will be referred to as corresponding to that direction of field current which would produce it.

Rule 2—Reversal of the field magnetism reverses the electromotive force generated by the armature if the direction of rotation is unchanged.

Rule 3—Reversal of the direction of rotation reverses the electromotive force generated by the armature if the direction of the field magnetism remains the same.

Reversing Residual Magnetism

The effect of reversing the residual magnetism of a generator is the first problem to which these rules will be applied. The discussion applies both to the shunt-wound generator, Fig. 1, and to the series-wound generator, Fig. 2.

For a certain direction of rotation *L*, let *P* be the direction of the generated electromotive force when the field magnetism corresponds to current in the direction *A*. According to rule 2, reversal of the field magnetism reverses the generated electromotive force and consequently if the residual magnetism corresponds to current in the direction *B*, the generated electromotive force is in the direction *Q*. Does it make any difference whether the field winding is connected to the brushes according to the lines *F F* or according to the lines *G G*? First, suppose that the connections *F F* are employed. When the residual magnetism corresponds to *A*, the generated electromotive force *P* forces current through the fields in the direction *A*, which is the proper direction for strengthening the magnetism. If the residual magnetism is in the direction corresponding to *B*, the generated electromotive force *Q* drives current through the fields in the direction *B*, which is still the direction of field current required for strengthening the magnetism.

Now change the field connections to *G G*. If the residual magnetism corresponds to *A*, then the generated electromotive force *P* drives current through the fields in the direction *B*, thereby weakening the magnetism. With the residual magnetism corresponding to *B* the generated electromotive force *Q* will send through the field windings a current which opposes the residual magnetism. From this it is evident that the machine cannot build up with the connections between the brushes and the field windings according to *G G*, but, whatever the direction of the residual magnetism, the generated current weakens it, whereas with the connections *F F* the generated current tends to increase the magnetism, whatever its direction, thereby causing the machine to build up. Of course, even with the correct connections there are many causes which may keep the machine from building up.

It is seen, therefore, that the same connections are required between the fields and the brushes for either direction of residual magnetism, but that with residual corresponding to *A* the generated electromotive force is *P*, and with the residual corresponding to *B*, the generated electromotive force is *Q*. Reversal of the residual magnetism, therefore, reverses the direction of the electromotive force generated by the machine.

Now let the direction of rotation be changed to *M* and the residual magnetism correspond to current *A*. The generated electromotive force has now the direction *Q* instead of *P*, according to rule 3. With the connections *F F* the current supplied by the armature reduces the residual magnetism, but with the connections *G G* it builds it. Similar reasoning

FIG. 2. SERIES-WOUND GENERATOR

with the residual corresponding to *B* shows that the connections *G G* are those required for building up. This shows that if the direction of rotation be reversed, it is necessary to reverse the connections between the fields and brushes.

It may be remarked here that to shift the brushes through an angle equal to the angular distance between adjacent poles has the same effect as reversing the wires connected to the brush holders. The actual angle through which the brushes should be shifted, if it is desired to change the direction of rotation without disconnecting the wires connected to the brush holders, is in most cases slightly greater or less than the angular distance between adjacent poles, so as to give the brushes the proper lead for the reversed direction of rotation.

These principles also apply to a compound-wound machine, Fig. 3, but here there are two branches through which the generated current flows. The direction of magnetism which the generated current tends to produce should be the same for each of these branches. If this is the case with the connections *F F*, it is also the case with *G G*, since reversal of the connections at this point reverses the current in both windings. If, however, the

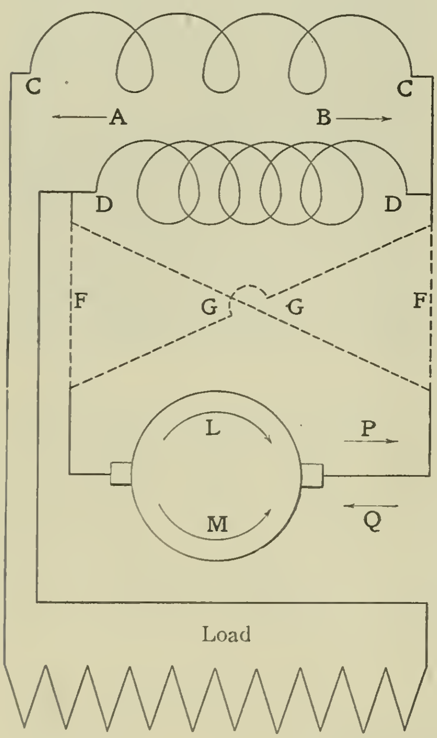

FIG. 3. COMPOUND-WOUND GENERATOR

fields be disconnected either at the points *C C* or *D D* and transposed, their magnetizing tendencies oppose one another when the generated current passes through them. Even though the two field windings both tend to magnetize the fields in the same direction, that direction may be such as to destroy the residual magnetism, just as was seen to be the case with a machine having a single field winding.

Generator as Motor

In studying the behavior of a machine as generator and as motor a fourth rule must be added to the three preceding.

Rule 4—When a machine acts as a motor, it generates an electromotive force, known as the counter electromotive force, which opposes, but is less than, the electromotive force applied to the brushes.

Fig. 4 represents the same machine as Fig. 1, with the fields connected according to *F F*. Supply current to the machine from a source of power, as shown. This sends current through the field winding in the direction *A*, and through the armature in the direction *Q*. The counter electromotive force must oppose the electromotive force applied to the

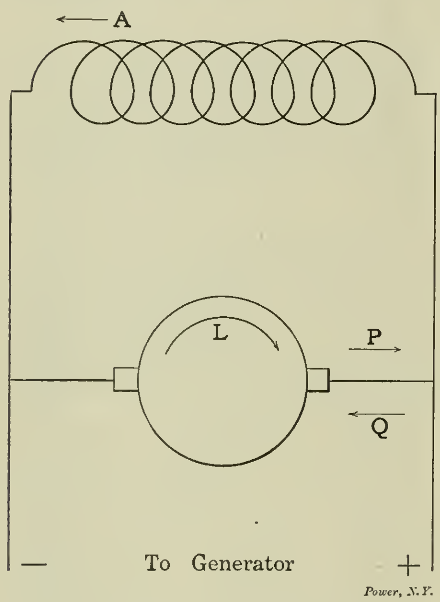

FIG. 4. SHUNT MACHINE AS MOTOR

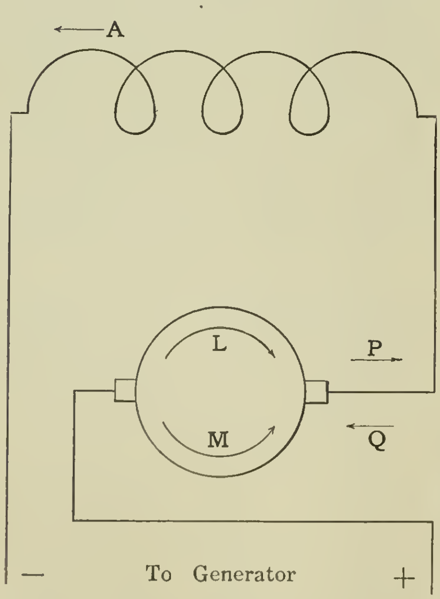

FIG. 5. SERIES MACHINE AS MOTOR

brushes, and hence have the direction *P*. But, as generator, with field current in the direction *A*, and connections as shown, the armature rotates in the direction *L* when producing this electromotive force. This is the same direction of rotation that the machine must have in order to generate. A shunt machine, therefore, acting as a motor, has that direction of rotation with which it must be driven in order to generate, supposing that the connections remain unchanged.

Fig. 5 shows the same machine as Fig. 2, connected according to *F F*. Pass current through the machine from a source of power in the direction *A*. The motor must run so that its generated electromotive force opposes the electromotive force of the source of power, that is, the counter-electromotive force must have the direction *Q*. To produce a counter electromotive force in the direction *Q* when the field current is in the direction *A* requires that the armature rotate in the direction *M*, which is opposite to the direction *L* in which the machine must be driven in order to generate. A series machine, therefore, operates as a motor with the direction of rotation opposite to that in which it must be driven in order to generate.

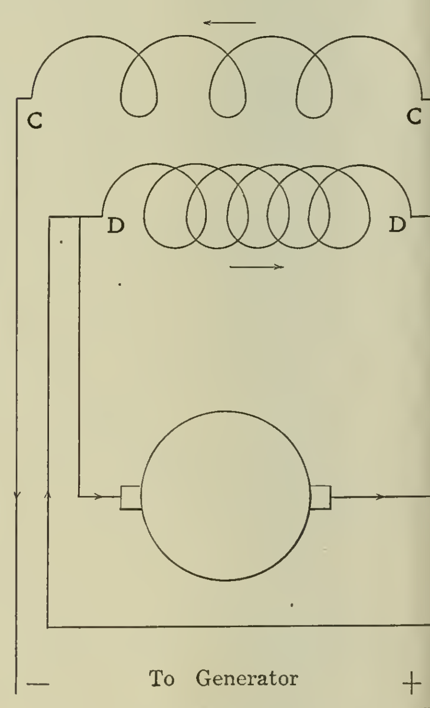

FIG. 6. COMPOUND-WOUND DYNAMO AS MOTOR

If the compound-wound generator, Fig. 3, be connected according to *F F* and supplied with current, the state of affairs shown in Fig. 6 exists. The two field windings oppose each other, giving a differentially wound motor, which is now seldom used. In a compound-wound motor the two fields act together, producing a stronger field as the load increases. To convert a compound-wound generator into a compound-wound motor, it is necessary to reverse the connections to one of the fields; that is, disconnect and transpose at either *C C* or *D D*. A compound-wound generator has the field windings belonging to a series machine and also those belonging to a shunt-wound generator. As a series machine it would be expected to run as a motor and as a generator in opposite directions, but as a shunt machine it would be expected to run in the same direction in either case. Suppose that it is desired to run it as a motor in the same direction that it runs as a generator. The shunt winding tends to cause this, but the series winding tends to cause the opposite, and the series is accordingly the winding to be reversed. When it is desired to have the machine run as a motor in the opposite direction to that in which it runs as a generator, the shunt winding must be reversed.

To test the connections of a compound-wound machine, run it as a motor with the shunt field open, keeping sufficient resistance in the circuit to prevent excessive current or speed, and note the direction of rotation. Next run it as a shunt motor, again noting the direction of rotation. If the machine is connected as a compound-wound motor the direction of rotation is the same in each case, but if it is connected as a compound-wound generator, the two trials produce rotation in opposite directions. It should be driven as a generator in the same direction that it runs as a shunt motor.

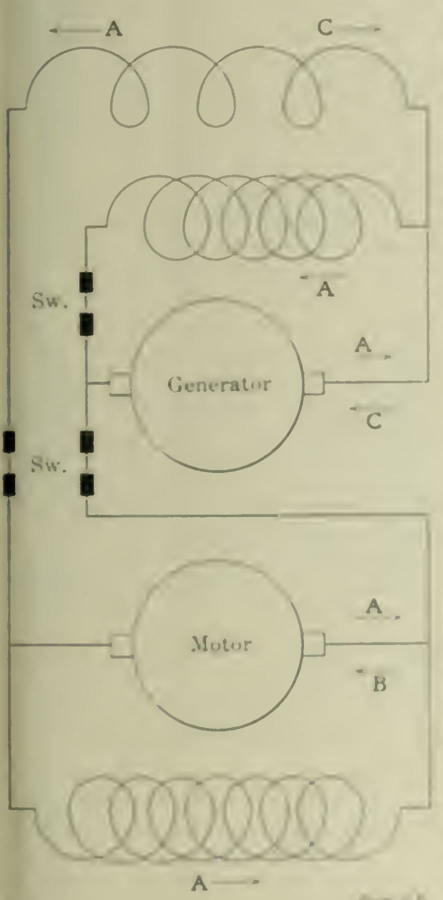

Fig. 7. Compound-wound generator driving shunt motor

A Reversal of Polarity

A special application of the foregoing principles is illustrated in the following problem: A compound-wound generator had as its only load a shunt motor running light. The shunt field of the generator was opened, after which the motor was disconnected. The shunt field of the generator was again closed, and the generator built up with reversed polarity. Why?

Fig. 7 shows the connections. Suppose the original direction of the currents in the various circuits was that indicated by the arrows *A*. The motor produces a counter electromotive force in the direction *B*, almost equal to the electromotive force of the generator. When the shunt field of the generator is opened, its electromotive force falls, owing to the decrease of field magnetism. The momentum of the motor armature causes it to continue rotating, and its electromotive force *B* excites the motor field in the same direction as originally, and also forces current through the armature and the series fields of the generator in the direction *C*. The generator thereby has its magnetism reversed, and when the shunt field is again closed this reversal of field magnetism causes it to build up with reversed polarity.

Drops of Ink to Make You Think

By the Ink Maniac

Yesterday has gone, today is short, tomorrow may never come, so if there is any money to save, get busy quick!

The Engineer Becomes Chatty and Confidential

Say! Have you read that book of Andrew Carnegie's yet? Well, it's called the "Empire of Business," and it's all right! All the way through he shows you've *got to save money!* I guess "Andy" knows what he's talking about when he says "Be thrifty." Why, out there at Gary, Ind., in the new steel plant, the gas from the blast furnaces—gas such as for fifty years they used to manufacture Pittsburg's famous atmosphere with—is now all saved, every bit of it, and all the big machinery and electric lights are run from this gas. They get [illegible] horsepower right along, and they say they don't have to buy coal for power. It's pretty near like getting something for nothing, ain't it? Of course, they have to put in a dust catcher and washing machines, so the gas won't spoil the machinery, but the fellow that won't spend a hundred dollars when it will save him fifty dollars a year is about ready for the scrap pile, in my opinion, when it comes to knowing what the word *investment* means.

The By-products of [illegible]

Maybe old man Armour didn't make some money out there in South Chicago [illegible] machinery and brains, too! Why, now, every old hog, they've got the "by-products" of [illegible] down to such a fine point that [illegible] every [illegible] of hogs they buy they sell a [illegible]

And I guess John D. is pretty wise to this saving game, all right. They used to pump petroleum, get some gasoline and coal oil out of it, and throw the rest away. But nowadays the old chemists dig down in their queer old laboratories, and then we hear of a new "vaseline" on the market, or a "non-fluid oil" or a new axle grease. And so it goes every year, more and more usefulness out of the same old stuff that we ordinary folks thought didn't contain anything new at all.

Explanation of "By-product"

Whether we read about a [illegible], or the expert butcher, or the men that save money, they always use the term "by-product." Now, that sounds kind o' swell and dignified, but I guess it's all right when you think about it. "By" really means "on the side," or extra. Just like when you order roast beef, and the waitress hollers: "Potatoes on the side," why you get them for nothing. So "by-product," when you boil it down, just means that you get something where you used to get nothing, 'cause you had been throwing it away.

The Engineer's Confession

Now, I've been interested in this kind of business lately. You know yourself that I've been an engineer on land and sea for twenty years, and I can keep an engine room slick and clean, without a [illegible] anywhere, and I'm pretty wise to indicators and things, and the electrical game too. Well, last spring I got a jolt that hurt my feelings for a little while. You know, when you jog along regular, and things go smooth, and the boss gives you a raise now and then, why you sort of feel your oats—I guess some fellow would say you get to be a big frog in a little puddle. That's the way I was last spring. But I've changed. I know now that a little frog in a big puddle is a whole lot better off than a big frog in a little puddle. A little frog not only has room to grow, but he is willing and dead anxious to, so as to [illegible] the big fellows [illegible] around him. The big frog can't hardly move around in his little puddle. Well, anyhow, [illegible] always some [illegible] a little better.

[illegible]

Well, [illegible] brought in some outside fellows [illegible] in my engine room. Honest, I didn't think they could do it [illegible] and [illegible] a lot of money. Those fellows were [illegible]. One of them was a [illegible] [illegible] fornia ham and, say, I'll bet he never wasted any of his time, any more than I have, sitting around with the manicure maids holding on to his hand.

I knew right off that he was a practical man, but I didn't believe him when he said the tall fellow was practical, too; at least, not at first. Well, this is what these fellows did: One day they came in, after I had got pretty well acquainted with them, and we made some changes in the firebox. The next day our regular coal truck didn't come but, instead, a new dealer dumped in a lot of dirt, at least that's what it looked like. They told me it was a dollar and three-quarters a ton cheaper than what we had been burning. I had always believed in buying the best coal on the principle that the best is none too good, and I didn't believe that that stuff would burn at all. But one of the men stayed with me for a couple of hours and showed me how it ought to be fired, and she held the pressure all right, and carried the load right through the evening peak without a bit of trouble.

Where the Saving Came in

Then I began to get interested, and wondered how many tons would be needed. I had always supposed that when you used cheap stuff you had to use so much more of it that it would make up for the low price. So it certainly was an eye-opener to me when we found that it didn't take a bit more of this new stuff every day than we used to use. And then I was pleased to find that although it looked like dirt, it really made less ashes by a third than I used to be getting with regular coal. When I got to figuring on this, I could easy see why the boss got interested, because we burn about ten tons a day most of the year, and $17.50 a day saved amounts to over $5000 a year!

And then something happened that I was mighty glad about. I had often told the boss that he could save a good deal of money on the water bill if he would save the condenser water from the refrigerating plant. But the boss was kind of "leary" about spending three or four hundred dollars on my sayso. These fellows were able to show him figures from other buildings, I suppose, and the boss said: "Go ahead and fix it up." Well, sir, it turned out even better than I thought it would, because the water bill is really $200 less a month than it used to be during the same season of the year, and that's about $2400 a year.

These fellows also seem to have a pretty good stand-in with some of the supply people, because they got us oil and ammonia and things like that at lower prices than I could ever get 'em for, even though the same label was on the can.

I'm real proud of my plant, now, and I'm glad I worked with these fellows instead of bucking them, because I get part of the credit for this $8000 a year that is saved. Some of the things that have been done are just what I have been yelling for during the last four or five years. So I don't think the consulting engineer is such a bad fellow, after all—that is, when he's got some good practical men with him that really know what I'm up against down here and who help me to make good. And the boss is so well pleased with everything that he gave me a raise the first of the year, and now "the goose hangs high."

The Garden Variety of Gas Engines

By H. W. Jones

As a rule, the expression "gas engines" conveys nothing to the mind. The writer or speaker may mean engines driven by gasolene or alcohol or distillate or producer gas or kerosene. This brief article, however, relates to gas engines burning *gas*—the kind that you get a bill for each month, the kind of bill that causes a man to increase his vocabulary, the kind concerning which each of us has tried in vain properly to express his inmost thoughts, finding that his mind refuses to act and all he can do is to get red in the face and pollute the air with his emotions.

The primary cause of large power-gas bills is, in truth, ignorance, in many cases equally divided between the user of the engine and the maker of the engine. The situation reminds me somewhat of the statement that "Some Americans are democrats and some Americans are republicans, but the Irish stick together and get all the offices." No matter what the kind of engine, the gas company gets all the money called for by the meters.

The makers of gas engines are to blame in a great measure for exorbitant gas bills because they permit people who do not and cannot make gas engines to sell machines claiming that they are engines, and gas companies are also blamable for allowing imitation gas engines to continue to drive away their business. The buyer is generally the innocent bystander who gets the full force of the brick and has only refuge in "language." And if you really want to hear language "as she is spoke," drop into the office of the man who has purchased one of these so-called gas engines at the time he gets his first gas bill. It is really quite interesting, as well as exciting. I have had this pleasure and I have wondered how it was possible for a man to have so much vitriol in his system and still live. This is especially true when it is that kind of a gas engine that "does not need an engineer to operate it; all you have to do is to pour oil on her and start her up." Words are inadequate with me. Not so with him. I am sure he used all the words there are and he invented several new phrases, one of which I am very proud to possess. How is this one: "An infernal damn piece of misrepresented mechanical iniquity?"

I struck another one of these cases recently. On a cold morning at about 9 o'clock I called at the factory of a man who had (or, rather, thought he had) bought a gas engine. An ominous calm of the kind that precedes a violent storm settled down upon me as I entered the office. The young lady there, knowing me, said: "Oh! Mr. Jones, go down stairs quick, the engine, the engine won't go, and Mr. Blank (the proprietor) is going on something awful!" Hurrying down, I saw Mr. Blank at the wheel making a noise like the blowing off of the pop safety valve of a locomotive. He was surrounded by twelve men—every man on the place—and all of them seemed to be affected with a very tired feeling.

When Mr. Blank saw me (he had been pulling on the flywheel until he was warmed up) he was silent for a few seconds and I have always wondered whether he was thinking what to say, or if he was waiting to get breath enough in his person in order to say it. What he said when he got started was much like the noise of a giant skyrocket just after it is fully ignited. His statements were too explosive to follow verbatim, but I gathered that the entire force had been working over the engine since early in the morning and that on the previous morning three men quit at 10 o'clock because of that "infernal damn piece of misrepresented mechanical iniquity."

Before his vocabulary was anywhere near exhaustion, Mr. Blank was called into the office and I looked over the engine and found the automatic inlet valve stuck. It was not five minutes after we got the engine started when he came down stairs again and in his hand was the gas bill; this was the climax. He was a heavy man and had a heavy voice. His face was *red*. His voice was raised to a high pitch. His oratory was magnificent, and his gestures sublime, but his language was, as the young lady had said, "something awful." His gas bill was $85 for an 18-horsepower engine pulling about 12 horsepower continuously, eight hours a day. After he had cooled down some he told me about it. The salesman had guaranteed that his gas bill would not be over $45 per month.

I persuaded this man to trade off that engine in part payment for a 25-horsepower real gas engine. He added 5-horsepower load on the big engine and his bill has exceeded $65 only once since it was installed.

The first engine had 45 pounds compression; the second had 85 pounds.

The first engine intake-valve spring was too weak and the intake valve opened partly on every stroke that the governor tried to cut out (hit-and-miss regulation), with consequent fuel waste.

The first engine's igniter could not be

set far enough in advance to ignite the mixture properly with so low a compression.

The second engine, well, it was a *gas engine*.

The moral is to find out what a gas engine ought to be, but don't pay too much attention to what interested persons tell you. I'll just suggest this much: Liberal compression and the mechanical construction in accordance with this compression is one of the greatest factors in economical and successful gas-engine operation. How much compression? O, 100 pounds and the indicator card should show a maximum of about 350 pounds; don't let anybody talk you out of it. But the makers must build their engine to stand the strain.

Remember that gas engines are not like politicians; we can't love them for the enemies they have made.

Test of a Six-Ton Jack

By G. A. Gilk

The object of this test was to obtain the efficiency of a six-ton jack, which in this case would be the actual load lifted divided by the theoretical load that should have been lifted, and the quotient multiplied by 100 so as to have the expression as a percentage. Since no means of directly loading the jack and measuring the load were available in the laboratory, an indirect method was resorted to. A beam 6 feet long was placed on the jack as in Fig. 1. The loads were applied at W. The force extended upward by the jack at L times its arm, 1 foot, must be equal to the force W exerted downward times its arm, 6 feet, the moment arms being both measured from A, so that

$$1\ L = 6\ W.$$

A jack lever 1 foot long was used with the jack, and the actual pulls required to raise or lower the different loads measured. From these pulls the theoretical loads were calculated, and by means of these two loads the efficiency of the jack at that load computed. The calculation of the theoretical load was as follows:

P = Pull in pounds at end of lever,

T = Theoretical load that jack might lift were there no losses,

h = Lead of thread in inches,

r = Length of lever arm in inches.

When P, the pull, travels around the jack once and the screw makes one revolution, the work done is

$$W = 2\ \pi\ r\ P \text{ inch-pounds},$$

[illegible] T is raised h inches, so that

$$W = h\ T \text{ inch-pounds}.$$

[illegible] the work done at the [illegible]

$$W = 2\ \pi\ r\ P = h\ T$$

$$T = \frac{2\ \pi\ r\ P}{h}$$

In the jack used for this test, h = [illegible] inch, r = 12 inches and

That Harwood Boiler

In the March 22 number, under the above caption, I notice a contradiction, in part, of the article on this subject that appeared over my name in the December 22 issue, wherein I stated that "the crack was not located under the lap, but ran parallel to the edge of the overlapping plate."

The article of March 22 states that after viewing the plate at the office of the State inspector the deduction was formulated that the "crack is plainly one of those internal cracks occurring, as is usually the case, just under the edge of the rivet heads and so hidden by the inside sheet as to be impossible of detection by any inspection short of unmaking the joint."

Now, as to the crack being hidden, I think the engineer's statement "that he removed some of the bricks and found that the steam was coming from a crack 18 inches long at the longitudinal seam" should be credited, especially when it is corroborated by everyone who saw the boiler before it was cut up, and by the State inspectors who examined the crack before the boiler was taken from its setting.

It may be that the writer of "That Harwood Boiler" drew his conclusions from the inside or convex side of the boiler sheet and in that case the crack may have been partially hidden by the lap, but he should remember that there are two sides to every boiler, the inside and the outside, and it is not necessary to take the joint apart, as he expresses it, to view the outside of the overlapping plate, the removal of a few bricks being all that is necessary.

I know that this procedure is not followed by inspectors when making inspections, but if there is any possibility of a lap-joint defect being discovered by the removal of a few bricks and as close an inspection of the outside of the lap as is given the inside lap, I think it would be an admirable innovation.

An instance of what can occur on the outside of a joint and not show on the inside was illustrated to me when the side wall of the setting of a boiler some thirty years old, that had been carrying 60 pounds of steam and was used for heating purposes, was removed. It disclosed the fact that the rivet heads on the longitudinal joint of the middle sheet had been burned and corroded so badly as to be practically destroyed, leaving the boiler in a very dangerous condition, which would probably have been discovered years before had the brickwork down to the joint been removed when making the annual inspections.

ARTHUR F. CLAWSON.

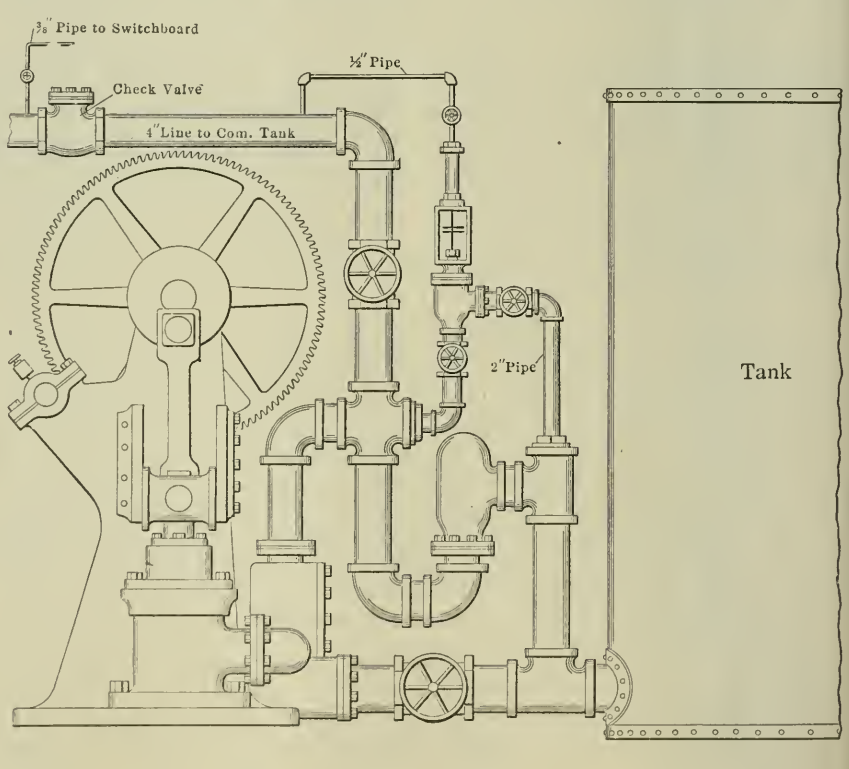
Lynn, Mass.

Pump Piping

The accompanying illustration shows the arrangement of suction and discharge piping in connection with a single-acting triplex power pump operating the compression-tank elevator system in any hotel building. The pump is belt-driven by an induction motor controlled by an automatic switch operated by pressure transmitted through the ⅜-inch pipe shown in the sketch, and adjusted to a minimum and maximum compression-tank pressure of, respectively, 100 and 110 pounds per square inch.

In order to secure the advantage of starting against zero pressure, thereby giving the motor an opportunity to attain full speed before beginning work against the minimum tank pressure of 100 pounds per square inch, a pump governor is rigged up to control a bypass through a 2-inch pipe connecting the discharge line to the suction pipe, as shown.

The philosophy of the device is this: The instant the compression-tank pressure attains the maximum of 110 pounds, and the pump is stopped through the medium of the automatic switch in the motor circuit, the pressure between the pump-delivery valves and the check valve in the discharge line immediately begins to subside by leakage through a very small aperture in the governor valve, and in one or two minutes is reduced sufficiently to permit free action to the governor spring in raising the valve and opening wide a passage to the large tank by way of the 2-inch pipe. This action of the governor permits a direct discharge into the suction pipe during the first few strokes of the plungers when the pump is again put in motion; but as the speed of the pump accelerates, a pressure is created beneath



SHOWING AN ARRANGEMENT OF SUCTION AND DISCHARGE PIPING the check valve, and this pressure, being transmitted through the ½ inch connection to the governor, depresses the valve, closes the bypass, and the water continues to pass on through the check until the pump stops, when the cycle of operations is repeated.

The most objectionable feature of the apparatus, aside from those objections which might be raised on general principles, involving such defects as continual trouble in keeping the switches in order, as well as the infernal noise of the gearing reverberating throughout the house, lies in the wear and tear and constant breaking of the pump-discharge valves and stems by reason of the tremendous impact of the valves against their seats.

The machine grinds away at a rather high rate of speed when in action, and this circumstance, combined with the fact that the area of discharge orifice for each plunger is covered by a single valve, might occasion an excessively high lift of the valve in order to give the necessary annular opening for discharge, as well as to compensate for inordinate water friction. At any rate, the valves came down against their seats with the force of a trip hammer at times.

The builders of the pump made no provision in its design for the use of an air chamber, evidently not intending or anticipating its employment in the service described, and the amount of head room, as well as the leeway laterally, will permit of running up from the riser out of the discharge chamber with a piece of pipe only 4x10 inches. The question is, will this suffice for an air chamber?

The motor for driving this pump is supplied with current from an outside source, while there are two boilers of ample size generating steam at a pressure of 75 pounds per square inch within 30 feet of the apparatus. These boilers supply steam for laundry and heating purposes principally, the drafts upon them for this service being well within their capacity. It might appear, therefore, that under the circumstances a good Duplex steam pump would serve the purpose of the elevator system far more efficiently than the present belt-driven rig, both from a thermal as well as from a mechanical point of view.

Chicago, Ill.

Repairing Worn Guides

The guides on a high-speed center-crank engine had become so worn, and the piston rod vibrated so, it was impossible to keep packing in the stuffing box and there was a constant blowing of steam, which condition was responsible for several broken rods and one cylinder head. The lower guides had become worn in the center (as is shown somewhat exaggerated at E), and the top guide could not be lowered, as at the ends the crosshead was comparatively tight; so the only real cure was to dress the lower guides true. As these were solid with the engine frame the undertaking was made more difficult.

The first step necessary was to determine how much was to come off the ends; therefore, the lowest point in the center of the guide had to be found by first trying the distance from AC and AE and finding this to be parallel (or if not, made so), taking a pair of dividers and scribing a line as shown by MM, setting the dividers so as to make this line low enough to take in the wear in the lower guides. Both sides were treated alike. Then we removed the top guides and carefully chipped the lower guides down at each end. We had several files heated and bent as shown at D. Around the guides down true to a straight-edge and scraped the surfaces perfectly true.

The crosshead had been sent to a machine shop, and as the difference of wear was not sufficient to allow room for a babbitt shoe it was necessary to plane off some of the casting and cut some slots as shown at C. Good hard babbitt was then run onto the crosshead and dressed to the required thickness. The crosshead had to be planed more on the lower side of the line AB than on the top, the distance being obtained by trueing a line through the center of the cylinder, then laying a straight-edge or small scale across the guides, and measuring from the center of the rod to the lower edge of the straight-edge, giving the distance the babbitt had to be dressed on the crosshead.

When the crosshead was finished we placed it in position, after coating the under side with red lead, and, by sliding it back and forth, any high or uneven places could be located on the lower guides, which, by the use of a hand scraper, were lowered, and we soon had a perfect fit. Then we replaced the guides and moved the crosshead back and forth to see that it had proper play. When the engine was started up the blowing of steam from the stuffing box was cured, and no further trouble was experienced.

REPAIRING A WORN GUIDE

Dashpot Troubles

In the replies on page 487 of the March 9 issue, regarding Ellsworth Davis' dashpot troubles, I notice that George W. Harding attributes them to too late a cutoff. As the engine is of the Corliss type, and running on a very light load, I do not see how it could be that.

I am operating a small Corliss engine with dashpots of the double-plunger type, leather-packed, which give the same trouble. On a very light load the head-end dashpot plunger will not seat, but hangs up until the hook drives it down. On anything better than one-fourth load it works very nicely. This dashpot has always worked this way, despite all that I could do.

I have always laid it to the fact that with a light load and a very early cutoff the steam was expanded down to such a low pressure, perhaps to no pressure, in the cylinder that none remained for compression. Consequently, with a boiler pressure of 150 pounds gage, on one of the valves and no compression whatsoever, the valve would work very hard and, as the dashpot plunger had lifted such a short distance, the vacuum in the dashpot was not strong enough to draw the plunger down.

The reason that the crank dashpot does not work on that account is because the crank end of the cylinder has a smaller area, due to the piston rod, and will not receive so much steam for compression.

H. E. Wagner.

Pomeroy, Ohio.

Referring to Ellsworth Davis' dashpot troubles, I had a similar experience, which I found easy to remedy.

It was on a single-eccentric nonreleasing Corliss engine. The dashpot would work fine on light load and low steam pressure, but when the atmosphere was leaked by hand I found the trouble on the valve stems and bent on the valve, due to insufficient lubrication at that place the steam pressure was high or the cutoff was long, the excessive friction was too much for the dashpot to overcome.

To get rid of this I drilled holes in the bonnet behind the washer on the valve stem, and made a groove to them so that the steam would have a tendency to equalize the pressure. Afterward I had two collars made, with two set screws spaced 90 degrees apart, and placed one on each valve stem, so they would come up against the shoulder on the bonnet outside and hold the end next to the valve away from the bonnet next to the valve.

G. Clinton Smith.

Carmi, Ill.

Wrought Iron Pipe

On page 478 of the March 9 number H. E. Schuler tells us how wrought-iron pipe is made and states that to get wrought iron it must be specified as strictly wrought iron. My way of writing specifications and contracts has been: "All dimensions given for all sizes are inside diameter; all pipe shall be wrought iron and full standard weight; all steel pipe, and all pipe not full standard weight and perfect threads will be returned at the expense of the contractor."

It would seem that this was sufficiently stated so there could be no mistake, but I have returned steel pipe, pipe that was of "merchantable" weight only, and pipe that had no protection on the threads and consequently the threads were all battered.

It is surprising how many contractors will furnish light-weight merchantable pipe and steel pipe when it is expressly stated that it will be returned.

W. E. Crane.

Broadalbin, N. Y.

Curing Rubber

Will some reader tell me what will be the number of square feet of 1½-inch and 4-inch pipe surface required to raise a charge of rubber to be cured, using the 4-inch pipe as a manifold, making four coils? The total amount of rubber is about 400 pounds, distributed in 160 galvanized-iron pans weighing 770 pounds, soapstone weighing 2400 pounds and an iron grating weighing 1000 pounds, placed over the pipe. The tanks are placed in the heater on wooden slats, the temperature being 60 degrees Fahrenheit with a gradual rise in six hours to 270 degrees Fahrenheit. The size of the heater is 20x12x10 feet. It is made of matched boards inside and outside, and lined with asbestos paper, and there is a 3-inch air space between the walls. It is 100 feet from the boiler room. The boiler pressure is 80 pounds. The steam main is a 2½-inch pipe covered with magnesia pipe covering.

H. C. Stevens.

Naugatuck, Conn.

What is the Trouble with the Engine?

The accompanying diagrams were taken from an old style Fitchburg engine. What change should be made to get good dia-

Water Power

I was very much interested in the article by Thomas Wilson on "More Water Needed at Colliersville;" also the editorial, "Is Water Power Cheaper than Steam?"

It seems to me that there is a lamentable lack of care in the working out of many hydraulic propositions. In the February 9 number is a very interesting description of the plant at Milford, Me., by S. Rice. One would gather from this description that this plant was very successful in its operation. I am led to believe, however, that this is another of the plants which has not come up to expectations. It would be interesting to know something about its operation, with reference to its success as a commercial proposition, and as to whether it is true that so far it has been unable to develop anything like its capacity during the greater part of the season.

I am not able to state my authority, but I understand that this plant has been unable to develop the power which it was designed to deliver to one or more of the mills whose water rights it took in order to complete the development, and that it is not commercially successful.

I believe this is the case in many plants developed during the last eight or ten years, mainly because the records of flow on the rivers were not carefully and thoroughly investigated and the minimum flow was greatly overestimated. There has also been considerable difficulty from the fact that the maximum flow was equally underestimated, and a number of plants have had the misfortune to back up the water so far as seriously to inconvenience towns and manufacturing establishments along the river, so that the damages resulting from the backing up were so great as to cause much inconvenience to the owners of the water power.

This came principally because the spillway was not sufficiently large to allow the enormous volume of water due to freshets to flow over them without raising it to such a hight as to make trouble farther up the stream. It would seem advisable in any water-power development not only to take the Government records, but also to spend considerable time in the investigation of such records as may be found throughout the region where the development is to be situated. One cannot go too far back in looking up such records, and one cannot be too careful in examining for both maximum and minimum flow of the river.

Henry D. Jackson.

Boston, Mass.

Prony Brake Horsepower Curves

These curves give the horsepower of a prony brake having an effective arm length of 5 feet 3 inches, between the limits of from 5 to 100 horsepower and between 75 and 500 revolutions per minute. The curves were obtained as follows: Let

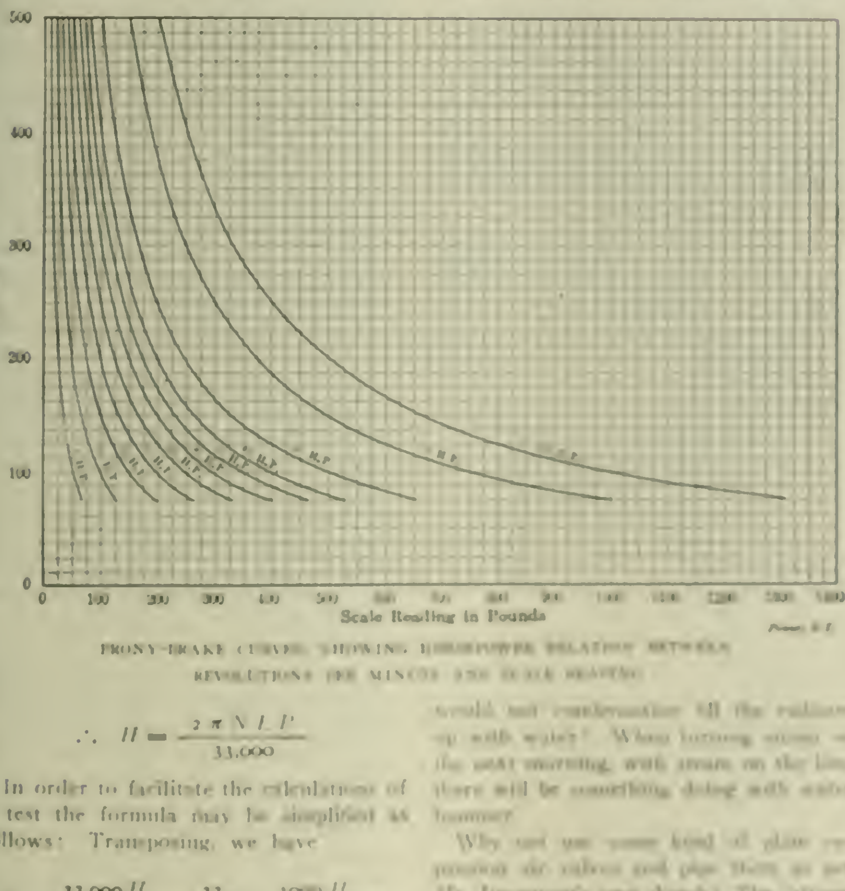
H = Horsepower,
L = Net length of brake arm,
N = Revolutions per minute,
P = Net load on the scales.

Then, the work of resistance, 33,000 horsepower, is evidently equal to the product of the load P into the distance through which it would travel if left free to rotate, that is,

$$2 \pi N L P$$

Or

$$33{,}000\, H = 2 \pi N L P$$



PRONY-BRAKE CURVES, SHOWING HORSEPOWER RELATION BETWEEN REVOLUTIONS PER MINUTE AND SCALE READING

$$\therefore\ H = \frac{2 \pi N L P}{33{,}000}$$

In order to facilitate the calculations of a test the formula may be simplified as follows: Transposing, we have

$$L = \frac{33{,}000\, H}{2 \pi N P} = \frac{33}{2 \pi} \times \frac{1000\, H}{N P} =$$

$$5.25 \text{ (nearly)} \times \frac{1000\, H}{N P}.$$

Therefore, if the net length of the arm is 5 feet 3 inches, we have

$$H = \frac{P N}{1000}.$$

It was from this last formula that these curves were plotted and it must be kept in mind that they hold for no other arm length.

George C. Olmsted.

Chattanooga, Tenn.

Substitute For Air Valves

Mr. Jorgensen recently described a way to overcome some of his troubles with his steam-heating system.

I suppose that he opens all of the radiator valves while his boiler is raising steam; but if he does not, how could a radiator warm up if anyone turns steam on after he has closed the check valve on the air line and there is back pressure therein to check the exit of the cold air?

If the back pressure (not vacuum) becomes the steam will circulate in the air line as long as there is pressure behind it. If anyone should choose to turn off a radiator, what will keep the vacuum thus created within that radiator from "inhaling" steam from the air pipes and keeping the radiator hot just the same, in spite of the fellow who wants to cool off? If this process continues long enough, would not condensation fill the radiators up with water? When turning steam on the next morning, with steam on the line, there will be something doing with water hammer.

Why not use some kind of plain expansion air valves and pipe them as per Mr. Jorgensen's own sketch? The "strong vacuum" will be formed within the radiators while the boiler is cooling off. This will keep a good enough circulation for some time if the check valve on the vent line is closed or if a check valve is so fitted as to forbid entrance of atmosphere to the system.

Alex. D[illegible]

Jamaica, N. Y.

Mr. Jorgensen's method of heating is one of the commonest in use for large buildings where it is not desired to install the more expensive vacuum system. It provides for the removal of the air from the radiators without the necessity of discharging it into the rooms, gives almost as good circulating features as the two-pipe system, and much better than the one-pipe system at only slight additional expense.

Mr. Jorgensen makes the statement that after having the valve in the air line closed for some hours at least there will be considerable condensed water in the air pipe of the lower end, and also a strong vacuum will be formed between this water and the radiator. I am certain that Mr. Jorgensen is in error in making this statement, and should he put a gage on the pipe where he imagines the vacuum to exist he would find that the pressure was above that of the atmosphere.

It is quite certain that in the system under discussion it would be impossible for any part of the piping to be under a pressure below that of the atmosphere, nor should there be any tendency for a vacuum to form due to the condensing of steam, the pressure of the steam in the pipe would at once destroy it.

H[illegible] P. K[illegible]

New York City.

Use of Wooden Wedge Rings

In the March 9 number there appeared an article on the use of wooden rings in pipe installation, and I wish to state my views on the subject. To install a pipe line of water mains of the size stated is quite an undertaking, as well as a costly one, and is usually a permanent installation; consequently, the use of wooden rings would not be practical, as it would only be a question of time, and a very limited time at that, before these wooden rings would become soft from decomposition and would become leaky and useless, thereby necessitating a renewal with, of course, more expense as regards time, etc., to say nothing of the interruption to the service.

It is also stated that a pressure of 150 pounds to the square inch was carried. As we are all aware, wood is more or less porous according to its nature, and, of course, in that class of pressure it was ordinary wood, as it would not be practical to obtain any special kind. These rings, in being formed in one ring, would necessarily have to be cut across the grain at some point in the circle, and it is obvious that with a pressure of 150 pounds the water would be forced through the pores of the wood to a greater or less extent, thus setting up an unsatisfactory job and hastening the work of decomposition.

As an illustration of the porous nature of wood, I recently had occasion to block off a [illegible] line on a low-pressure system and, having no [illegible] or plugs at hand, a [illegible] wooden plug was turned up and driven into the end of the pipe. Notwithstanding that the plug was about [illegible] inches long, and the pressure only [illegible] pounds, the water of condensation found its way out of the pores of the plug the entire length.

As the rings of the 14-inch main would be of approximately 4 to 6 inches face, and a pressure of 150 pounds to the square inch carried, it would appear to me that there would be something doing. In my opinion a much better method would have been to make a mold around the joint and a babbitting, after which the holes could be drilled as required and, with the addition of good gaskets, a good permanent job assured. While wood rings may answer in a temporary job, I believe that anything that is worth doing is worth doing well, especially in the case of a main pipe as large as 14 inches.

CHARLES H. TAYLOR.

Bridgeport, Conn.

Actual Cost of Power

Writing upon this subject in the March 16 number, W. N. Polakov says: "Therefore, it follows that by knowing his actual cost of power the engineer will only learn that the good or poor work of the sales department has made him produce cheaper or more expensive power. What will he gain through such knowledge?"

An engineer who can figure power cost, including fixed charges, depreciation and taxes, and the unit cost of power produced, will be able to keep out the "slick article" that comes around to the back door and says: "How do you do? I see you have quite a plant here—ah, pretty big boilers, nice engines; how big are your boilers?" And if the engineer is "easy," he proceeds to give the dimensions of his boilers and engines, the "slick article" all the while "jollying" the honest fellow and taking in the whole plant, to enable him to do some figuring when he gets outside.

Now, if the engineer can figure the cost of power, etc., he can go to his employer and demonstrate that he can produce a kilowatt-hour as cheaply as Edison. Also, if he can demonstrate intelligently that there are 14,500 heat units in one pound of coal and the boiler absorbs about 9000 heat units per pound, the rest going up the stack, etc., and that the so-called steam specialists cannot get any more heat units out of a pound of coal than the engineer can, isn't that worth knowing? It should satisfy him and his employer that about the best anybody can do is to have the correct proportions of heating and grate surfaces, provide the proper amount of air for combustion purposes, stop leaks through the brickwork, keep the fire level and bright, feed regularly, maintain a constant steam pressure, prevent the safety valve from blowing unnecessarily, etc.

With all these things in mind, why can't the engineer do the figuring as well as the "expert"? There is nothing mysterious in steam engineering ordinarily that one man can master and another cannot. The fact is, the "expert," having a glib tongue, manages to influence the owner or manager more readily than the less polished engineer and, the chances being that the owner does not know any too much about the practical side of engineering, he tells the "expert" to go ahead.

Then what happens? The specialist takes stock of the fittings and packing, inventories the coal in hand and proceeds to cut wages. Of course, he shows a temporary saving—after which the owner begins to wake up, as a rule. I challenge any expert to make a saving in my plant.

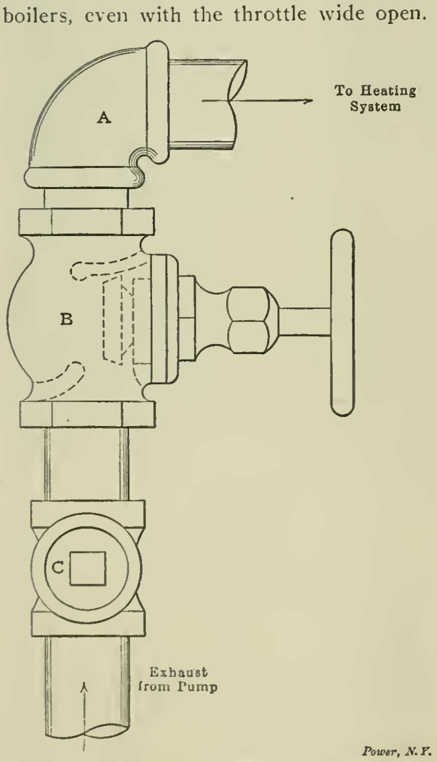
Engineers, wake up and get what belongs to you. Educate yourselves in the business and put the experts out of business, so far as your plants are concerned.

H. E. SAMUELS.

Brooklyn, N. Y.

Cause of High Back Pressure

One of our duplex boiler-feed pumps got to acting sluggishly and at times would not run fast enough to supply the boilers, even with the throttle wide open.



CAUSE OF HIGH BACK PRESSURE

On account of extended radiation it had become necessary to raise the back pressure on the pump to about 12 pounds. I noticed that it was when this high back pressure was being carried that the pump ran so slowly. I removed the plug at *C*, between the pump and exhaust valve *B*, and put on a pressure gage.

When I started the pump with 10 pounds back pressure on the heating system the gage at *C* showed 25 pounds back pressure. I removed the globe valve *B* and put in a gate valve, and have had no more trouble.

As the globe valve was of generous proportions, and had about the same area of opening as the gate valve, I think the high back pressure was caused by the sharp turns in the path of the steam, caused by the globe valve and the ell *A*.

Decatur, Ill.

Setting Gas Engine Valves

After reading the articles of Mr. Hollman, page 167, January 19, and Mr. Tilden, page 416, March 2, I wish to offer the following addition to the discussion:

Nearly all engines of 100 horsepower or less are single-acting and, therefore, have no crosshead nor guide by which the position of the piston can be marked. If the clearance between the valve stem and valve-operating mechanism is too great, the valve will not be held open long enough; if too small the valve may not seat, owing to particles of dirt being caught between parts of the mechanism. The valve stem will also elongate, owing to the heat of the exhaust gases. If a piece of thin paper is held between the valve stem and rod the time of opening and closing can be told by the gripping and freeing of the paper.

Mr. Tilden evidently has never timed the valves on a gas engine or he would find that he is mistaken about the setting. The gases after explosion will drop in pressure, and if the exhaust valve did not open until the end of the stroke, there would be a pressure of from 30 to 50 pounds. The piston during the first part of the exhaust stroke will have to work against excessive back pressure, as the valves and passages are not large enough so that the pressure will fall instantly to atmospheric.

The writer has taken indicator diagrams which show that the pressure does not fall to nearly atmospheric until almost half the stroke has been made. The exhaust valve, therefore, is opened about 30 or 40 degrees before the end of the stroke, so that the pressure will drop to about 2 or 3 pounds during the exhaust stroke.

The exhaust valve closes on the dead center. If the inlet valve opens before the exhaust valve closes there is danger of a back-fire and consequent loss of the fresh mixture. For this reason it is customary to open the inlet valve after the crank has moved through an angle of 2 or 3 degrees.

During the suction stroke a column of gas and air has been set in motion and the inertia of this mixture will cause it to flow, even while the piston is reversing. This insures a larger amount of mixture. For stationary engines the inlet valve will be held open for from 4 to 10 degrees on the compression stroke.

As the valves are operated by cams, they can be opened and closed any time during a revolution, depending on the design of the cam.

It takes certain appreciable time for the flame to pass entirely through the mixture. The maximum explosion pressure is obtained when the volume of the mixture is the smallest, or in other words the compression pressure is the highest at the instant the *entire* mass is ignited. Therefore, the flame must be given time to propagate itself through the mixture by the time the piston starts on the power stroke.

L. J. BUSCHMAN.

Cleveland, O.

In a letter on page 416 of the March 2 number, E. G. Tilden gives his opinion on "Gas Engine Valve and Ignition Timing." I cannot agree with him when he says: "The fact that the gas mixture is burned in the cylinder has nothing whatever to do with the proper valve setting," for it is just this one fact which is the reason for opening the exhaust valve ahead of the dead center.

At the end of the expansion, before the exhaust valve is opened, the burnt gases in the cylinder are still under a pressure higher than atmospheric, say 25 or 30 pounds, and have a considerably higher temperature than would be the case if they had expanded to atmospheric pressure.

The idea in opening the exhaust valve about 40 degrees (on the crank) ahead of dead center is to allow the gases to come down to atmospheric pressure by the time the piston reaches the dead center. This results in two advantages: There is less back pressure on the piston, when it expels the burnt gases, and these gases have now a lower temperature and consequently do not heat the cylinder walls so much, which, again, allows a more complete new charge.

The exhaust valve ought to be kept open until about 10 degrees after dead center, thus allowing the exhaust pressure to come down to atmospheric pressure or even less, as the inertia of the outrushing column of gas may produce a slight vacuum, whereupon at about 12 degrees the inlet valve is opened and kept open until from 30 to 35 degrees after dead center. At this point the pressure produced by the piston starting on its compression stroke will be sufficient to check the rush of the fresh mixture still coming in, according to the law of inertia, which applies to any moving body. This is the point where the valve should close.

This way of valve setting proved to be very satisfactory with two three-cylinder 60-horsepower engines running at 240 revolutions per minute. In the first place the cams were designed to open and close on dead centers. As a result it was almost impossible to keep the engine cool, and in case of an overload back-firing commences almost immediately. Cleaning out the water jacket and lowering the compression did not seem to have any effect at all. Finally a change in the cams was decided on, and the herein-discussed valve setting was tried, first on one engine. The result was striking, the engine being able to carry about 10 per cent. overload without back-firing. With the cams fixed up in the same way, the second engine produced the same results.

Of course, I agree with Mr. Tilden inasmuch as it is impossible to improve upon any engine, the cams of which are designed for valves to open and close on dead centers, by simply advancing or retarding the time of opening. A new cam must be made, which keeps the valve open for more than 180 degrees (measured on the cam shaft), say 105 to 115 degrees.

W. A. ARNOLD.

Los Angeles, Cal.

The Barrus Universal Calorimeter

In reply to the criticism of Charles B. Cooke, Jr., in a recent number, I will say that what is there stated is all right in theory, but is not the actual case.

If Mr. Cooke will carefully examine a "Barrus universal calorimeter" he will find it exactly as described in the article which appeared in the December 29, 1908, number. Or, if he will look up the report of the committee on Standard Method of Conducting Boiler Trials, Volume XXI of the *Transactions* of the American Society of Mechanical Engineers, under appendix XVII he will also learn that its "exception" is a possible. The same report, under appendix XV, states (and that statement was arrived at only after thorough research) that among others, the Barrus calorimeter, when properly handled, gives results which are accurate within one half of 1 per cent. For scientific research and when the moisture exceeds 2 per cent., the committee recommends that "A steam separator should be placed in the steam pipe as near to the steam outlet of the boiler as convenient, well covered with felting, all the steam made by the boiler passing through it and all the moisture caught carefully weighed after being cooled. * * * A throttling or separating calorimeter should be placed in the steam pipe just beyond the steam separator for the purpose of determining the amount of moisture remaining in the steam after passing through the separator."

The per cent. of moisture caught in the separator is determined as in the ordinary separating calorimeter. The total per cent. of moisture in the steam is the sum of the percentages as found by the separator and by the calorimeter.

It might clarify Mr. Cooke's conceptions of the fundamental principle of the [illegible] gage if I say that it (the principle) depends upon the following physical facts. To make a concrete example: The total heat in one pound of dry and saturated steam at a pressure of 100 pounds per square inch absolute is very nearly 1186 B.t.u. The total heat at atmospheric pressure is very nearly 1146 B.t.u. Then, in being throttled from 100 pounds to 14.7 pounds, "doing no work," the steam gives up 40 B.t.u., which are available to evaporate moisture in the steam or to superheat the steam or both. If the thermometer in the calorimeter registers in the neighborhood of 212 degrees Fahrenheit it is a very good indication that the steam is still wet when leaving the calorimeter base gage. It also indicates that all the 40 B.t.u. have been utilized in evaporating moisture and the heat balance does hold so far as the part of the moisture evaporated by the 40 B.t.u. is concerned. By adding the per cent. of moisture thus obtained to the per cent. found by the separator the total per cent. is found.

The assurance that the steam is dry when leaving the separator rests upon comparisons with other calorimeters of recognized accuracy and by checks made with apparatus arranged according to the recommendations of the A. S. M. E. committee report.

CHARLES N. CRANE.

Palo Alto, Cal.

Knock in an Engine

The knock in I. W. Bryan's engine mentioned in the March 2 number, page 415, is most likely caused by varying compression. I think he will find the cause by taking diagrams during both the knocking and the silent periods and comparing them. The engine has a high piston speed, and if the pressure in the exhaust line falls a little under a somewhat light load the compression might not be enough to cushion the reciprocating parts before the knock. That the knock is heard more at the crank end might be due to steam clearance or a later closing of the exhaust at that end. The knock would be continuous if the clearances of the [illegible] were at fault.

Albany, N. Y.

Boiler Accident Fatal to Engineer

On March 14, a boiler located at Greenfield, N. H., met with a rather peculiar accident. It is a portable boiler, locomotive type, with the engine on top, the firebox end resting on wheels and the rear end supported on blocking. It was fed by a well known lifting injector, the water entering the water leg about 1 foot below the crown sheet and 4 inches from the port, the supply being taken from a barrel nearby. The width of the water leg was 3 inches, the shells being about 5/32 inch thick and supported by forty ¾-inch staybolts, 6.5 inches center to center; the firebox is 2 feet wide, 3 feet high and 4 feet long, and there are thirty 3-inch tubes 12 feet long.

The engineer started up at 7 a.m., as usual, carrying about 60 pounds of steam, and, according to one of the workmen, was sitting beside the boiler, a few inches from the water leg, eating a lunch when the boiler blew up. An examination made by the writer revealed the fact that the staybolts of the water leg had been torn from their holes in the outer shell, allowing both the outer and inner shells to bulge, and also allowing the contents of the boiler to rush out through the holes left by the staybolts and severely scald the engineer, who died about four hours afterward.

The fusible plug, on being removed, appeared to have been badly corroded on the outer end, but had started to melt; in fact, about two-thirds of the metal had melted out before the fire was extinguished by the escaping steam and water, the inner end of the plug being intact. An iron plug was found screwed into the bottom of the water column in place of the usual nipple and valve.

The man in charge informed the writer that he had been in the boiler room about a half hour before the accident occurred and saw about 6 inches of water in the gage glass, the steam gage recording about 60 pounds (the safety valve was set to blow at 80 pounds). He was positive that there must have been water in the boiler at the time of the accident, but everything points to an absence of water; in fact, the position in which the engineer was found, and a statement made by an employee who had left the boiler room not over five seconds before the accident occurred, go to prove that there was little, if any, water in the boiler at the time.

This employee stated that as he ascended from the boiler room to the "glory hole" above the boiler room, he noticed the engineer take hold of the valve on the inspirator as though to start it, and immediately afterward there was a noise as of something being ripped asunder, then the rush of escaping steam.

Although the engineer was severely scalded, there was no sign of his having been struck with boiling water at 60 pounds pressure, nor was there any sign on a wooden partition, located about 5 feet from the boiler, that it had been struck with water, and as there was no escape for it except through the holes left by the staybolts, it is reasonable to expect that the drop in pressure was gradual and not immediate, as would be the case had the shell burst, or a head blown out, and while the writer would not go on record as saying that the accident was caused by low water, everything points to that conclusion.

R. P. Guy.

Bennington, N. H.

Pitting in Condenser

The steel plates of a countercurrent barometric jet condenser show signs of serious pitting, due to the circulating water containing some sulphuric acid. The cast-iron casing of the circulating pump is also affected. Will any reader who has experienced and overcome similar trouble give a suggestion?

George Hughes.

Horwich, England.

Criticism

The surface condenser has been much criticized in its time, and seems to be passing through another spell. Some engineers say that, having bought a "bunch" of tubes in a cast-iron box, they have removed several of the tubes, thus decreasing the cooling surface, and at the same time giving the exhaust steam more space, and that the vacuum has been greatly increased.

A strange part of it is that the amount of condensing water used remains the same in each case, or even less, after removing the tubes.

This would seem to indicate an overcrowded condition of the tubes in certain types of surface condenser, decreases the velocity of the exhaust steam, also the rate of heat transfer through the tubes to the cooling water flowing therein.

It is practically impossible to design a large piece of apparatus that will give entire satisfaction in all respects, the "first crack out of the box." After one or more are built and operated many criticisms can be offered and numerous changes suggested before the apparatus can be called a complete success.

Frequently a change in design means a change in patterns, and even a change in machines required to do the finished work in turning out the apparatus. This is necessarily expensive, and for this reason many manufacturers are not fond of making changes.

A designer, no matter how well experienced, is quite incapable of at first designing anything in the line of machinery that cannot be criticized. The layout of the steam piping in a modern power plant is probably criticized as much as, if not more than, any other part of the equipment. The piping system is one of the most difficult parts of the design, that is, from the designer's standpoint, in arranging and placing the apparatus, valves, piping, etc., in a large station, to insure continuity of operation, minimum friction and condensation losses, etc. For instance, valves may be placed in the most inaccessible positions conceivable, unless the designer imagines himself the operating engineer for the time being when designing his system. Then again the piping system is usually the last thing installed, and the designer is held down to certain fixed conditions and has little or no choice at all in arranging the system.

It is an easy matter to criticize, but the man who does so honestly and intelligently, and can offer a solution to the difficulty, is a man worth while, a man worth knowing.

William F. Fischer.

New York City.

Dynamo Failed to Generate

In starting up for the first time the dynamo in a local mill refused to generate. It was a 10-horsepower 110-volt compound-wound motor. We found the dynamo running at about the speed marked on the name plate, and a test showed that there were no open circuits in the field or elsewhere. The brushes were also carefully adjusted. We decided that it would require only a little outside excitation of the fields to make it "pick up." We procured a few batteries, and applying this current to the fields of the machine, the voltage came up to about 15 volts, but immediately died down when the battery current was taken away. We then decided it was necessary to increase the speed. A smaller pulley was provided and the speed increased about one-third.

Even after this the dynamo would not build up without applying the batteries and could not be made to build up from residual magnetism. After the voltage was once raised it operated satisfactorily until shut down, when it was necessary to go through the same process on starting again.

The design for a compound motor required a shunt field of higher resistance and less current than a plain shunt motor, as the series-field winding assisted in producing the necessary torque. Owing to this resistance, enough current could not be got through the fields at starting to produce the reaction on the armature. To have got satisfactory results it would have been necessary to put on a set of coils of lower resistance. This was not done as another machine was substituted.

Some Useful Lessons of Limewater

Showing How to Construct a Simple Primary Electric Battery; Some Interesting Experiments in This Very Useful Branch of Study

BY CHARLES S. PALMER

In the last lesson we planned the apparatus for making hydrogen, for collecting it in several quart fruit jars, and for testing it in various ways. By this time you will have got yourself sufficiently familiar with the main points so that you can proceed directly to making and collecting several jars of hydrogen. But remember to test a tumbler or two of the gas, as told in the last lesson, to be sure that you have driven the air out of the generating flask before you collect any hydrogen; because hydrogen and air make a very lively explosive mixture. We will suppose that you have collected one or two jars of hydrogen and are waiting for the other jars to fill. Of course, if your hydrogen generator gets "tired," you can replenish it by opening the cork and quickly dropping in half a dozen more pieces of the coiled zinc; and if this does not wake it up, you can also add a little more of the diluted sulphuric acid. Remember that every time that you open the generating flask you must throw away the first gas that comes off, keeping a flame away from it, afterward collecting a tumbler to see if it burns quietly enough to make it safe to collect more jars of the hydrogen.

The First Test

The first test, keeping your jars covered with cardboard and mouth downward, is to study the burning of hydrogen by lighting a long splinter and thrusting it up into the jar. The way to do this is to lift the jar from the cardboard cover, hold the jar mouth downward and thrust the lighted splinter up into the jar, gradually turning the jar so that it will be horizontal. You will notice that the hydrogen burns with a soft flame, which may be pinkish or yellowish, and that the splinter is extinguished in the hydrogen, the hydrogen itself burning in the air and naturally reigniting the lower part of the splinter, for the hydrogen flame is very hot. You will also note that as the hydrogen is consumed, the flame retreats up into the jar, being, of course, followed up by the advancing supply of air from the outside. Another thing that you cannot help noticing, especially if your attention is called to it, is that the inside walls of the jar become covered with a faint thin layer of sweat or dew. You can easily distinguish this from any of the drops of water which may cling to the inside walls of the jar, these drops being, of course, the original water from the pneumatic trough. This dew or sweat on the inside walls of the jar comes from the condensation of the water which is formed by the burning of the hydrogen with the oxygen of the air. In its nature it is exactly the

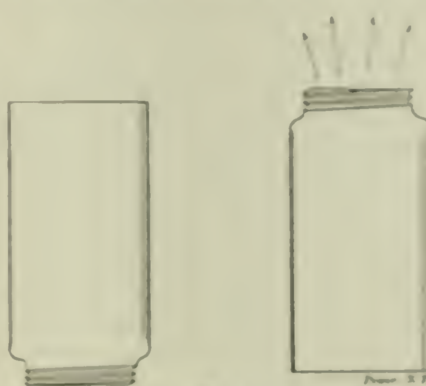

FIG. 1

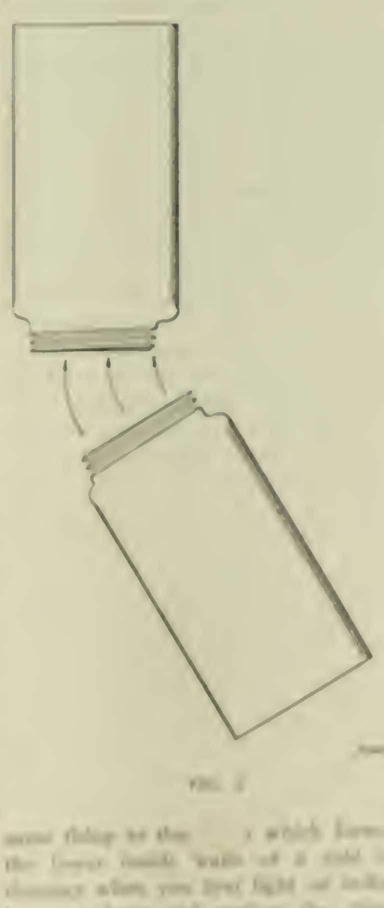

FIG. 2

same thing as the [illegible] which forms on the lower inside walls of a cold lamp chimney when you first light an ordinary kerosene lamp and replace the chimney over the flame; only in the case of the oil-burning lamp, the water comes from the burning of the hydrogen part of the oil, while in this experiment the dew or sweat comes from the burning of the pure hydrogen.

In fact you remove the splinter from the hydrogen pretty soon after the hydrogen is lighted, you can place the jar mouth upward, cover it with a pasteboard cover after the flame has died out, and test it with limewater. Of course, you will not get any precipitate of plain carbonate of calcium, because the sole product of the burning of hydrogen is simply water, and the only carbonic-acid gas which could appear in any quantity would be from the burning of the carbon in the wood splinter.

Testing the Lightness of Hydrogen

The next experiment is to test the lightness of hydrogen. A simple way to do this is to take a jar of hydrogen, remove the pasteboard cover (holding the jar mouth downward) and wait, counting 25 or so slowly and evenly. Then thrust a lighted splinter up into the jar of hydrogen which has been held mouth downward. The hydrogen will ignite with a slight explosion, owing to the mingling of the air with the lower layers of hydrogen; and then the rest of it will burn quietly, probably, in the usual manner, but you must not be surprised if several little variations come in incidentally from time to time. This is part of the game, and if you work carefully, keeping your wits about you, nothing very serious will happen. Now reverse this experiment by taking a full jar of hydrogen and, holding it mouth upward, remove the pasteboard cover, wrapping a towel around the jar for safety, and count as slowly. Then thrust your lighted taper down into the jar and you probably will get no result, because the light hydrogen will have escaped from the jar. In case you should get an explosion after having the jar mouth upward and open while you are counting so, it simply indicates that you did not wait quite long enough to let the light hydrogen escape, and you can repeat the experiment, holding the one jar open mouth downward and the other jar open mouth upward, until you fix definitely the right interval so that you will have hydrogen left in the mouth-downward jar and no hydrogen in the mouth-upward jar. See Fig. 1.

Another way to test the lightness of hydrogen is shown in

Fig. 2, where you take a plain empty jar, empty except for common air, and pour a freshly prepared jar of hydrogen *upward* into it, as shown. You can easily do this by holding the jar of hydrogen in the right hand and the jar of air in the left hand, when the invisible hydrogen will flow upward, as shown by the direction of the arrows in Fig. 2.

The Diffusion Experiment

Next, we will carry out the "osmose" or diffusion experiment, described and figured in last week's lesson. Such a full description was given then that it is not necessary to repeat this, except to remind you that if you prepare the apparatus you have a closed pipe bowl or porous jar connected with a closed tube 15 or 20 inches long, the lower end of which dips

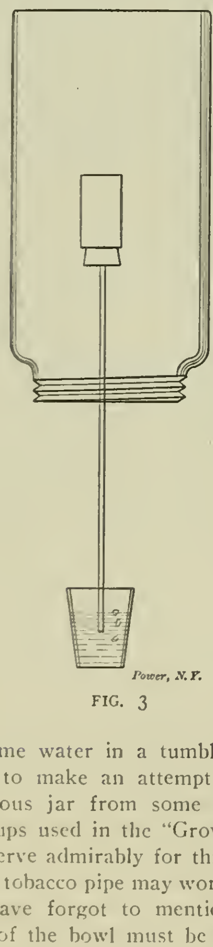

FIG. 3

below some water in a tumbler. It will pay you to make an attempt to get the little porous jar from some dealer (the porous cups used in the "Grove" primary battery serve admirably for this purpose). But your tobacco pipe may work; although I may have forgot to mention that the opening of the bowl must be closed with a well-paraffined cork, and the stem of the bowl—not the bowl itself—should also be covered with paraffin. This paraffin can be easily painted on, after it has been melted. The whole point of this experiment is to place an open jar of hydrogen mouth downward over the bowl of the pipe, or over the porous cup, and to get a few bubbles of air or gas forced out at the bottom of the open tube below the water, as shown in Fig. 3. If you get even a bubble or two to come up through the water in the tumbler, you will be able to prove that the jar of hydrogen acts on the porous cup as though the hydrogen were full of an internal pressure, and the explanation for this was given in the last lesson. This is one of the most remarkable experiments that you will ever perform; and it will pay you to make good on this, for it is a case of an intimate connection between physics and chemistry, a connection that you will have forced upon you at every step.

The Explosiveness of Hydrogen

The next experiment will illustrate the explosiveness of hydrogen and, although it was not described in the last lesson, yet you can easily prepare it on the spot. Get a tin can, as shown in Fig. 4, holding about a pint and having a small opening, say ½ or ¾ inch wide. Clean, wash and dry the can, and bore a small hole in the bottom, say about 1/20 inch wide. Close up this hole with a little wooden plug, such as a pointed match, then fill the jar with water, place your finger over the mouth, invert it in the pneumatic trough and fill it with hydrogen. As soon as it is full of hydrogen remove the tin can from the water, holding it mouth downward, and set it over a couple of bricks, as shown in Fig. 4. Then pull out the pointed match from the little hole at the top of the can and light the jet of escaping hydrogen at that point with a match or burning splinter.

The hydrogen will burn at the little opening with an almost invisible flame; but you can prove that it is burning by holding there an unlighted splinter, which will ignite from the hot hydrogen flame. Probably in a few seconds, almost certainly in a few moments, this hydrogen flame will begin to sing, at first in a very high key, and gradually sinking to a lower tone. Now stand 3 or 4 feet away from the can and await developments, which will end in an explosion. Of course, you can see that as the hydrogen is burning off at the top, the air is passing in at the narrow mouth at the bottom to take its place; and pretty soon the inside of the can will be filled with an explosive mixture of hydrogen and air. As this explosive mixture increases in quantity in the inside of the tin can, and as the explosion gets ready to take place, usually being advertised by sudden lowering of the tone of the singing flame at the top of the can, there follows a sharp report and the can may be blown several feet into the air, owing to the backlash from the open mouth pointed downward.

This will well illustrate the explosive nature of the mixture of hydrogen and air. You can see that as the air contains only one-fifth of its volume of oxygen, a mixture of the air with hydrogen does not make as explosive a combination as would result if you could mix pure hydrogen with pure oxygen. Such a mixture, composed of two volumes of hydrogen with one volume of oxygen, is frightfully explosive, and is dangerous in large quantities. A mixture of two volumes of hydrogen with one volume of oxygen is called by the Germans "knall gas;" that is, freely translated, "bang gas;" and although it may be taking some liberties with language, yet it might not be a bad thing if we had a good name in English for this explosive mixture.

There are many other experiments which you could perform with hydrogen and also with oxygen, if you could get a couple of small rubber gas bags; but you can read about these in the books. One of these experiments consists in filling a gas bag with hydrogen directly from your generator, not by displacement of water, but by leading the gas directly to the bag from the hydrogen generator. Then the rubber gas bag is connected with a rubber tube, having on the end a common clay pipe. This pipe is dipped into a bowl of good soap suds and, by gentle pressure, bubbles may be blown which can be tossed off into the air, when they rapidly ascend, just as do the common rubber toy balloons which, you know, are filled with hydrogen. If you should have the good luck to get hold of a gas bag, so that you could perform this experiment, you will find it quite fascinating to make the soap bubbles of hydrogen and toss them off into the air, lighting them with a long, burning splinter, when they burn with a soft flame and a slight yellow puff or flash. This yellow color comes from the sodium in the soap, soap being merely a "salt" of sodium, with the fatty acids, stearic, palmitic, or oleic.

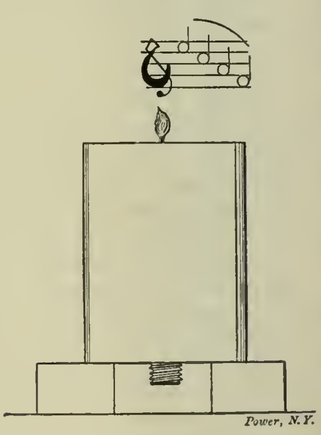

FIG. 4

If you should carry this experiment of the gas bag farther you could mix one volume of hydrogen with two volumes of oxygen and could blow bubbles of the explosive "knall gas;" but in that case you would have to use the greatest care to keep the flame away from the pipe or the opening of the gas bag; and if you should cover the surface of a dish of soapsuds with a good layer of bubbles of this "knall gas" (two volumes of hydrogen with one volume of oxygen), your ear drums would testify to the violence of the report produced by lighting these bubbles, and also to the possible danger of treating this mixture of oxygen and hydrogen carelessly.

"Lead Burning"

There are one or two points which could be further noted in this lesson, not that you will be able to try the experiments immediately, but you cannot help running across their application now and then, and you should know about them. I refer to the use of the plain hydrogen flame in "lead burning," and the use of the pure oxyhydrogen flame in the so-called calcium or limelight, and also the use of the new gas, "acetylene," made from calcium carbide and water. Acetylene and calcium carbide can wait a few weeks, but there can be no harm in your knowing now that lead burning simply consists in the quick and dexterous manipulation of a plain hydrogen flame on sheet lead. The description and study of the lead-burning apparatus, while by no means difficult or complicated, would take us a little too far away from our present purpose.

The oxyhydrogen blowpipe, on the other hand, consists of a metallic jet carrying the oxygen, surrounded by a jacket delivering the hydrogen, and so arranged that the hydrogen and oxygen can burn at the same point in the proportion of two volumes of hydrogen to one volume of oxygen. Instead of hydrogen, of course, one can use common coal gas or city gas, or even air saturated with gasolene, ether, alcohol, or similar combustible and easily vaporizing liquids. In all these cases, whether the burning gas is hydrogen or city gas, an intense heat is produced by the assistance of the pure oxygen, aided, of course, by the oxygen of the outside air. The heat of such flames is sufficient to melt steel, to melt even platinum, one of the most infusible of metals, and when this jet of burning oxygen and hydrogen is turned onto a stick of quicklime, it makes it so hot that it glows with a brilliant white light second only to sunlight and the electric arc.

There are many other experiments which may be tried with hydrogen, and some of them you will try from time to time; but one of them you can try right now. You will remember it was mentioned in the last lesson that we do not use nitric acid with zinc in making hydrogen, although you can use either hydrochloric acid (muriatic acid), or sulphuric acid. Take a strip of zinc and pour a little nitric acid over it. You will note the heavy, corrosive choking brown fumes. These fumes are the so-called "nitrous" fumes; they are produced by the reducing action on the nitric acid and the oxidizing action of the nitric acid on the hydrogen; and this is an illustration of the great chemical battle which is waged everywhere and always, in nature, between oxidizers such as nitric acid and reducers such as hydrogen and the other chemical metals.

One thing you must note here in handling nitric acid, and that is that you should perform experiments with it in a good draft, say just before your furnace door or in front of an open window. Never breathe these brown fumes from nitric acid, for they are frightfully irritating and poisonous to the throat and lungs, and a good dose can easily produce a kind of an acute pneumonia.

These experiments will introduce you fairly well to the study of the metallic gas hydrogen, chemically metallic, but there is another chapter which we must study to illustrate what is meant when we speak of hydrogen as a metallic gas. In one of the last lessons I used the terms "anode and cathode" in speaking of the electrolytic cell. There are one or two simple experiments which you can easily try and which will assist you greatly in getting some fundamental notions, not only about the chemistry of hydrogen, but also about electric batteries and the simple laws of the electric current. About all you need for our present purpose is to get a few feet of common insulated copper wire, as coarse as possible, a small strip of zinc, say 1 inch by 4 inches, another one of copper, and a small pocket compass. You will be surprised to see how much chemistry you will get out of this outfit with the help of your old friend, limewater.

Reciprocating Engines Show Best in Second Test of Scout Cruisers

Unofficial figures of the performance of the three scout cruisers "Birmingham," "Salem" and "Chester," in their second competitive coal-economy test, finished March 31, indicated a victory for the engines of the "Birmingham," which are of the reciprocating type.

The test was a run of 30 hours at 15 knots' speed. According to the figures given out, the "Birmingham" in 24 hours consumed [illegible] tons of coal and [illegible] tons of water. The "Chester," which has Parsons turbines, used [illegible] tons of coal and [illegible] tons of water, while the "Salem," which has Curtis turbines, used [illegible] tons of coal and [illegible] tons of water.

The annual meeting of the National Association of Cotton Manufacturers will be held at the Mechanics' Fair building, Boston, April 28 and 29. Among the papers to be presented which will interest power users are those upon "Commutator Grinding," "Economy in Steam Generating" and "Proper Care of Machinery."

A press dispatch states that in [illegible] township, three miles north of [illegible], Pa., there has been discovered a species of bituminous coal closely resembling cannel coal.

Some Gas Engine Calculations Based on the Volumetric Analyses of Fuel and Exhaust Gases

By A. L. [illegible]

The heating value per cubic foot of a gas may very readily be determined by means of a gas calorimeter, and this forms a very essential element when testing a gas engine for efficiency. If, however, it is desired also to determine the proportion of air to gas in the mixture, the volume of exhaust gas and the heat carried off by the exhaust, some other method must be employed. Volumetric analyses of the gases, if carefully and accurately made, give data which may form the basis of such calculations.

The principal combustible constituents of any fuel gas are carbon monoxide (CO), hydrogen (H), methane or marsh gas (CH_4) and ethylene gas (C_2H_4). The usual analysis gives the proportion of these by volume, and knowing the heat value of each in B.t.u. per cubic foot, the heat value of the gas is readily determined by multiplying the fractional part of each constituent by its heating value and adding together the products.

Table 1 gives the weights per cubic foot and heat values at 62 degrees temperature, Fahrenheit, and atmospheric pressure:

TABLE 1. WEIGHT AND HEAT VALUES OF GASES AT 62° F.

Gas	Symbol	Weight per Cubic Foot, Pounds	Heat Value in B.t.u. per Cubic Foot
Carbon monoxide	CO	[illegible]	[illegible]
Hydrogen	H	[illegible]	[illegible]
Methane	CH_4	[illegible]	[illegible]
Ethylene	C_2H_4	[illegible]	[illegible]

The exhaust gas contains steam and CO_2 from the combustion of hydrogen and carbon, together with nitrogen and, if an excess of air was used in the mixture, oxygen. The proportion of dry gases [illegible] readily be found with the Orsat apparatus for flue-gas analysis. The steam present condenses upon cooling the sample of gas, and can be determined only by calculation from the analysis of the dry gas.

[illegible] example, assume the following analyses of fuel and exhaust gases from a gas engine using producer gas:

PRODUCER GAS.

	Per Cent.
CO	[illegible]
H	[illegible]
CH_4	[illegible]
C_2H_4	[illegible]
CO_2	[illegible]
O	[illegible]
N	[illegible]

EXHAUST GAS.

	Per Cent.
CO_2	[illegible]
O	[illegible]
N	[illegible]

The heat value of the gas is computed as follows:

CO, 0.27 x 320.6	86.5
H, 0.12 x 324.7	38.9
CH_4, 0.025x 990.7	24.8
C_2H_4, 0.004x1579.4	6.3
Total heat value, B.t.u. per cubic foot	156.5

In the combustion of the producer gas, oxygen is required in the following proportions:

(1). One cubic foot of CO + ½ cubic foot of O makes one cubic foot of CO_2.

(2). One cubic foot of H + ½ cubic foot of O makes one cubic foot of H_2O.

(3). One cubic foot of CH_4 + 2 cubic feet of O makes one cubic foot of CO_2 + two cubic feet of H_2O.

(4). One cubic foot of C_2H_4 + 3 cubic feet of O makes two cubic feet of CO_2 + two cubic feet of H_2O.

The CO_2 contained in the exhaust gases comes from items (1), (3) and (4), together with the CO_2 contained in the producer gas. Furthermore, in case of items (1) and (3), the volumes of CO_2 produced by combustion are the same as the volumes of CO_2 and CH_4, while in case of item (4) the volume is double. To determine the volume of CO_2 resulting from the combustion of one cubic foot of the gas, therefore, it is necessary only to add the proportions of CO, CH_4, and CO_2, and double the C_2H_4. In the case assumed, $0.27 + 0.025 + 0.025 + 2 \times 0.004 = 0.328$ cubic foot. From the analysis of dry gas in the exhaust, there is 0.139 cubic foot of CO_2 per cubic foot of exhaust. Dividing 0.328 by 0.139 gives 2.36 as the number of cubic feet of dry exhaust gas per cubic foot of producer gas burned.

The air supplied per cubic foot of gas may be computed from the nitrogen in the exhaust gases. The proportion of nitrogen in the present case is 81.5 per cent.; $0.815 \times 2.36 = 1.92$ cubic feet of nitrogen per cubic foot of gas burned.

The gas carries 55.3 per cent. of nitrogen, and the quantity of nitrogen in air supplied per cubic foot of gas is, therefore, $1.92 - 0.553 = 1.367$ cubic feet. Since air is composed of 79 parts nitrogen and 21 parts oxygen, the quantity of air supplied per cubic foot of gas was $1.367 \div 0.79 = 1.73$ cubic feet. The air required for combustion was as follows:

		Cu. Ft.
CO	$\frac{0.27}{2} \times \frac{1}{0.21}$	= 0.643
H	$\frac{0.12}{2} \times \frac{1}{0.21}$	= 0.286
CH_4	$0.025 \times 2 \times \frac{1}{0.21}$	= 0.238
C_2H_4	$0.004 \times 3 \times \frac{1}{0.21}$	= 0.057
Total		1.224

The excess air, therefore, is $1.73 - 1.224 = 0.506$ cubic foot per cubic foot of gas taken in by the engine.

Heat Rejected in Exhaust

From Table 2 the specific heat of the dry exhaust gas may be computed. The

TABLE 2. SPECIFIC HEATS OF EXHAUST GAS CONSTITUENTS AT 62° F.

Gas.	Symbol.	Specific Heat, B.t.u. Per Pound.	Weight Per Cubic Foot.	Specific Heat, B.t.u. Per Cubic Foot.
Oxygen	O	0.2175	0.0840	0.0183
Nitrogen	N	0.2438	0.0737	0.0180
Carbon dioxide	CO_2	0.2170	0.1156	0.0251

foregoing computations gave 1.92 cubic feet of N, 0.328 cubic foot of CO_2 and $0.046 \times 2.36 = 0.108$ cubic foot of O per cubic foot of gas consumed. The heat required to raise the temperature of one cubic foot of the dry exhaust gas one degree, therefore, is as follows:

N, 1.92 x0.0180	0.0345	B.t.u.
O, 0.108x0.0183	0.00197	B.t.u.
CO_2, 0.328x0.0251	0.0082	B.t.u.
Total	0.04467	B.t.u.

The heat carried off by steam is determined from the following considerations: One pound of hydrogen plus eight pounds of oxygen produce nine pounds of water vapor or steam. Also, in methane one-fourth of the entire weight is hydrogen; that is, one pound of hydrogen unites with three pounds of carbon to make four pounds of marsh gas. Similarly, one-seventh of the weight of ethylene gas is due to hydrogen.

Referring to Table 1 for the weights per cubic foot, and to the assumed analysis of producer gas for the proportions of these constituents, the steam produced per cubic foot of producer gas is computed thus:

From		Pound.
Hydrogen	$0.12 \times 9 \times 0.00527 \times 9$	= 0.00569
Methane	$0.025 \times \frac{9}{4} \times 0.04205 \times \frac{9}{4}$	= 0.00236
Ethylene	$0.004 \times \frac{9}{7} \times 0.07356$	= 0.00038
Total weight of steam		0.00843

The pressure of the exhaust being assumed as that of the atmosphere, the heat contained in the steam at the temperature of saturation, above 62 degrees, is:

Heat of vaporization 966x0.00843	8.14
Heat of liquid (212—62)x0.00843	1.26
Total heat, B.t.u	9.40

The heat per degree of superheat above 212 degrees is $0.00843 \times 0.48 = 0.00405$ B.t.u., 0.48 being taken as the specific heat of superheated steam.

Suppose the temperature of the exhaust is 600 degrees. The heat rejected per cubic foot of gas is:

	B.t.u.
In dry gases, 0.04467 × (600—62)	24.03
In steam, heat of liquid + vaporization at 212°	9.40
In steam, superheat, 0.0405 (600—212)	1.57
Total heat in the exhaust per cubic foot	35.00

The percentage of the heat supplied in the producer gas that is rejected in the exhaust, therefore, is

$$\frac{35}{156.5} \times 100 = 22.4 \textit{ per cent.}$$

Should Sine or Cosine be Used in Computing the Discharge Area of Bevel-seated Valves?

By F. R. Low

There was some disagreement in the discussion upon safety valves by the mechanical engineers a short time ago as to whether the lift should be multi-

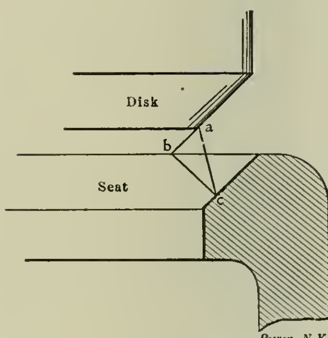

FIG. 1

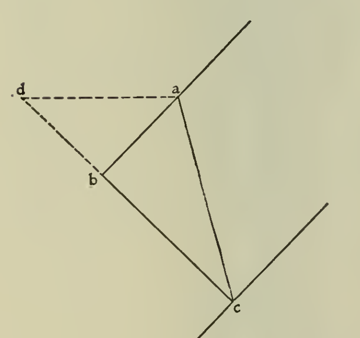

FIG. 2

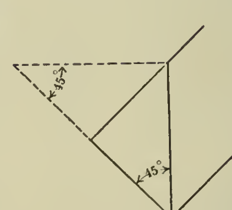

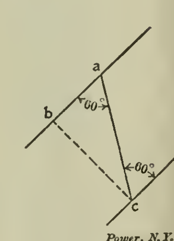

FIG. 3 FIG. 4

plied by the sine or by the cosine of the angle of the seat in order to get the area of the opening available for the discharge of steam.

There could, of course, be no such confusion about so simple a matter if everybody understood the problem alike and meant the same thing when speaking of it.

It all depends upon whether the angle taken is that which the bevel of the seat makes with the vertical or with the horizontal; with the axis through the spindle or with a line at right angles thereto.

In Fig. 1 the valve is shown lifted

vertically from its seat the distance a c but the width of the passage opened for the escape of steam is only b c. Now, b c is the sine of the angle at a and the cosine of the angle at c. In Fig. 2 this triangle is reproduced upon a larger scale and the dotted portion added. The little triangle a b d is similar to the larger triangle a b c, and in it the angle at a is the same as that at c in the larger triangle. But this is the angle which the seat makes with the horizontal and b c is the cosine of this angle.

When the rule says "multiply by the sine," the angle made by the lines a b and a c meeting at a is meant, i.e., the acute

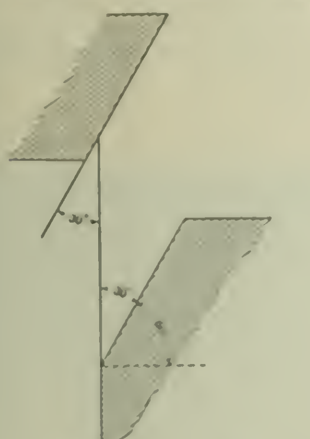

FIG. 5

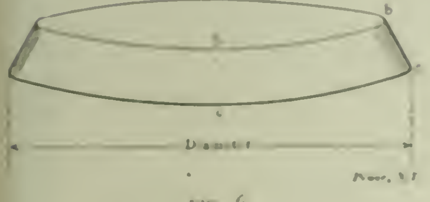

FIG. 6

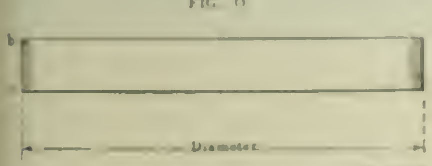

FIG. 7

angle between the line of the seat or the face of the valve and a vertical drawn across it.

When the rule says "multiply by the cosine," the angle made by the lines b c and b a, Fig. 2, meeting at c is meant, i.e., the acute angle made by the line of the seat with the horizontal or by a line b c at right angles to the seat with the vertical. With the common 45-degree bevel it does not make any difference, for both these angles are equal and the sine and cosine are the same. See Fig. 3.

Practically the only other angle used for a beveled seat is 60 degrees, and this is made with the seat 60 degrees to the vertical, as in Fig. 4, and the width of the passage b c is the lift multiplied by 0.866, the sine of 60 degrees.

It would avoid confusion always to speak of the bevel as of that angle which it makes with a vertical. If, for example, a seat were beveled as in Fig. 5, it should be called a 30-degree seat and not a 60-degree, the 60-degree angle being with the horizontal.

The smallest area for the escape of steam is the surface of a frustrated cone made by carrying the line b c around the circle, as shown in Fig. 6. This area will not be found exactly by multiplying b c, found as just described, by the circumference of the inner edge of the seat, which would give the surface of a cylinder of that diameter and of the length b c, Fig. 7. To be accurate, half the side b c should be multiplied by the sum of the circumferences at b and at c. The difference is too small, however, to bother with in so imprecise a problem as the discharge of a safety valve.

Preparation of Boilers for Inspection

By J. E. Terman

Engineers are vitally interested in the safety of the boilers under their charge, for in the average plant the engine room is located so that the engineer's exposure to personal danger from an explosion is almost as great as that of the boiler attendant, and if no other reason existed, this should make him cautious.

One of the most important requirements conducive to a safe boiler, aside from a few very necessary rules of operation, is that thorough expert inspections, both internally and externally, be made periodically to determine if injury has resulted from use. It is best to have such expert inspection at least once a year, but regardless of who examines the boilers, it is the moral duty of the engineer-in-charge to know by actual observation just what condition his boilers are in. For average conditions of operation, about three inspections should be made by the engineer each year. The purpose of the writer is to describe how boilers may be prepared for inspection.

Cooling Down a Boiler

The time that may be taken to cool a boiler varies with the equipment of each plant; in some instances one or more boilers being always idle, there is no need of hastening the cooling-off. When conditions require that a boiler be cooled off quickly for any purpose, it can be accomplished without injury by going at the job in a systematic manner. The first step is to find how the heat to be dissipated is distributed.

Assuming that we have an ordinary 72-inch horizontal return-tubular boiler, running at 150 pounds pressure, to be cooled to 100 degrees Fahrenheit for satisfactory inspection work, the heat to be dispelled in accomplishing this cooling will be about as follows:

The setting will be composed of approximately 75,000 brick, and it can be assumed that the average temperature of the setting walls, running at 500 degrees Fahrenheit, and to reduce it to 100 degrees Fahrenheit would require the extracting of about 7,500,000 B.t.u., using 0.2 as the specific heat of brickwork. The water and steam in the boiler will contain approximately 2,000,000 B.t.u., and the material of which the boiler is constructed 10,000 B.t.u. above the amount contained at 100 degrees Fahrenheit.

Assuming these figures to be approximately correct, it is readily seen that the setting is a very large reservoir of the heat that is to be expelled. The only practical way of dissipating the heat contained in the setting walls with fair speed and without injury, is by means of the stack; that is, by passing large quantities of relatively cool air over the surfaces to conduct the heat away. To accomplish this rapidly all openings in the setting and flue doors should be closed and the damper and fire doors left open, or, in other words, the boiler left just as it would be in operation, with the exception of the fire doors.

While this seems too a simple and obvious requirement, it would be surprising to many, who have not had experience in this line, to know how many boiler attendants imagine that the greater the number of doors left open in a setting the more rapidly the heat will escape, while the reverse is true.

Although the air passing through the setting and boiler carries away the heat from the boiler and contained water, as well as from the setting walls, there is another means of dissipating the heat contained in the water and boiler, if it may be at hand, for accelerating the flow of feed water. For this purpose cool water should be fed in very slowly and the blowoff valve opened just enough to maintain the water level at some point in the gage glass, and not until the setting has properly cooled should the water be let out of the boiler. It is not likely that serious strains will be set up in a boiler in cooling down, as long as the water level is kept up in the ordinary working scale. In some plants it is practice to make a blowing out the water as soon as the pressure has fallen as low as possible, regardless of the temperature of the brickwork, subsequently cooling the boiler and shell by a stream of cold water from a hose. This is very bad practice and frequently leads to leaky tubes and seams.

Cleaning the Combustion Chamber

When the setting has cooled sufficiently the ashes should be raked out of the combustion chamber. Some engineers, instead of raking them out, make a practice of wetting them down with a hose. This should not be done as it dampens the ting walls and it is dangerous for the inspector.

Many a serious burn has been received by crawling into a combustion chamber which has been treated in this manner and sinking through a cold crust of 6 or more inches into red-hot ashes. Inspectors soon become wary of these conditions. It is really surprising how long heat may be retained beneath ashes in a combustion chamber. The writer has seen sawmill boilers, where wood was burned, which had been idle a week, and although everything was apparently stone cold, red-hot ashes could be found a foot below the surface in the chamber back of the bridge-wall.

For proper inspection the grates of a boiler should be raked clean of ash and clinker, for it is extremely unpleasant, and painful, to crawl through a bed of clinkers, as anyone who has tried it can testify.

In the vertical or locomotive type of boiler the grate bars should be removed entirely, for corrosion is extremely liable to occur on the furnace sheets at the grate level, and a proper inspection can rarely be made with the grate bars in place.

Cleaning the External Surfaces

The external surfaces of water-tube boilers cannot be too well cleaned to aid inspection, unless it is at the tube ends, where accumulations caused by leaks may be present. These should be left to be cleaned by the person making the inspection. Such accumulations attract attention to the leaks, and the amount and nature of the accumulations assist the inspector in forming a correct opinion of the importance of the leaks. The foregoing reasoning applies to evidences of leaks at any point along the seams, shell or tube ends of all types of boiler. The blowoff pipes should be exposed for examination, as rapid corrosion frequently occurs on the piping to this attachment, and if it is not arranged so that it can be easily inspected, the equipment is defective, and proper changes should be made. The same reasoning applies to mud drums, where such devices are used, and while it is advisable to protect them from the heat and ashes, the protection should be readily removed to permit proper inspection.

Cleaning Internal Surfaces

If the inspection is for the purpose of determining the cause of a bag, or a leak at a seam, or tube end, or any similar defect, the interior surfaces should not be disturbed until after the inspection has been made, for convincing evidence of the cause of such defects may be removed in cleaning. However, the boiler should be opened, to permit drying out. If no defects as mentioned are known to exist, the boiler should be scaled and thoroughly washed out. This applies especially to the bottom of the return-tubular type, where accumulations of scale make it difficult to detect grooving at the seams, and other types of corrosion.

A necessary condition to permit comfortable and thorough internal inspection, where other boilers are being operated at the time of the examination, is that the valves connecting the boiler with the steam main and feed line be tight. An excellent precaution is to have all the valves to these connections locked shut during the cleaning and inspection of a boiler.

With the agitation for enactment of laws to prevent loss of life by boiler accidents, it would not seem amiss that such a requirement as locking the valves on a boiler during inspection and cleaning be added. This precaution also applies to the blowoff valve, where several boilers are connected to a single blowoff line, for doubtless the greater number of accidents due to scalding have been caused from this connection, owing to its apparent harmless nature, being on an open line. The experienced inspector soon learns to make it a fast rule, in plants where other boilers are in operation, to see that the blowoff valve on a boiler he is about to enter is closed, and he never takes anyone's word for it.

Attachments

Where safety valves are equipped with discharge pipes, they should be arranged so that a section next to the valve can be easily removed, to permit examination of the springs and moving parts. The steam gage should be removed from the boiler, so it may be compared with a test gage, and any necessary connections made.

Except in rare instances, there is no justification for placing in a boiler any apparatus which will interfere with easy access through the manholes, or proper inspection of the interior surfaces; if such conditions do exist, the attachment should be arranged so that it can be removed when an inspection is to be made.

The points here given are only some of the main features for the average plant; numerous other details for each specific case will suggest themselves to the progressive engineer, who is endeavoring to obtain the maximum benefit from such examinations.

The United States Civil Service Commission announces an examination on May 5 to secure eligibles from which to fill a vacancy in the position of mechanical assistant, at a salary of from $900 to $1200 per annum, in field investigations, Bureau of Plant Industry, Department of Agriculture. Applicants should have a knowledge of refrigerating machinery, and it will be necessary that the appointee be of slender physique on account of the limited space available in which some of the work must be done. Application form 1093 should be secured. Apply to the commission, at Washington, D. C.

Catechism of Electricity

Installation of Induction Motors

1017. *What consideration should govern the location of an induction motor?*

It should be placed where it is easily accessible for inspection, oiling or cleaning, and repairs. It must not be exposed to moisture, leaky steam pipes or dirt and coal dust. It should receive proper ventilation and should be mounted so that there is sufficient distance between its pulley and the pulley on the machine driven by it to permit the belt to drive efficiently and without excessive tension.

1018. *What kind of foundation is most desirable?*

A heavy timber or a concrete foundation as shown in Fig. 286 is best. It should be sufficiently heavy and so well bonded that there will not be any vibration. The foundation of the motor and of the driven machine should set with respect to each other so that the two shafts are parallel, in order that the rotor or rotating parts of the induction motor may "float" in its bearings.

1019. *In lining up a belted induction motor with the driven pulley what special precautions should be observed?*

The position of the motor with respect to the driven machine should be such that the belt will be tight enough to run without slipping, but not so tight that the bearings become unduly heated. The crowns of the two pulleys should be as nearly as possible alike to prevent the belt from wabbling; the greatest diameter should be at the center of the pulleys so that the belt will travel true and allow the rotor shaft to float. The belt must be free from grease and dirt, else it is likely to slip and flap, and the edges of the belt must stretch equally or there will be an objectionable sidewise movement of the belt on the pulleys.

1020. *In alining a direct-connected induction motor, what special precautions should be observed?*

The shafts of the machines to be coupled must be in perfect alinement with each other, and this alinement must be maintained by building the foundations so that they will not settle or vibrate.

1021. *If the motor is to be geared to its load, what points should be considered?*

The shafts must be carefully adjusted to parallelism and set the specified distance apart. The pinion should fit securely on the motor shaft, but not so tightly that it cannot be forced on or off with moderate pressure. If the pinion is driven on by heavy blows with a ram or sledge the rotor conductors are liable to be jarred out of place and damaged.

1022. If it is desired to use the motor in other than an upright position, what changes are necessary?

Ordinarily induction motors are made so that the only change necessary for operating them in other than an upright position is the shifting of the bearing brackets either 90 degrees or 180 degrees, as the case may be, in order that the oil wells shall remain in their proper position.

1023. Are there any special precautions to be observed when shifting the bearing brackets?

Care must be taken to replace them so that the rotor is properly centered. The air gap between the rotor and the pole faces must be the same at all points.

1026. What should be the capacity of the conductors and fuses in the motor circuit with respect to the full-load motor current?

For ordinary service the conductors and fuses should have a capacity 1½ times the full-load current. Where elevators or hoists are operated by the motors or wherever heavy starting duty is required of them, the capacity of the fuses should be 2½ times the full-load current.

1027. What size of conductor would be necessary for wiring up a two-phase induction motor, requiring 43 amperes, for ordinary service?

The capacity of the conductor, according to answer No. 1026, should be 1½ × 43 amperes = 64.5 amperes. Referring to the table under [illegible] No. [illegible] showing the carrying capacities of copper wires, it will be found that [illegible] work a No. 5 B. & S. gage conductor is the smallest size that will safely carry this current.

1028. What size fuse should be employed in a three-phase motor circuit if the motor requires 43 amperes at full load and is to be used at a hoist?

For hoist work the fuses should be rated at 2½ times 43 amperes; that is, they should be capable of carrying 2½ × 43 = 107.5 amperes without melting. Referring to answers Nos. [illegible] and [illegible], a [illegible] fuse of [illegible] amperes in either the open or inclosed [illegible] type would serve the purpose.

OPERATION OF INDUCTION MOTORS

1029. Are the starting conditions of different induction motors about the same?

No, they differ widely. Some start with full-load current and full-load torque, while others require two or more times their full-load current in starting under similar conditions. Two-phase and three-phase induction motors start with a higher torque and lower current than do single-phase induction motors.

1030. What is objectionable about a large starting current?

It is highly inductive and has very bad effects on the regulation of the supply circuit.

1031. In the operation of an induction motor how may the starting current be kept down?

By inserting resistance in the rotor circuit at the time of starting or by starting the motor on a voltage lower than the normal line voltage.

FIG. 286. SUBSTANTIAL FORM OF FOUNDATION FOR AN INDUCTION MOTOR

1024. In assembling an induction motor just received from the factory, what points should be observed?

The bearings and oil wells must be carefully wiped clean and the shaft rubbed with oil before being put into place. Only the highest grade of dynamo oil should be used in the bearings and they must be filled to such a hight that the surface of the oil comes above the lowest edges of the oil rings. The oil rings must revolve freely and carry sufficient oil to flood the bearings.

1025. In wiring up an induction motor how is one to know what size conductor to use?

The size of conductor to use is, of course, determined by the amount of current the motor requires. The full-load current for an induction motor is usually stamped on the nameplate. When it is not, the builder should be asked to specify it.

Washington Meeting of the A. S. M. E.

The announced program for the Washington meeting of the American Society of Mechanical Engineers is as follows:

TUESDAY, MAY 4, 8:15 P.M.

Informal reception at the New Willard hotel.

Address of welcome by Hon. Henry B. F. Macfarland, president of the Board of District Commissioners.

Response by President Jesse M. Smith.

WEDNESDAY, MAY 5

Professional session at 9:30 a.m.

Sight-seeing automobile trips about the city, at 10 a.m., for the ladies.

Reception of members and guests by the President of the United States in the East Room of the White House at 2:30 p.m.

Trips to nearby points of interest at 3 p.m.

Illustrated lecture by F. H. Newell, director of the Reclamation Service, on "Home-Making in the Arid Regions," at 8:15 p.m.

THURSDAY, MAY 6

Short professional session at 9:15 a.m.

Trips for ladies to points of interest in and about the city at 9:45 a.m.

Special [illegible] to Mount Vernon at 2 p.m.

Social session. Address by Rear Admiral Melville on "The Engineer in the Navy," at 8:15 p.m., to be followed by presentation to the National Gallery of a portrait of Rear Admiral Melville, with acceptance by Dr. C. D. Walcott, accepting the portrait.

FRIDAY, MAY 7

Professional session at 9:30 a.m.

It is possible that during the convention there will be [illegible] of a [illegible] [illegible] to which members and guests have be invited.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for March, 1909, was (weekly and monthly) 190,000.

April 6................ 42,000
April 13................ 37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents PAGE

Handling the Peak Load

If a flexible expanding and contracting grate could be designed, by means of which the correct relation of grate area to generator output could be maintained, a measurable reduction in the coal cost per kilowatt-hour would result. In power plants where the peak load for a short time amounts to three or four times the average load, the economical handling of this peak becomes a serious problem.

Generating units which may be operated without a marked loss in efficiency over a range of output from three-fourths load to an overload of fifty per cent. are common, and when not in operation do not eat into the coal pile.

When the average, the maximum and the minimum demands and their probable duration are known, generating units may be selected of such capacity that the entire range may be covered by two or three, and the steam cost per kilowatt-hour vary but little from the average, whether operating on the peak or on the lightest run.

But it is somewhat different in the boiler plant. Here an area of grate surface sufficient for the utmost needs of the service must be kept in readiness for use all of the time. Banked fires cost money in more ways than one, and not the least cost is in the investment involved in boilers where this method is followed; and in various directions designers are working to increase the output of boilers without appreciably reducing the efficiency.

Experiments with this end in view have been numerous. In one instance the grate area under a boiler was doubled by the installation of an additional stoker at the rear end of the boiler, on the grates of which the fire was banked during part of the day. Whatever this combination lacks of realizing the highest efficiency in operation and the loss that obtains in a banked fire at one end of the boiler during a part of the time, it probably costs less in investment and in operation than two boilers, each equipped with one stoker.

In another attempt along the same line oil burners were installed under a portion of the boilers, to be used on the peak load. Oil is a more expensive fuel than coal in most localities, but the fire does not need banking when not in use, and it was thought that the cost of using some oil fuel part of the time would be less expensive than using coal for all of the fires.

In still another case oil burners were installed above the coal fires, with the intention of burning all of the coal possible on the grate, and with the oil burners so designed that the necessary air for their operation would enter the furnace with the oil, thus increasing the volume of hot gases, if not also the temperature of the furnace.

In the first and last of these three experiments to make an efficient and elastic boiler-room equipment the investment in boilers is reduced to the lowest practicable amount, while in the second, although the boiler investment is not reduced, the waste attending the slow, inefficient burning of coal in banked fires is avoided.

The Progress in Marine Engineering

From September 25 to October 9 of this year the State of New York will commemorate the three hundredth anniversary of the discovery of the Hudson river and the one hundredth anniversary of the successful introduction thereon of steam navigation. For nearly twenty centuries the river flowed on undisturbed by man, save when the savage propelled himself from shore to shore on a floating log, or when later he burned a hollow in a log, in semblance of a boat, or, as his mental capacity broadened, built his canoe of the bark of trees and propelled it by crude paddles. Thus as recently as a hundred years ago the motive power for boat propulsion was human muscle.

It is difficult to realize this now. The gigantic steamships of today are so common that they attract slight attention; yet they had a beginning. Fulton did not construct a modern seamship, but he applied the power of steam to the paddle-wheel of a boat and revolutionized the then existing method of ship propulsion. The history of invention contains almost countless instances of great discoveries which were the outgrowth of small beginnings. There were steam engines in crude forms long before Robert Fulton was born; and men had attempted the propulsion of ships by steam, but they had not grasped the requirements necessary for commercial success.

Today, when it is announced that a valuable discovery has been made, or a new invention has been perfected, the inventor finds scores of capitalists ready to back him with their money, provided it is worth while. Not so with Fulton, however, for while he was at work upon the "Clermont," which the disbelieving public called "Fulton's Folly," tokens of encouragement were few and far between. It was only after the run from New York to Albany, one hundred and fifty miles in thirty-two hours, the entire run having been performed by the power of steam, that the significance of his achievements was realized. The old Hudson river had not witnessed a sight even approaching this since the "Half Moon" sailed over the same course nearly two hundred years before.

The advancement in steam navigation during one hundred years has been marvelous. Today the Hudson river is the pathway of thousands of steamships. The run to Albany is made day and night by steamers of types unequaled throughout the world; the waters of the river are cleaved by the prows of the "Lusitania" and "Mauretania," the largest and fastest steamships in the world—magnificent monuments to the growth of marine engineering in one hundred years.

While it is true that Fulton did not build the first boat propelled by steam, he inaugurated the great movement of steam navigation, and he has justly been called "the father of American steamboating."

Safety for Boiler Attendants

An article on another page of this issue suggests that the valves leading to the steam main and other lines on a boiler which is being cleaned, inspected, or repaired, be locked shut, to prevent accidental opening of them while someone is inside the boiler. Such a requirement added to municipal or State boiler laws would apparently be a step in the right direction.

As has been previously stated in these columns, the only excuse for the existence of laws licensing engineers and firemen, and supervising boiler construction, is the avowed purpose of throwing safeguards around human life. Should not the lives of the boiler attendant or inspector, or the boiler repairman, be safeguarded with as much zeal as those of other employees, or the casual passer-by or lounger around the plant?

We frequently read of some frightful accident in a plant, where a boiler attendant has been imprisoned in a boiler and scalding steam or water turned on, the general cause being an ignorant fellow operative, who has opened some valve without knowing the fearful consequences that would result, and the accident is soon forgotten, the general opinion being that until more intelligent operatives are demanded, such accidents will occur with more or less frequency. Such reasoning is without foundation, for only a few men in a plant should have authority to open and close valves, and to prevent accidents due to their forgetfulness or from the zeal of the fool meddler, a lock would be very effective.

It is, without doubt, desirable to prevent making any rules governing boiler operation or construction that are not absolutely essential to safety. For regardless of how complete rules may be made, conditions not contemplated will arise, and in such cases, with a few simple rules the judgment of the individual inspector can be relied upon to adjust the details to suit each case. Notwithstanding this recognized need of brevity, we think such a rule as here advocated would be a very proper addition, and, if enforced, it would be as certain of accomplishing the purpose for which it was intended as any of the rules with which we are familiar.

Characteristics of the Turbine Pump

The article published under the above title by Frederick Ray in our issue of March 23 has attracted a great deal of attention from practical engineers and possible users of pumps of this class as well as from pump designers. In fact, it was at the user of the pump that the article was directed, the curves indicating possibilities and performances of given pumps under varying conditions, rather than the effect of varying factors in the pump itself.

It was only a few years since the centrifugal pump was restricted to a comparatively narrow field and served only a few purposes, as where large quantities of liquid had to be lifted against low heads. For such purposes, especially for the handling of sewage, the pumping out of excavations, etc., the valveless and pistonless centrifugal offered particular advantages, and it has become so associated in the public mind with this class of work that it has been difficult to secure an appreciation upon the part of pump users of the progress which has been made in the development of this type of pump and the extension of the field to which it is applicable.

Today there is hardly a service for which the centrifugal or turbine type of pump is not ready to compete with the piston variety. In several of the large power plants of the country they are successfully used to handle the boiler feed against high boiler pressures. Mr. Ray's article shows in a simple and easily understandable way the real merits, capabilities and limitations of the type. The relations of head, horsepower required, efficiency and capacity are admirably brought out in the diagrams which he furnishes, and a little study of the article will put the engineer or power user into possession of the latest and best information attainable as to what is available and capable of accomplishment in this line.

Turbine versus Reciprocating Engines

We have several times referred to the three scout cruisers in which the United States Navy is trying out the comparative merits of the turbine and the reciprocating engine. These are the "Birmingham," with reciprocating engines, the "Chester," with Parsons turbines, and the "Salem," with Curtis turbines.

The vessels are built to the same model, having a trial displacement of [illegible] tons and designed for something like [illegible] horse horsepower.

Trial runs at 10 and 15 knots have been made with the following results, in tons of coal consumed:

	At 10 Knots	At 15 Knots
"Birmingham" (Engines)	[illegible] tons	[illegible] tons
"Chester" (Parsons)	[illegible] tons	[illegible] tons
"Salem" (Curtis)	[illegible] tons	[illegible] tons

These results are unofficial and interesting only for comparison. At the lowest speed the reciprocating engine is at a decided advantage, requiring only three-quarters as much coal as the Parsons turbine and about three-fifths as much as the Curtis. The "Chester" is a four-screw boat, while the others have but two screws each. Our advices do not say whether all of the turbines were used on the slower trial. If they were not the Parsons turbine had the advantage of working more nearly to its capacity.

The turbine, depending for its operation upon the "interaction" between jet and blade, is much more sensitive to departure from the speed for which it is designed than the piston engine, and its improved showing at the 15-knot speed is very apparent. Calling the consumption of the "Birmingham" 1, that of the "Chester" is [illegible] at the lowest and [illegible] at the 15-knot trials, while that of the "Salem" is [illegible] and [illegible] respectively.

It will be very interesting to see how the results will compare at the 25-knot speed which the vessels are expected to make.

A License and Inspection Bill for Wyoming

There is before the legislature of the State of Wyoming an act to constitute a State Board of Inspection for Steam Boilers and for the examination and licensing of engineers. The bill, curiously, [illegible] its title and notwithstanding [illegible] in the text it provides that "there" shall be one and [illegible] authorizes the appointment of but one inspector. All boilers, with the usual exceptions, are to be inspected annually and tested by hydrostatic pressure to exceed the working pressure allowed in the ratio of one to [illegible]. A fee of [illegible] for each boiler is required when there is but one boiler and [illegible] for each additional boiler when there is more than one in a plant.

The fee for the examination of applicants for license is [illegible] for first-class engineers, [illegible] for second-class engineers and [illegible] for third-class engineers. The license must be renewed each year, the renewal being [illegible]. If an engineer feels that he has been unjustly refused a license, [illegible] an engineer holding a license of the grade of that for which he is applying and the engineer with the inspector are to select another, these two with the inspector to give the man another examination, which shall be final.

The relative proportions of different expenses in power generation in the electric stations of Massachusetts have been found to average as follows: For each dollar received from the consumer [illegible] cents is spent for fuel, [illegible] cents for wages at the station, [illegible] cents for maintenance, repairs and [illegible] cents for [illegible].

Telescope Ash Elevator

For steam plants such as are usually located in a basement or subbasement, and not a few of which are without access even to an alley, the problem of ash disposal becomes a matter of considerable moment. In the photographs reproduced herewith is shown a device well adapted to this purpose.

This elevator, which is of the "telescopic" type, has been especially designed by the Chain Belt Company, Milwaukee, Wis., for elevating ashes from a basement and discharging them directly into a wagon drawn up at the curb. See Figs. 1

FIG. 1. TELESCOPIC ASH ELEVATOR EXTENDED THROUGH SIDEWALK READY TO DISCHARGE INTO WAGON

and 2. When not in use, it can be let down again through the opening in the sidewalk and left standing in its corner, where but little space is occupied. See Fig. 3.

The elevator frame, head and boot are of all-steel construction, well braced and stiffened. The buckets are of malleable iron, carried on an interlocking-chain belt particularly adapted to service of this character and placed at such intervals as to give satisfactory capacity at a minimum of power for operation, it is said.

By means of the special links, the elevator is locked at every point, thereby eliminating the possibility of an accident

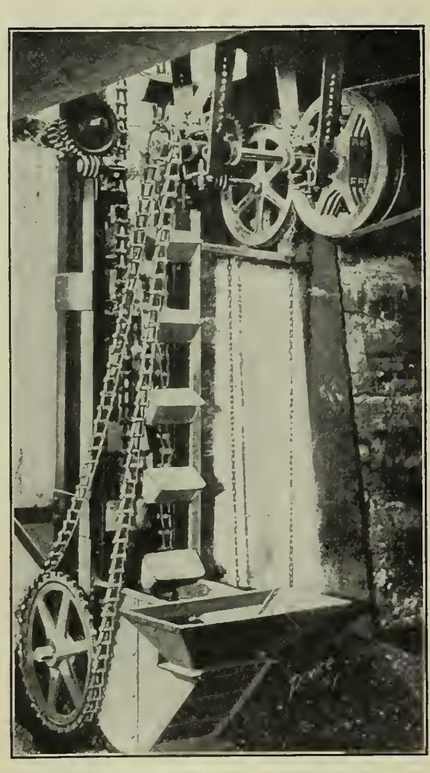

FIG. 2. TELESCOPIC SIDEWALK ASH ELEVATOR EXTENDED

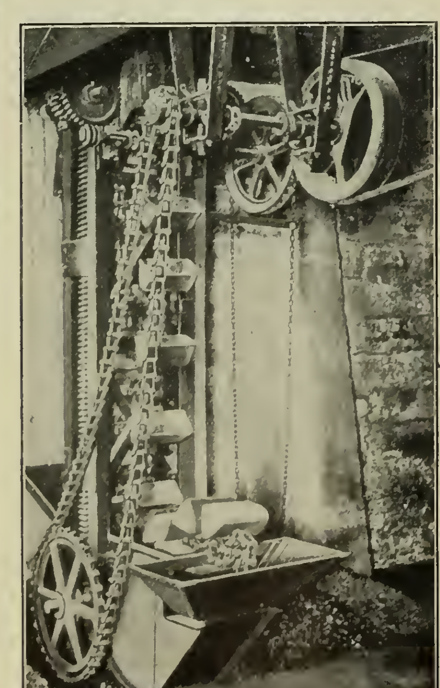

FIG. 3. TELESCOPIC SIDEWALK ASH ELEVATOR LOWERED

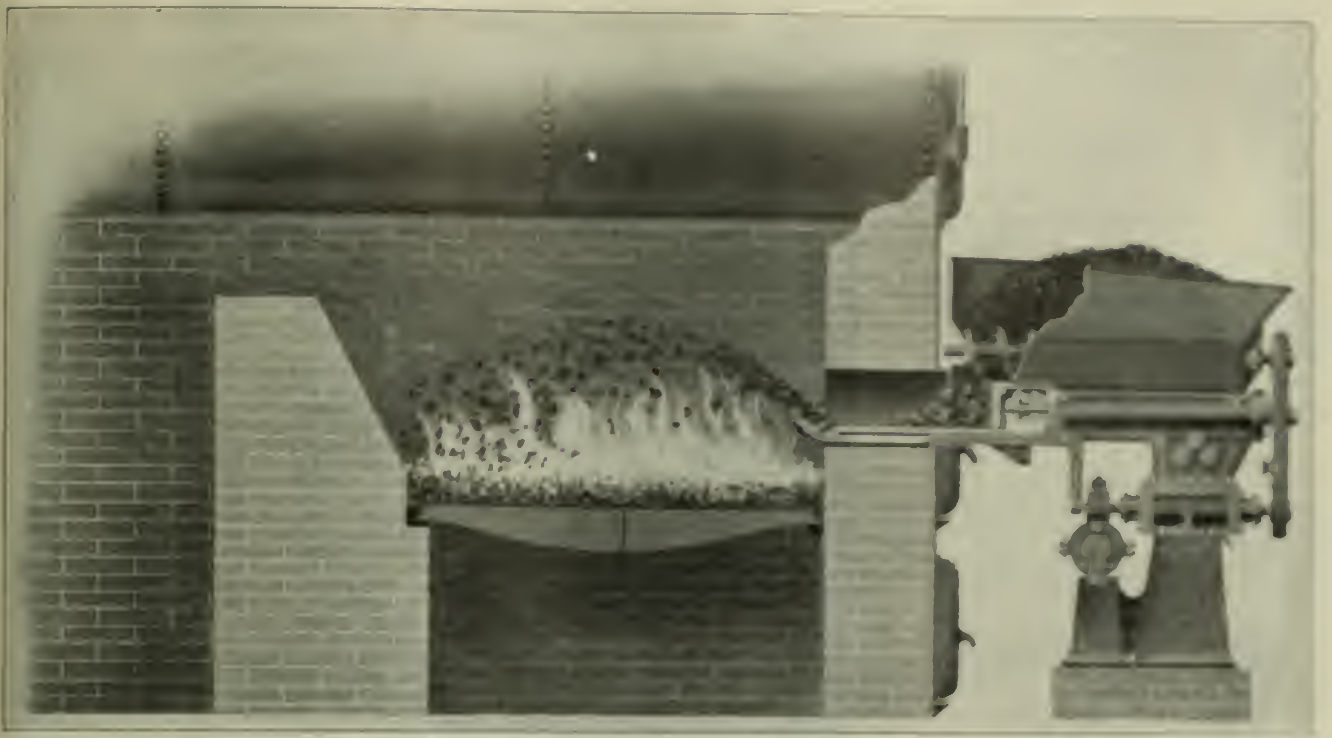
and telescoping the apparatus, which would cause considerable damage.

The mechanism for raising and lowering the elevator consists of racks and pinions operated by a worm-gear drive which takes its motion from the same countershaft that operates the elevator belt. Where convenient, a small electric motor may be used to transmit power to the apparatus, but the intermittent character of the service will, in most cases, make connection to shafting more economical.

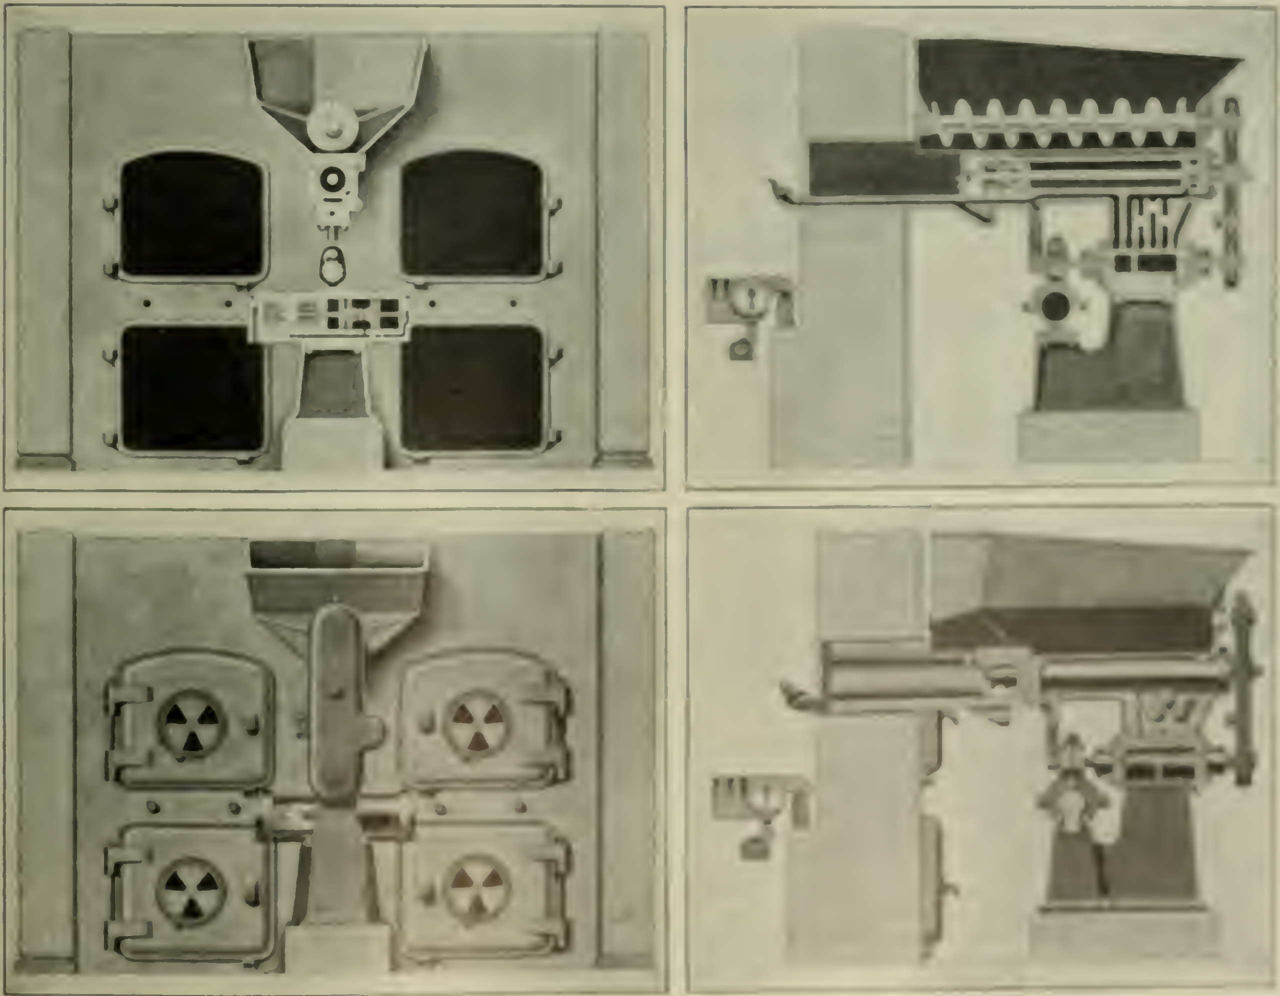
Erie Foundry Company's Stoker

The Erie stoker is of the overfeed plunger or shovel type. It consists essentially of a coal hopper, with an opening in the bottom at the end nearest the boiler; a conveyer for agitating or carrying the coal from the rear of the hopper to an opening at the front, where it falls by gravity in front of the plunger; a main cylinder and trough in which reciprocates a plunger piston which, with variable stroke, throws the coal to the different parts of the firebox. The variable stroke is given to the plunger by means of a rotary valve, from which three separate steam ports lead to the rear end of the cylinder, and three choke plugs, one for each of the steam ports. The office of the choke plugs is to vary the amount of steam reaching the rear end of the cylinder through the various ports. As the valve operates, the ports stop full open in front of their corresponding steam passages in regular succession. By choking down the steam with the choke plug nearest the rear of the stoker until that port is almost closed, there is obtained a very light stroke of the plunger, thereby distributing the coal over the grate near the fire door. The other two choke plugs operate in turn in the same manner, only they are so adjusted that more steam is admitted on the second stroke than on the first, thus distributing coal over the middle portion of the grate, and more on the third stroke than on the second, thereby scattering the coal over the rear end of the grate. By adjustment of the choke plugs any desired arrangement of distribution may be obtained.

The conveyer is controlled by a small reciprocating steam motor, which also operates the valve that controls the speed of the plunger to provide a uniform



THE ERIE FOUNDRY COMPANY'S STOKER



FRONT AND SIDE ELEVATIONS OF THE ERIE STOKER amount of coal for each stroke. A deflector attached to the front of the trough is designed to spread the coal to the sides of the furnace as it is delivered by the plunger. This deflector is the only part of the stoker exposed to the fire, and it depends for protection upon exhaust steam from the stoker, which passes through it. By having the stoker located outside of the firebox, if anything goes wrong it can be repaired without inconvenience; and being between the two fire doors, if there is a breakdown it is a simple matter to hand-fire until repairs are made. It is also to be noted that practically no change is necessary in the construction of the firebox.

The stoker may be used with either natural or forced draft, no change to the grate bars being necessary, and any operating engineer can install it without the services of an expert. It is built by the Erie Foundry Company, Erie, Penn.

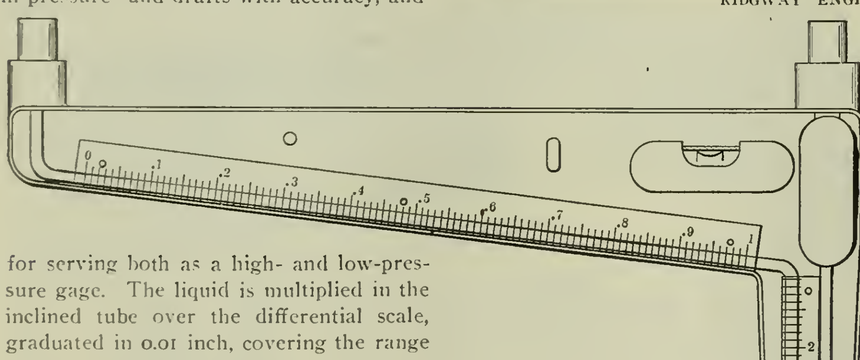
Ellison Differential-Direct Draft Gage

In this draft gage a combination of a differential and direct draft gages in one simple instrument has been made. It is intended for measuring high fluctuations in pressures and drafts with accuracy, and for serving both as a high- and low-pressure gage. The liquid is multiplied in the inclined tube over the differential scale, graduated in 0.01 inch, covering the range of low intensities of drafts and pressures, beyond which the percentage of error becomes too small to be of importance to be multiplied and the liquid turns downward into the vertical tube over the direct scale, of 5-inch equivalent water head, graduated equivalent to 0.1 inch and easily subdivided into small fractions by reason of the small diameter of the bore of the indicating tube and the wider spacing of the graduations for oil to represent water.

The liquid used is 39-degree Baumé oil, having a constant capillary attraction for which the gages are corrected, the rise of the liquid in the chamber and the specific gravity are compensated for in the design and arrangement of the scales, so that the indications represent the equivalent of distilled water directly on the single reading scales without any corrections or calculations whatsoever.

The gage is made in four capacities, comprising a 6-inch, a 6½-inch, a 7-inch and an 8-inch. In the 6-inch gage, the first inch of equivalent water head is multiplied ten times, having a scale 10 inches long; and in the 6½-inch gage, the first 1½-inch equivalent head is multiplied ten times, having a scale 15 inches long. In the 7-inch gage, the first 2 inches of equivalent water head are multiplied five times, having a scale 10 inches long; and in the 8-inch gage, the first 3 inches of equivalent head are multiplied five times, having a scale 15 inches long.

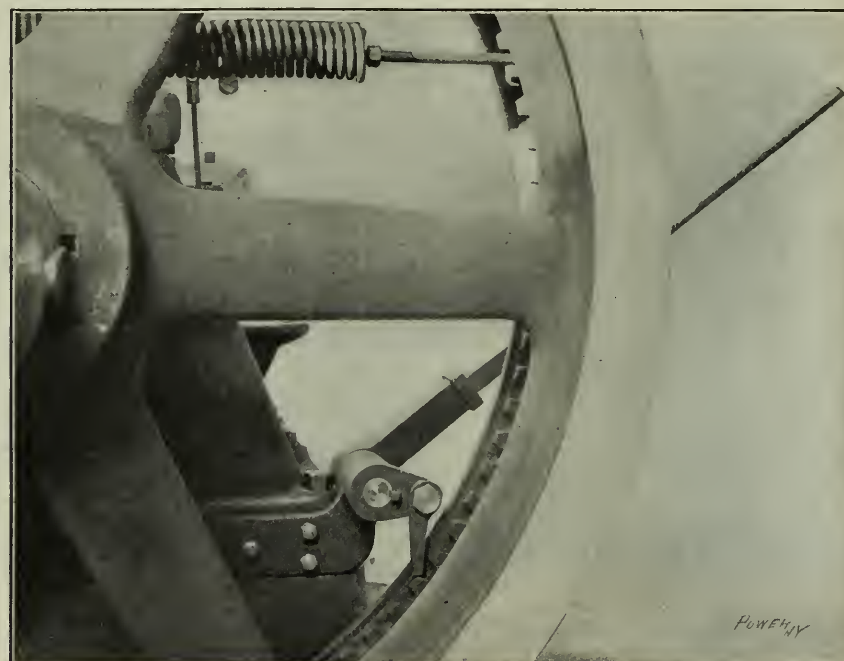
The frames are of aluminum, polished and buffed on the outside; and the scales are of a special, noncorrosive german silver. This instrument is manufactured by Lewis M. Ellison, 6238 Princeton avenue, Chicago, Ill.



ELLISON DIFFERENTIAL-DIRECT DRAFT GAGE

Engine Turning Device

An engine-turning device that will appeal to engineers and others interested in Ridgway engines is shown herewith. The device is bolted to the frame of the engine and consists of a ratchet attachment which engages in teeth on the rim of the flywheel. By this means the largest engine made by the Ridgway Dynamo and Engine Company, Ridgway, Penn., which also makes the device, can be moved from its center. When not in operation the handle bar is removed and the ratchet part thrown back out of engagement.



RIDGWAY ENGINE-TURNING DEVICE

A. I. E. E. Annual Meeting

The annual convention of the American Institute of Electrical Engineers will be held at the Hotel Frontenac, Thousand Islands, Frontenac, N. Y., beginning Monday, June 28, next. A tentative list of papers to be presented includes the following:

"Split-Pole Converters and Storage-Battery Regulation at Gary, Ind." By J. L. Woodbridge.

"The Reduction in Capacity of Induction Motors Due to Unbalancing in Voltage." By S. B. Chartres and W. A. Hillebrand.

"The Heating of Induction Motors." By Alexander M. Gray.

"Generators for 100,000 Cycles." By E. F. Alexanderson.

There will also be three power papers, by D. B. Rushmore, and two educational papers, by H. H. Norris.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer

Steam Superheats when Expanding in a Receiver

In a pamphlet on "Compound Engines" I read the following: "It is said that drop cannot be detrimental to economy because steam expanding freely in this way (in a receiver) loses no heat but becomes superheated, and at the lower pressure contains every unit of heat it contained at the high."

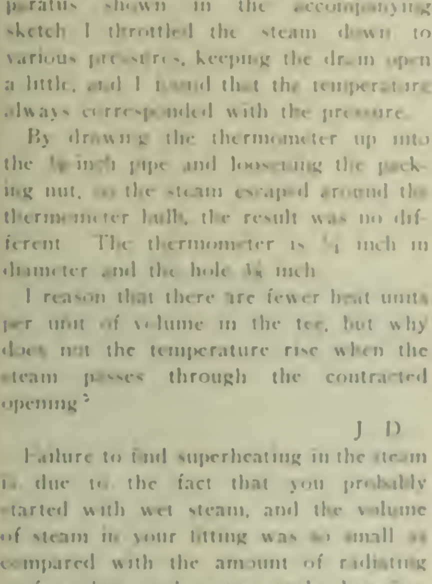
To prove that this is a fact I tried the following experiment. With the apparatus shown in the accompanying sketch I throttled the steam down to various pressures, keeping the drain open a little, and I found that the temperature always corresponded with the pressure.

By drawing the thermometer up into the ⅛-inch pipe and loosening the packing nut, so the steam escaped around the thermometer bulb, the result was no different. The thermometer is ¼ inch in diameter and the hole ⅜ inch.

I reason that there are fewer heat units per unit of volume in the tee, but why does not the temperature rise when the steam passes through the contracted opening?

J. D.

Failure to find superheating in the steam is due to the fact that you probably started with wet steam, and the volume of steam in your fitting was so small as compared with the amount of radiating surface that condensation took place faster than superheating, and the heat generated by expansion was absorbed in the evaporation of the moisture at the temperature due to the pressure rather than in elevating the temperature of the mass. In order to make the experiment effective you should have the surfaces abundantly protected by nonconducting material and assure yourself that the steam is dry when it reaches the apparatus. A demonstration of the fact that steam superheats when expanded under these circumstances is found in the throttling calorimeter, which is very much along the line of the apparatus that you have devised.



APPARATUS USED IN THE EFFORT TO PROVE THAT STEAM SUPERHEATS WHEN EXPANDING IN A RECEIVER

Lumps of Scale in Boiler Tubes

When we run the flue scraper through the boiler tubes we sometimes strike lumps of hard scale. What causes these lumps?

E. F.

Some of the tubes are leaking at the back end and the water is drawn into the tube and there evaporated, leaving behind all of the dissolved solid matter, which sticks to the tube in the form of scale.

Cause of Pound in Check Valve

Every time a certain plunger of our duplex feed pump sends water into the boiler the check valve in the feed line pounds. What is the probable cause?

F. G.

The motion of the plungers may be uneven, allowing the water in the pipe to come to rest. Every time the moving water stops, the check valve will seat with more or less noise. Or the discharge valves in the pump may be in such shape that they do not close promptly and the water flows back into the pump cylinder until the closing of the check valve in the feed line stops it.

Angle of Deflection, etc., of Crank Shafts

I am anxious to know a few things about crank shafts:

(1) What is meant by the angle of deflection? I have read that for a double-throw shaft of a compound steam engine it is between 0.000270 and 0.000412 second.

(2) How can I determine the equivalent twisting moment, or the angle of twist on, for instance, one of the double compound engines in the Interborough station in New York? The high-pressure cylinder is 42 inches in diameter, the low-pressure cylinder 86 inches, the stroke 5 feet, the revolutions per minute 75, the steam pressure 175 pounds per square inch, the crank shaft 34 inches in diameter at the bearings, the length of the shaft 25 feet 3½ inches, and the flywheel generator weighs 370,000 pounds.

(3) What is the strength of that shaft, and how is it calculated against the bending by the weight of the generator and for the twisting strain produced by the crank effort?

H. H.

(1) Deflections are not usually measured in angles and you probably mean angle of torsion. This term means the angle of twist in the shaft between any two points.

This angle is

$$\theta = \frac{M\,s}{C\,I},$$

where

θ is in radians $\left(\text{radian} = \frac{180}{\pi}\ \text{degrees}\right)$

M = Twisting moment on this length of shaft (foot-pounds);

s = Length of section of shaft in feet;

C = Shear modulus of elasticity, for steel = 12,000,000;

I = Moment of inertia of the shaft section = $\frac{\pi r^4}{2}$ for solid shaft and $\frac{\pi r^4}{2} - \frac{\pi r_1^4}{2}$ for hollow.

(2) The angle of twist is found as already explained under question (1).

To find the equivalent bending moment proceed as follows:

Find the maximum bending moment (M_b) between the bearings by the usual method of beams.

$$M_x \text{ at } X = R_1 \times a$$
$$M_y \text{ at } Y = R_1 b - X (b - a)$$
$$M_z \text{ at } Z = R_1 c - X (c - a) - Y (c - b)$$

The greatest of these moments will be the maximum bending moment.

Maximum twisting moment (M_t) = *Maximum crank thrust* × *Crank arm*.

To combine these moments to get the equivalent bending moment, the most reliable formula is Grashof's

$$f = \frac{r}{I_1}\left\{\tfrac{3}{8} M_b + \tfrac{5}{8}\sqrt{M_b^2 + M_t^2}\right\},$$

where I_1 is the bending moment of inertia $= \frac{\pi r^4}{4} - \frac{\pi r_1^4}{4}$ for a hollow shaft such as the Interborough engines [illegible] and r is the outside radius of the shaft and r_1 the inside radius.

Therefore the combined moment is equivalent to a bending moment

$$M_e = \tfrac{3}{8} M_b + \tfrac{5}{8}\sqrt{M_b^2 + M_t^2}$$

(3) Grashof's formula gives a value for the maximum fiber stress f due to the combined moment. This value should not exceed the tensile strength of the steel divided by a suitable factor of safety, usually 5 or 6.

Hence,

$$f = \frac{[illegible]}{6} = [illegible]$$

pounds per square inch. If

$$\frac{r}{I_1}\left\{\tfrac{3}{8} M_b + \tfrac{5}{8}\sqrt{M_b^2 + M_t^2}\right\} = f,$$

the shaft is safe.

Book Reviews

THE GAS ENGINE. By Forrest R. Jones. Published by John Wiley & Sons, New York, 1909. Cloth; 455 pages 6x9 inches; 142 illustrations. Price, $4.

This book has the merit of presenting a treatment of the subject which differs from the usual testbook routine, as well as some material not ordinarily found in such books. The author devotes a rather disproportionate amount of space to automobile practice and a correspondingly meager quantity to stationary engines. The discussions of ignition systems, the physical properties of gases, combustion, fuels and gas producers are especially clear and satisfying and the tables compiled from the Geological Survey coal-test report will be found of immense convenience by anyone practically interested in gas producers.

NOTES ON HYDROELECTRIC DEVELOPMENT. By Preston Player. McGraw Publishing Company, New York. Cloth; 68 pages, 4¾x7 inches. Price, $1.

This little work is intended to indicate general lines along which investigation should be made to afford a basis for forming a correct opinion of the merits of any proposed undertaking in the line of hydroelectric power-plant development from the investor's viewpoint. Generating electric energy has reached such a degree of perfection that what competition means must be thoroughly understood before hydroelectric enterprises are taken up. The author has divided the work into two basic inquiries: "What will be the cost of making any development?" and "What receipts may be expected from the undertaking?" and he has presented an intelligent method of seeking correct answers to the inquiries.

HEAT ENERGY AND FUELS. By Hanns von Jüptner. Translated into English by Oskar Nagel. McGraw Publishing Company, New York, 1908. Cloth; 310 pages, 6x9 inches; 118 illustrations; 137 tables. Price, $3.

Barring Chapter II, on Forms of Energy, Professor von Jüptner has produced a remarkably clear-cut and useful textbook. The title is somewhat a misnomer and the confused and abstruse discussion in the chapter mentioned could have been omitted with distinct advantage. The author's attempt to explain work in terms of distance, surface and volume is not clear and might easily be misleading to a student.

The remainder of the book deals with fuels, their analysis, their utilization by combustion and partial combustion, and the measurement of high temperatures. This part, constituting the bulk of the work, is excellent. The tables giving the composition of various grades of the different fuels could have been made more convenient for general reference by grouping them together in an appendix, but as the book was written for college use, the location of each table in the text referring to it is but logical.

The discussions of peat and lignite, which usually receive scanty attention in a book of general character, are most satisfying and the chapters on producer gas and water gas and the means of making them are particularly complete and clear.

ALTERNATING CURRENT MACHINES. By Samuel Sheldon, Hobart Mason and Erich Hausmann. Published by D. Van Nostrand Company, New York, 1908. Cloth; 360 pages, 5½x8 inches; 236 illustrations. Price, $2.50.

This is the seventh edition of Dr. Sheldon's excellent textbook, and it shows the effects of extensive revision. The original edition of the book impressed the reviewer as being a conspicuously fine example of college textbook, and an honest opinion of the present edition might be regarded as fulsome eulogy, so the reviewer will refrain. It may be well to inform those who are unfamiliar with the work that it is intended for use in technical colleges and not for unassisted study by beginners. It is remarkably clear in exposition, but a knowledge of mathematics as far as elementary calculus is necessary for the student to derive the proper degree of learning from its contents.

WASHING AND COKING TESTS OF COAL. By A. W. Belden, G. R. Delamater and J. W. Groves. Issued by the United States Geological Survey, being Bulletin 368. Paper; 54 pages, 6x9 inches; illustrated. Gratis upon application.

The investigations described in this report were undertaken by the Government for the general purpose of increasing efficiency in the utilization of the fuel supply of the United States by devising improvements in washing and coking coals. The washing tests of coal were made to determine the possibility of so improving the quality of the coal as to render it available for the production of coke. The coking tests were made to determine the possibility of utilizing the various coals in this way or to devise improvements in coking practice. The washing tests have demonstrated the fact that many coals which are too high in ash and sulphur for economical use under the steam boiler, or for coking, may be rendered of commercial value by proper treatment in the washery. The coking tests have demonstrated that many coals which were not supposed to be of economical value for coking purposes may be so rendered by proper treatment in the washery and coke oven. The bulletin describes the washery plant established by the Survey at Denver, Colo., and gives the analyses of and the results obtained with numerous coal samples.

Books Received

"The Internal Combustion Engine." By H. E. Wimperis. D. Van Nostrand Company, New York. Cloth; 326 pages, 5¼x8½ inches; 114 illustrations; tables. Price, $3.

"Heavy Electrical Engineering." By H. M. Hobart. D. Van Nostrand Company, New York. Cloth; 338 pages, 5½x9 inches; 188 illustrations; 19 plates; tables; indexed. Price, $4.50.

"The Theory of Electric Cables and Networks." By Alexander Russell. D. Van Nostrand Company, New York. Cloth; 269 pages, 5¼x8½ inches; 71 illustrations; indexed. Price, $3.

"The Mechanical Appliances of the Chemical and Metallurgical Industries." By Dr. Oscar Nagel. Published by the author. Cloth; 307 pages, 5¾x9¼ inches; 292 illustrations; indexed. Price, $2.

"Steam Pipes, Their Design and Construction." By William H. Booth. The Norman W. Henley Publishing Company, New York. Cloth; 183 pages, 5¼x8½ inches; 62 illustrations; tables; indexed.

Obituary

Jasper R. Rand, vice-president and director of the Ingersoll-Rand Company, died of pneumonia in Salt Lake City on March 30. Mr. Rand was the son of Jasper Raymond Rand, one of the founders of the Rand Drill Company, and was born in Montclair, N. J., September 3, 1874. He was graduated from Cornell University in 1898 with the degree of mechanical engineer, and served in Porto Rico in the Spanish-American war as a member of the first New York Volunteer Engineers. During 1899-1900 he was president of the Imperial Engine Company, at Painted Post, N. Y., leaving that position to take the presidency of the Rand Drill Company, which he held until 1905. In that year he was elected vice-president and director of the Ingersoll-Rand Company, which was his chief interest until the last. Mr. Rand was a member of Alpha Delta Phi fraternity, of the Spanish War Veterans, of the American Institute of Mining Engineers, of the American Society of Mechanical Engineers, of the Engineers' Club, of the Cornell Club and of the Alpha Delta Phi Club of New York.

Personal

E. Whitaker, formerly chief engineer of the Weil & Mayer buildings, New York City, has become an inspector for the Engineering Supervision Company, also of New York.

Harnessing Power in Greater New York

The Work of the Boiler Inspection Bureau; How Engineers and Firemen Are Licensed, and How Life and Property Are Safeguarded

BY A. C. ROWSEY

Deep-rooted in the mind of the average New Yorker was a thought that filled his soul with peace as he read of the devastation of San Francisco and Messina. It was the thought that his city, his "Great New York," is not likely to be visited by such upheavals; his is a city upon a rock, against which the might of the elements would unavail. But he was unaware, and he does not today realize, that mightier than the force of any earthquake, the heat-and-power channels of his city, honeycomb its rock foundation and the city is really resting upon a many-mouthed volcano roaring with millions of units of power capable of causing a cataclysm

[illegible] HANSON, THIRD DEPUTY POLICE COMMISSIONER, NEW YORK

almost greater than the mind of man can conceive.

Fettered and guarded by sleepless eyes, this titan force throbs and struggles in stupendous potentiality under the very sidewalks of the city, upon which the New Yorker, blissfully unconscious of danger, treads to and from his affairs. From the subcellar of his office building it threatens death and destruction. And as he sleeps in contented ignorance, the monster in the basement is struggling frantically to shatter the house and rend its tenants.

Three times in forty-six years it has broken some of its manacles. It may break another any day. But twenty-eight men, the staff of the Boiler Inspection Bureau of the police department, hold with a tight grip the reins of a living harness made up of the interwoven responsibilities of 1400 firemen, 12,716 engineers and 7000 patrolmen. A flaw in a fetter may not release the giant, but if traceable to the neglect of any man in the harness it means the ending of that man's connection with the organization, be he engineer, fireman or patrolman.

No city in the Union is without its subterranean monster of heat and power, but New York is peculiar in that the control of it is so nearly perfect. In less than twenty-four hours it can be strangled to death and every engineer and crew mobilized at police headquarters.

A cursory reading of the annual reports of Police Commissioner Bingham, or of his predecessors, gives but a faint idea of the importance and varied activities of the work and the system of the boiler inspection bureau under Third Deputy Commissioner Hanson's direction. Still less does it yield clean-cut outlines of boundaries of responsibilities of the bureau, engineers and owners in the enforcement of the so-called "Engineers' License Law." For this reason, inspectors and examining engineers from nearly every State are frequent visitors to the bureau to form a closer acquaintance with the system.

Wherever a new system of State or municipal supervision of heat and power is organized its model has been found in the New York bureau. That its adoption has not been more general is due to the estimated cost of operation. Yet in New York its maintenance is only slightly in excess of its income, while its income is a very welcome contribution to the city's police-pension fund.

Incidentally, the maintenance cost is absurdly small compared to the tremendous supervision for which a staff of only twenty-eight men can, with accuracy and precision, reach every boiler, yield engineer or fireman to every boiler room in the city within a day, and [illegible] down any or all plants in [illegible].

Cost of Administration and [illegible]

The entire cost of administration is [illegible] annually. The income during [illegible] was [illegible]. Old debts collected [illegible] this sum to [illegible]. The cost of administration is distributed as follows:

[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
Total	[illegible]

The [illegible] of the bureau is derived from the annual compulsory inspection of every boiler in the greater city. For this inspection a fee of $[illegible] per boiler is charged, if a boiler is found in good condition. If the boiler is condemned, ordered repaired or shut down for any cause, no license to operate is issued and no fee is collected. Thus, in [illegible] there were 17,[illegible] boilers in New York. If they had all been found in good working order

[illegible]

the revenue would have been $[illegible] and the [illegible] would have been within $[illegible] of the [illegible]. But of the total number only [illegible] were found to be in good working order and licensed for a year. [illegible] of the [illegible] not licensed were [illegible] the boilers and had been removed out of the city, some going to [illegible].

It may be interesting to [illegible] how these boilers are distributed:

[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

Portable, for scows	119
Portable, for barges	255
Portable, for schooners	5
Portable, for elevators	5
Portable, for steam carriages	7
Portable, for floating baths	1

Inspectors and Inspection Districts

To facilitate the inspection of these boilers the city is divided into nine inspection districts, and one inspector detailed to each district. Seven of the inspectors are patrolmen, who were formerly boilermakers, engineers or machinists;

JOHN LYNCH, EXAMINING ENGINEER N. Y. BOILER SQUAD

two are Civil Service appointees. Each is provided a horse and wagon, a driver and a hydrostatic pump. The inspectors are assigned as follows: One to Staten island, borough of Richmond; one to the borough of Queens and precincts 160 and 161; two to the borough of Brooklyn and Coney island; one to the borough of the Bronx; four to the borough of Manhattan (four districts).

Upon the inspectors' reports licenses are made out in duplicate. One copy is sent to the owner of the plant and the other is given to the engineer. The law declares that the license must be paid for within twenty-four hours. City departments, however, have a habit of holding up payments for their licenses two or three months, and while bad debts against private boiler owners may be turned over to the corporation counsel for collection, it is impossible to sue city departments.

As soon as a license is made out Lieut. Henry Breen, who is in command of the bureau, becomes personally responsible to the police department for the fee or the license; he must have either one or the other. Recently, in clearing up the books, he discovered a debt, against a boiler in Brooklyn, incurred thirteen years ago, before the consolidation. The corporation counsel collected the fee for him.

Incidentally, owing to the more intensive service demanded of boilers, the vigilance of the inspectors has been increased, it having been found that the modern boiler deteriorates more rapidly than the old-style, and that the standard of life—twenty years—of a boiler is fast being lowered.

The fee of $2 a year paid by the owner entitles him to three distinct guarantees upon his plant: (1) That his boiler is safe; (2) the privilege of ascertaining the ability of his engineer to take care of his plant; (3) the privilege of ascertaining the qualifications of the firemen to do their work. Thus, for $2 paid for the annual inspection of a boiler, the boiler-inspection bureau undertakes, when it issues a license, all the responsibility of the boiler room where the licenses will hang. This brings us to the supervision of the boiler-room crews of the city:

Supervision of Boiler-room Crews

A coal passer, oiler or general assistant to an engineer, who is a citizen of the United States either by birth or adoption, and has served his two years, may be promoted to fireman, if the owner of a plant in a communication to the bureau signifies his desire to have the employee examined as to his qualification for such a position, the chief engineer under whom the man works at the same time certifying the time of employment in his room and that he is a person of good character, both of which statements must be sworn to.

According to the law the apprenticeship "on a building or buildings in the city of New York or on any steamboat, steamship or locomotive" must be "for a period of not less than two years;" but unless the owner states in the letter with the application that he wishes to employ the man at a certain plant, the applicant will be refused the examination for a license. The formalities being O. K., however, the board of examiners of the bureau will give the applicant a practical test in the care of a boiler, and if he is found competent he will be granted a license, within six days, good for one year, but at any time revokable by the police commissioner or the board of examiners appointed by him, upon proof of deficiency in a trial before the bureau's examiners who issued the license. Should an owner or lessee employ a man as a fireman or engineer who is not licensed for the particular plant at which he is at work a week's notice to quit is given. If the man is not supplanted, the owner or lessee may be arrested for "endangering life and property."

Requisites for Third-grade Applicants

Should a fireman, oiler or general assistant to a licensed engineer of New York City wish to take an examination for the position of third-grade engineer, the first requisite is a letter from an owner asking that the man be examined as to his capacity to handle the plant (stating the full equipment of the plant) as a third-grade engineer. The second requisite provides for verified statements from three licensed engineers in good standing in New York City, who must state where and when the applicant put in a total of five years' working time in boiler rooms. One of these statements must be rendered by the chief engineer under whom he put in the last part of his time, and all the statements must be verified before notaries.

An application blank is then given the applicant. In this he must state that he is at least twenty-one years of age, a citizen by birth or naturalization, and if the latter the date and place of his naturalization, his weight, hight, the color of his hair and eyes, and the dates, addresses and numbers of the boilers upon which he has put in his time. He is required to swear to the accuracy of these statements, which must be in his own hand-writing. The bureau then gives him three vouchers, to be filled out by the engineers who have already certified for him, these vouchers being in affidavit form and de-

MICHAEL FITZPATRICK, EXAMINING ENGINEER STEAM BOILER BUREAU, N. Y.

claring that the statements made by the candidate in the application are true to the endorsers' own knowledge. The vouchers must be sworn to, also. When he hands in the signed vouchers the applicant is slated to take the examination for third-grade engineer.

The Bureau Busy in the Meantime

While the candidate has been busy getting his vouchers signed a searching inquiry has been going on in the bureau.

Every boiler that has ever been in New York is represented by a card in an elaborate card-index system. A boiler can be located by its means in two minutes, either by knowing the name of its owner, or its license or serial number, location (past or present), or by the name of any engineer or fireman who has ever worked upon it.

In like manner, every licensed engineer and fireman can be located in an equally short time, every room they ever worked in and the number of the boiler in each place can be ascertained. A glance at a few cards gives an accurate description of the personal appearance of each engineer and fireman and a detailed itemization of plants they have handled. There is no guesswork, the information is compiled every day.

More than this, the signature of every engineer or licensed fireman can be found by looking at the date of his last visit to the bureau, which is recorded on his card, and glancing under that date down the alphabetically arranged pages of the "Signature Book" which every engineer and licensed fireman signs when he calls for the renewal of his license, or for a transfer to another plant.

Thus, when the applicant for examination for third grade engineer appears and says he is a licensed fireman, and shows a license issued to "John Doe," fireman on boiler No. —, the card for Fireman John Doe is taken out. If it says that John Doe has red hair and the candidate for engineer's license has black hair, he is known to be a "ringer" sent by the red-haired one to take an examination for him. Trouble gathers for him with the red hair, while he with the black hair is arrested and the vouchers are summoned to the bureau to explain.

Again, the chief engineer who swears that John Doe worked for him five years on boiler No. —, may be discovered by the index cards to have been less than five years in charge of that boiler. His card may show that he has been either out of work, out of town, or working at another plant part of the time. Trouble starts for him, for he has perjured himself twice, once in the voucher verifying John Doe's statement and once in his preliminary certification.

Then, too, the cards of all of the certifying engineers may show that they did work on the boilers for the time they stated, and as stated by John Doe, but the signatures to their statements and vouchers may bear no resemblance to their signatures in the "Signature Book." John Doe is then in hot water. He has committed forgery. It will be seen that the system effectually checks fraud before an examination takes place.

THE EXAMINATION

When the papers are found to be correct the candidate is taken in hand by Patrolmen Michael Fitzpatrick and John Lynch, both licensed engineers. Their examination is wholly oral. It does not pretend to follow the model of the Civil Service. The examiners must be satisfied that the candidate will not endanger life and property if placed in charge of a plant. To this end they examine him upon the following subjects: Construction of boilers, connections to boilers, care of boilers, construction of pumps, operation of pumps, construction of engines, operation of engines.

There is a large slate on the table before the candidate. He may figure and rub out as much as he chooses, all under the eyes of the examiners. As the subjects are covered, a rating is given on the back of the application. There is no point system; the terms used are "Excellent," "Good," "Fair," "Poor." If he gets "Poor" on the first five subjects he is bound to be "Poor" on the balance and will be rejected. "Good" on the first five will counterbalance "Poor" on the last two.

Assuming that the applicant passes for the grade, he is then put through a second examination, this time upon the handling of the equipment to which he is going. If the plant consists of a tubular boiler and a pump, 80 pounds pressure allowed, and he shows himself able to handle it, he is given a license, but it will read that he is a third-grade engineer, licensed to operate "one tubular boiler, No. —, and a pump with 80 pounds pressure," at that one plant only.

A card is prepared for the index file and the number of the boiler, the equipment of the plant, his examination rating, his address, the address of the plant and the date of his examination for the grade are recorded on the card. He is then ordered, under pain of having his license suspended or revoked if he violates the order, to make an absolutely truthful report of the condition of his plant every month. He is told that the bureau reserves the right to inspect his plant any time of the day or night, and if he is caught with defects not reported, or exceeding the pressure allowed, he will be taken into custody for endangering life and property.

If he goes on strike after beginning the day's work and leaves the plant unguarded, he is liable to arrest for misdemeanor. If he is caught intoxicated the mildest penalty will be a year "on the shelf," the severest, denial of the right to work in New York at all. And he is given an exact history of the boiler, its age, repairs, defects and peculiar danger points.

By this it can be seen that the [illegible] of the administrative work of twenty-eight in the bureau is, by license, [illegible] through the virtual appointment of every engineer in charge of a plant an inspector without pay but with full burden of the responsibility of his particular plant upon his shoulders.

MONTHLY REPORTS

The monthly reports, which are printed, are made upon blank forms. Their questions must be answered clearly and they cover the entire plant. If a defect is noted an inspector from the bureau makes an official test. Upon his report the bureau has power to compel repairs or to shut down plants.

Thus a full detailed inspection of the 17,464 boilers of New York takes place every month and, with the annual official test, there are really thirteen actual inspections a year at the cost of only $2 per boiler. Incidentally, making the engineer an inspector by virtue of his license means the stationing of an attaché of the bureau in every boiler room in the city.

In addition to this supervision, there is at the service of the bureau the entire force of 7000 patrolmen of Greater New York, to enforce its regulations on owners and lessees, engineers and firemen, to insist upon repairs, to prevent the operation of condemned plants or boilers and to prevent the employment of unlicensed crews.

Is a complaint received that an unlicensed engineer is operating a boiler? By telephone the complaint is transmitted to the nearest police station. A man from the reserve force hurries to the boiler room and demands to see the engineer's license. If he has none, he takes the engineer back to the station house together with the owner or lessee, if he can find him. The bureau prepares the prosecution.

Is an unlicensed boiler installed somewhere? Again, the station house is notified and the man on reserve [illegible] to arrest the man in charge, be he licensed or not.

Is a boiler going into a building? The patrolman on post notifies the bureau. If the bureau has no information of the plant, it will send an inspector to find out why the boiler is [illegible].

Is there a drunken fireman or engineer in a boiler room? The man on post arrests the unfortunate. The plant is closed down and a report is made to the bureau, [illegible] of that boiler room [illegible]. Charges are made against the guilty man and he is given a trial before the examiners who licensed him. On that [illegible] he is [illegible] of his license [illegible] for good and all. The index card records his fate.

[illegible]

but one responsibility, that of making prompt repairs when notified.

Neglect on the part of the owner results in the bureau reaching out with that long arm, the uniformed force, and taking actual control of the plant, even, as the law states, "in cases deemed necessary, the appliances, apparatus or attachment for the limitation of pressure may be taken under its control."

Others Eligible for Third-grade Licenses

The fireman, oiler or general assistant for five years to a licensed engineer of New York City, heretofore referred to, are not the only persons eligible for examination for a third-grade engineer's license. Those equally eligible are a fireman, oiler or general assistant to the engineer on any steamship or steamboat, or any locomotive engineer, for five years, who shall have been employed for two years under a licensed engineer in a building in New York City; a fireman, oiler or general assistant to the engineer on any steamship or steamboat, for the period of five years, who shall have been employed for two years under a licensed engineer in a building in New York City; or a fireman, oiler or general assistant who has served as a marine or locomotive engineer or fireman to a locomotive engineer for a period of five years and has been a resident of the State of New York for a period of two years; or a person who has learned the trade of machinist or boilermaker or steamfitter and has worked at such trade for three years, exclusive of time served as apprentice, or while learning such trade; and also any person who has graduated as a mechanical engineer from a duly established school of technology, after such person has had two years' experience in the engineering department of any building or buildings in charge of a licensed engineer of New York City.

Unless the stranger in New York can show a certificate as engineer issued to him by a duly qualified board of examining engineers existing in pursuance to law in a State or Territory of the United States, and can prove that he is the identical person to whom the certificate was issued, he will not be permitted to take an examination for an engineer's license.

In some States and Territories there are no legal boards of examiners of engineers; men from those States, although they may be experts and may have served twenty years in boiler rooms, are absolutely debarred from the supervision of boilers in this city. Their local union cards are not received as credentials.

After the license is granted it lies with the examiners whether the engineer shall do the work he wants to do or not. Although the owner of a portable hoisting engine requests the examination of a man who has come out of an office building and is willing that he shall run his engine, the board may and does decline to permit him to undertake the place, on the ground that an office-building man, never having worked on hoisting machinery, is liable to kill someone. So they exercise discretion in permitting men to work on different classes of work.

Three Grades of Engineer

The bureau recognizes three grades of engineer, third, second and first. The third grade alone is compulsory for the care of a plant. The second grade may be obtained after two years in the third grade. The examination takes in the operation and care of dynamos. The first-grade examination may be had at the request of an owner, as in every other case, after one year in the second grade. The subjects are operation and care of ice machines, use of the steam engine and indicator.

The owner of a building, whose candidate for fireman or any grade of engineer fails to pass his examination, has the right to send two licensed engineers to the bureau to examine the candidate upon the subjects given. The bureau reserves the right to instruct its examiners to interrogate the candidate on the same subjects where they find the visitors were not sufficiently painstaking.

In Boston and a few other large cities, the horsepower and steam pressure regulate the grade of an engineer. In New York, however, a third-grade engineer may be found operating a huge plant. There is no legal provision against this.

PORTABLE ENGINEERS' PLANT CARD

it has been pointed out as a weakness in the system. But it is only fair to say that although men in charge of some of the largest plants in the city have only third grade licenses, they are invariably men of superior ability, and often graduates and post graduates of technological institutes, who could pass with ease almost any kind of an examination in mechanics.

Restrictions of Licenses

Although the engineer's license is good for one year, it is only theoretically so. Practically, the license is good for one year provided the engineer remains in charge of the particular plant it covers for a year. A system of transfer examinations prevents him from "free-lancing" about the city on his one year's license and brings him to headquarters as soon as he leaves his job, for examination, at the request of the next prospective employer, upon his ability to handle his new plant.

For, pursuing its actuating principle, the safeguarding of life and property, the bureau has divided engineering into five distinct classes as follows:

(1) Portable, double drum.
(2) Hoisting.
(3) Steam shovel.
(4) Engineer in charge of shafting.
(4) Engineer in charge of office building.

If a man leaves an office building and is sent by the owner of a hoisting plant to the bureau for examination as to his fitness to run his plant, he will be rejected unless his index card shows that he has had experience in running a hoisting engine previous to his last place in the office building. If he insists that he has had experience not on the card, he is given an examination on running a hoisting outfit. If he cannot satisfy the examiners that he will not kill anyone, he is refused a transfer to the new job. His place in the office plant being filled, his license is of no value to him, for he cannot, although licensed for a year, run any boiler in the city until he has been transferred to it by the bureau.

So through each of the divisions of engineering. If experience is shown, the transfer is granted.

It can easily be seen that this system of licensing, for particular plants, examination on the floor, transfers and examinations for transfer and the practical suspension of the license during periods of idleness, all recorded on the card index, give the bureau an absolute measure of the ability of every fireman and engineer in the city, their movements and past performances day by day and their whereabouts at all times. They can never get away from the supervision of the bureau once they are licensed.

Establishment of the Card-Index System

Previous to the appointment of Deputy Commissioner Hanson, about three years ago, all these records of the bureau were kept in huge books. They were awkward to handle, their pages were torn and dirty and some of the writing had become illegible from many causes. The information they conveyed was incomplete.

After looking over the work of the bureau, the deputy commissioner decided to bring it up to date. To that end he installed Lieutenant [illegible] and half a dozen young patrolmen, and proceeded to reduce the records to card-index form. It took [illegible] nearly a year before the task was completed. At the end of that time the heavy books were closed. [illegible] synopses on the reverse of each card [illegible] back to the books but rarely, [illegible] assertion, but the synopses on the cards are found generally to be sufficient.

At that time the headquarters of the bureau were located in Manhattan and a branch was maintained, with separate records and files, at Brooklyn police headquarters. Shortly after the cards were completed, the deputy commissioner closed the Brooklyn branch and centralized the activities in the Manhattan bureau. This has necessitated a renumbering of all the cards into one general index covering all boroughs. The consolidation created an immense amount of labor, but the result in increased efficiency and economy of administration is more than compensating.

The index is arranged under the following subject heads: "Boilers," "Portable Boilers," "Stationary Boilers," "Idle Boilers," "Boiler Tests," "Engineers," "Portable Engineers," "Stationary Engineers," "Firemen," "Portable Firemen," "Stationary Firemen."

For permission to copy the engineers' cards a donation of $500 to the police pension fund was offered Commissioner Bingham. The offer was rejected.

The steps of certain of these cards, reproduced herewith, illustrate the contents of the cards. They are back-checked by a second series under the following heads: "Street and Number Address of Plants," "Boilers in the Bronx," "Boilers in Queens," "Boilers in Richmond," "Boilers in Manhattan," "Street Numbers of Plants in Greater New York," "Owners of Plants in Greater New York."

The illustrations are of the "Engineer's Card," "Stationary Engineer's Plant Card," "Portable Engineer's Plant Card" and "Boiler Test Card." The fireman's cards are similar. The engineers' and firemen's cards as well as the owners' plant cards are good for [illegible]

STATIONARY ENGINEERS' PLANT CARD

records. All the cards are 7x9¾ inches in size, ruled front and back, and each is of a color different from the others.

The boiler cards are reviewed every day and those due for the annual inspection are listed. Ten days before the day the inspection is due, a notice is sent to the engineer. He is required to be ready for the hydrostatic-pressure test. So as to delay and inconvenience the owner or lessee as little as possible, the day and hour of the inspector's call are given.

Inspectors' Reports

The bureau then routes its inspectors overnight and knows just where they are working. Pressure one-third more than that allowed is the standard test. On their return every day to the bureau, the inspectors' reports are compiled, and where licenses are issued entries are made in full in the boiler accountbook. The license is made out and the following day it is on its way to the plant by messenger, a patrolman. He is charged with so many specified, numbered licenses and must bring back the license or the fee. City departments alone receive credit. Others must pay on delivery.

Payment for Licenses

Upon receipt of a couple of hundred dollars, entries of which are made in a boiler cashbook and checked off with a date stamp on the boiler accountbook, the money is sent to the bookkeeping department of the police department, where the custodian of the pension fund, under bond, certifies to receiving payment for licenses whose numbers are given, together with the serial numbers of the boilers. He has a full set of the serial numbers so that at a glance he can see whether all the listed boilers have been licensed. If they have been licensed and there is no fee, it is up to the bureau to explain. If there is no license issued to a boiler it shows plainly in the blank space opposite the unchangeable number of the boiler.

Boilers condemned retain their numbers, but are assorted as "Idle Boilers," until new boilers are installed. The numbers are then given to the new boilers. Where plants go out of business after the condemnation of a boiler and take power from some other source, the fact is noticed on the boiler card.

The Guiding Principle of the Bureau

In all its operation the bureau is guided by the one principle, the saving of life and property, to which it owes its creation. In 1862 the number of boiler explosions in New York became alarming. It was rumored that there was a plot to blow up the city. A committee of citizens was appointed to investigate. Unable to perform the task, they called in the police. Patrolmen were placed on guard in the boiler rooms of the city.

Gradually the work drifted into the hands of the police, and the bureau, the first of its kind in the world, was organized as part of the police department's supervision of life and property.

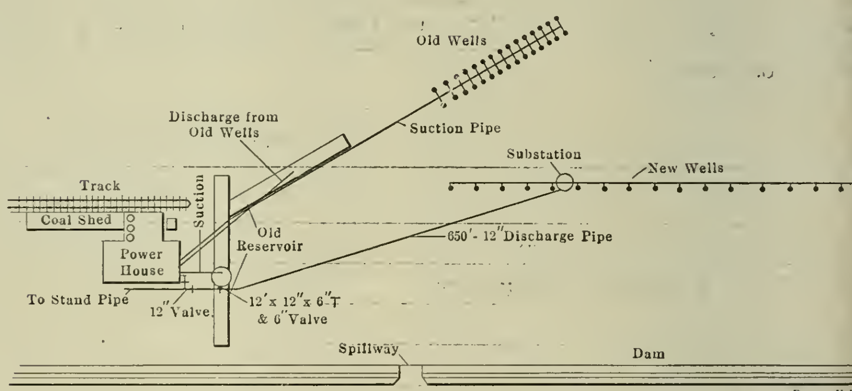
There have been several unsuccessful attempts to remove the bureau from police-department supervision.

Municipal Plant at Marshfield, Wisconsin

By Louis B. Carl

In 1904 the city of Marshfield, Wis., purchased the local electric-light plant and water works for $150,000. The power house was 1½ stories, the engine room, 36x84 feet, containing two 12x15-inch high-speed McEwen engines operating at 270 revolutions per minute, belted to two 50-kilowatt 1100-volt 133-cycle Westinghouse and Fort Wayne alternators; a No. 8 Wood arc machine; a 20 and 12 by 15-inch Worthington and a 16 and 8 by 15-inch Smedley duplex steam pumps, used to pump water into a standpipe 15 feet in diameter by 120 feet high, located about two miles from the plant. The Smedley pump was so connected as to be able to pump from thirty-two 2-inch driven wells into the standpipe or into the reservoir, or from the reservoir into the standpipe. The Worthington could pump only from the reservoir into the standpipe. With the exception of a small spring in the reservoir, the thirty-two wells constituted the entire water supply for a city of about 7000 people. The wells were driven about 22 feet and when working at their best did not give over 75 gallons per minute. The switchboard was of wood, and was equipped with the necessary meters, switches, etc.

The boiler room adjoins the engine room on the east, being a 35x40-foot 1½-story brick building containing two 60-inch by 18-foot return-tubular boilers, an "Excelsior" feed-water heater, a 6 and 4 by 6-inch Fairbanks-Morse duplex boiler-feed pump and a "Metropolitan" injector. The uptakes were connected to a brick chimney 88 feet high, with an internal diameter of 4 feet and an external diameter of 8 feet at the base and 6 feet at the top. There were also a 70-kilowatt Wood alternator and a No. 8 arc machine located in a factory and used to carry the load part of the time.



PLAN OF GROUNDS, MARSHFIELD (WIS.) PLANT

The outside work consisted of about 5 miles of transmission lines, with 38 arc lamps, and about 7½ miles of 12-, 10-, 8-, 6- and 4-inch cast-iron water pipe. One hundred and twenty acres of second-growth timber, on which the plant was situated, went with the purchase. In 1907 the people voted $35,000 of improvement bonds for the purpose of rebuilding the plant and obtaining a reliable water supply.

The Remodeled Plant

In the engine room, as remodeled, are two generating sets, one consisting of a 14x30-inch Corliss engine running at 120 revolutions per minute, and driving with a 15-inch double leather belt a 100-kilowatt 2300-volt 60-cycle alternator running at 900 revolutions per minute, and the other unit comprising an 18x42-inch Corliss engine running at 100 revolutions per minute, and driving with a 30-inch double leather belt a 225-kilowatt 2300-volt 60-cycle alternator running at 600 revolutions per minute. The exciters are direct-mounted on the generator shafts.

The generators and engines are of the Allis-Chalmers standard make. The engine cylinders are lubricated by Manzel automatic force-feed lubricators and the bearings are supplied from a gravity-oiling system, consisting of a 100-gallon tank located near the roof and connected to the different bearings by brass pipe. The eccentrics are lubricated with Albany grease. All the drains lead to a three-section Turner oil filter, having a capacity of 75 gallons per twenty-four hours, located in a basement between the engine cylinders. The oil is elevated to the tank by a small rotary hand pump.

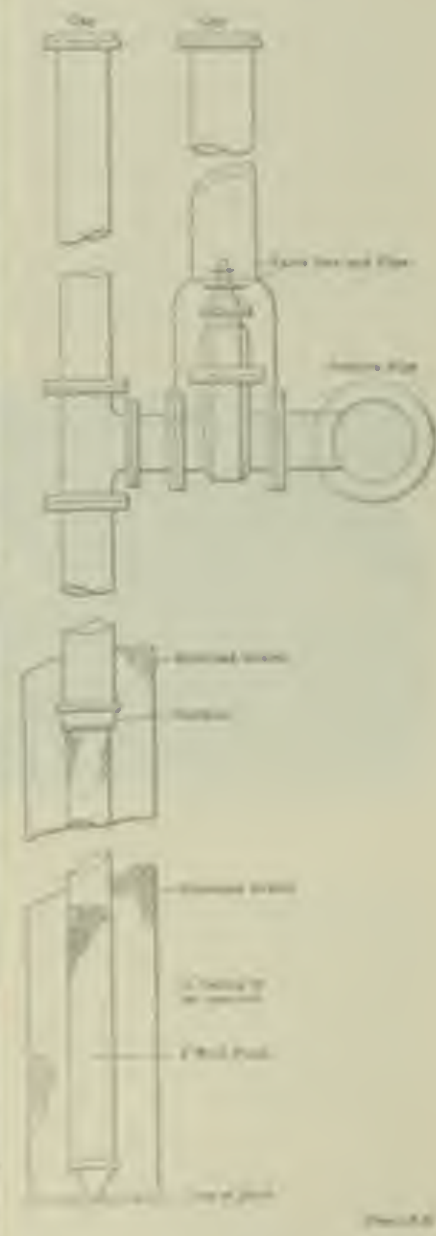
The switchboard consists of four 30x90-inch Vermont blue-marble panels, of which two are generator panels containing three ammeters, one voltmeter, one 3-pole 3000-volt automatic oil switch, one field switch and a ground-detector lamp, with the necessary plugs. There is a swinging bracket located on the 100-kilowatt generator board containing a synchroscope and exciter voltmeter. There is one feeder panel containing three ammeters and three oil switches, also a 3-phase wattmeter.

The remaining panel is for the arc system and contains one ammeter, one oil switch, three stab switches for each of two circuits and one 3-phase wattmeter. At the right of the switchboard is located the arc-lighting apparatus, consisting of two Fort Wayne 35-light tub transformers, with regulators supplying 52 arc lamps. All leads from the generators to the switchboard are lead-covered cables laid in conduit. The lightning arresters are mounted outside of the building. There is also located in this room a motor-starting panel of slate, 24x60 inches, containing one automatic 3000-volt 20-ampere double-throw oil switch and one three-phase wattmeter. In the back of this board are mounted two 200-horsepower auto transformers.

In the boiler room there are three 18-foot by 72-inch return-tubular boilers, containing seventy 4-inch tubes and having 30 square feet of grate surface. The boilers have "American" pop safety valves and steam gages. There is a separate stack to each boiler, 36 inches in diameter and 100 feet above the ground. The feed-water apparatus consists of a 200-horsepower Cochrane open heater, which heats the water to 208 degrees Fahrenheit, a 6 and 4 by 6-inch Gardner duplex feed pump and an 8 and 5 by 10-inch Marsh pump. The feed pipe from the pumps to the front of the boilers is 2-inch brass, to which each boiler is connected by a 1½-inch brass pipe having two gate and one check valves. The blowoff is 1½ inches in diameter and contains a gate valve and a blowoff valve with renewable disk. Wilmington lump coal is used, having a heating value of about 11,000 B.t.u. and costing $2.50 per ton in the bin. The coal is weighed and brought into the boiler room in a car holding 1000 pounds. The storage capacity is 250 tons.

The piping consists of standard wrought-

TWO VIEWS IN THE ENGINE ROOM OF THE MUNICIPAL PLANT AT MARSHFIELD, WIS.



ELEVATION OF WELL AND CONNECTIONS

iron pipe with extra-heavy cast-iron flanges and fittings; all bends are made with long-sweep elbows. Crane valves are used throughout the plant. The leads from the boilers, which are 6-inch and contain two valves, are connected to the top of an 8-inch header which is 60 feet long and has a drop leg at each end drained by traps discharging into the heater. The connections for the engines and the water-works pumps are all taken from the top of the header. Separators above the engine throttles are drained by traps located in the basement and discharging into the heater. A 5-inch header at right angles to and connected with the 8-inch header supplies steam for the feed pumps and whistle. All steam pipes are covered with air-cell asbestos covering.

New Wells for the Water Works

After a thorough test covering considerable territory it was decided to locate sixteen new wells about 600 feet south of the power house, spaced 45 feet apart.

Water-works Substation

At about the center of the line of wells a substation was built of brick, laid in cement and made water-tight. The substation is 18 feet below the surface and 10 feet above, having an inside diameter of 12 feet. In this station is located a vertical 3-stage DeLaval centrifugal pump running at 1120 revolutions per minute, with a capacity of 600 gallons per minute under a head of 120 pounds. A Westinghouse 75-horsepower 3-phase 2300-volt induction motor is located 14 feet above and direct-connected to the pump. This set is started by an auto-starting switch located in the engine room. As soon as the pump is started the pressure in the pump casing acts on a diaphragm and opens a valve, allowing oil to run into a gang feed, whence it is carried to the different bearings by brass pipe.

As the average pressure carried on this pump is 70 pounds, it was tested at that pressure and delivered 750 gallons of water per minute. To keep the wells sup-

SWITCHBOARD IN MARSHFIELD PLANT

VIEW OF MARSHFIELD PLANT

plied it was decided to build an impounding reservoir covering eight acres and holding approximately 25,000,000 gallons. A dam was constructed across a valley through which a ditch ran. This ditch drains about 1200 acres of land. After finding the direction of the underground flow, which is about 8 inches in twenty-four hours, two intake wells, 12 inches in diameter, were drilled to bedrock and filled with gravel, through which the water filters to feed the other wells.

They were drilled with a 12-inch drill which was followed up with a 12-inch steel casing until rock was reached, when a 4-inch point from 16 to 26 feet long was connected to a 4-inch pipe and lowered in the casing. The space between the point and casing was then filled with screened gravel to within 14 feet of the surface, where a tee was located in the well pipe which was connected to the suction pipe through a gate valve. The suction pipe varied from 6-inch at the extreme end to 10-inch at the pump. These are all flowing wells at the depth of the suction pipe which keeps the pump primed.

After the gravel was placed in the casing the casing was withdrawn. For pulling this casing, a heavy cast-iron collar, with an internal diameter of 15 inches, was slipped over the casing. Wedges having teeth on one side similar to a pipe wrench were then driven between the casing and collar. With the aid of two 30-ton hydraulic jacks the casing was pulled about 12 feet per hour.

In General

When the city purchased the plant there were about 4500 lights, whereas now there are 9500. The water connections have also been increased from 180 to 315. Nearly all the services were on a flat rate, but have now been changed to meter rates, for both light and water.

The city has also replaced all 4-inch mains with 6-inch pipe, besides having laid about 5000 feet of new 6-inch mains. There have also been installed 12 new hydrants and four arc lights. Although the average pressure carried is 70 pounds, in case of a large fire the standpipe can be shut off, when 110 pounds can be maintained at the hydrants by direct pressure.

The plant operates twenty-four hours per day with four men, two on each shift of 12 hours. The day load consists of about 75 horsepower in motors, besides the pumping.

Operating Expense

Although no exact records are available, the following will give a general idea of the operating expenses for November and December, 1908. As the steam pump uses about 650 pounds of coal per hour, that amount will be deducted. The pump operated 208 hours, therefore it used $208 \times 650 = 135{,}200$ pounds, which, deducted from the 626,000 pounds used during November and December, leaves 490,800 pounds to be credited to the rest of the plant; and 490,800 pounds at $3.50 per ton equals $860.30. Supplies and repairs cost $73.96, and labor cost $530, making a total of $1464.26. As there were 74,800 kilowatts generated,

$$\$1464.26 \div 74{,}800 = \$0.019$$

per kilowatt at the switchboard.

O. L. Dorschel is superintendent of the plant and had charge of rebuilding the system.

Proposed License Law for Philadelphia

There is an act before the legislature of Pennsylvania providing for the better protection of life and property by the competent operation of steam boilers and engines, and for the examination and licensing of engineers in charge thereof. It appoints a chief engineer and twelve assistants, one for each of the twelve districts into which the State is divided. Engineers holding licenses of cities of the first, second or third class, which are already provided for, shall be granted a license without examination. The fee is $3 when the license is granted and $1 for each renewal.

Danger from Water Hammer in Steam Pipes

Cases in which Water Hammer Damaged Piping and Valves; with Hints as to How These Conditions Might Have Been Avoided

BY HOWARD S. KNOWLTON

The importance of preventing water hammer in steam pipes is not always fully appreciated by operating engineers. The study of steam-plant accidents shows that every year lives are lost and property damaged through the fracture of pipes or valves by water hammer. A number of cases occurring recently are presented in the following paragraphs in the hope that engineers working with steam mains, valves and drains will be able to avoid similar troubles:

Case 1—The initial conditions were pipes 250 feet long, newly erected and uncovered. The drain to the trap, Fig. 1, was blocked by cement jointing material and rust. The stop valve A, cutting off steam from a boiler other than that shown, and the boiler shutoff valve B were closed in order to enable the joint at E to be repaired. The valve C was left open. Water accumulated in the pipe before the stoppage of the valves and cooled during the time of closure. When the valve B was opened a fracture occurred at the point shown. The steam pipe was of cast iron 6 inches in diameter, and the boiler pressure was 65 pounds per square inch. The cause of the fracture was the opening of the steam valve B, the mistake being to rely on a steam trap for draining a new pipe. A large drain cock, without a waste pipe, should have been fitted close to the pipe. The arrangement of the pipe was also bad, and it should have been fitted with a drain pipe provided with a small test cock, or a float telltale, and a large drain cock to be subsequently connected to a steam trap. The test cock or float would have enabled the engineer to ascertain if the water were below the horizontal length of pipe before he opened the drain cock or the valve B. Test cocks used in such cases should be very small, and opened for a short time only; otherwise the discharge from them may be sufficient to disturb the surface of the water in the horizontal length of pipe, and thus start the water hammer they are intended to prevent.

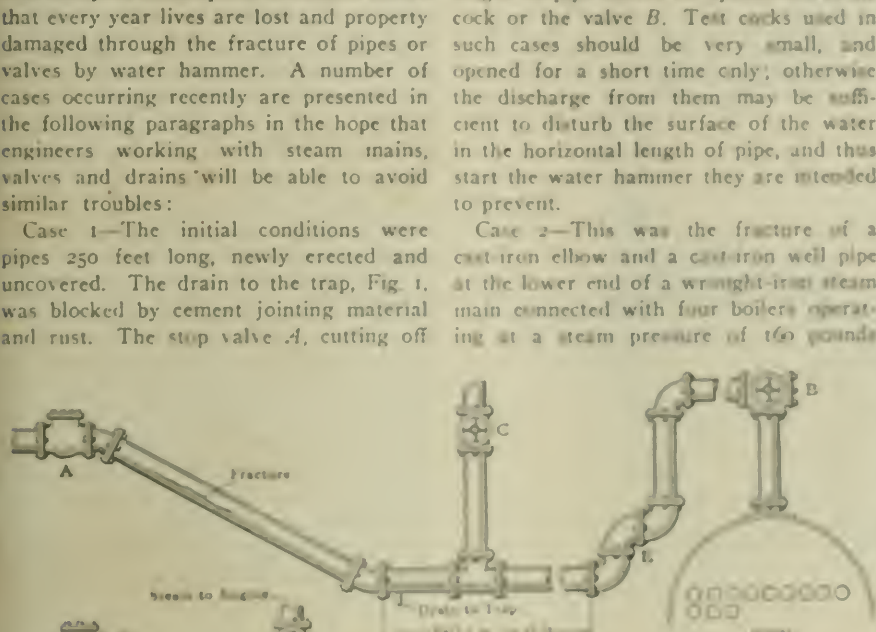


FIG. 1

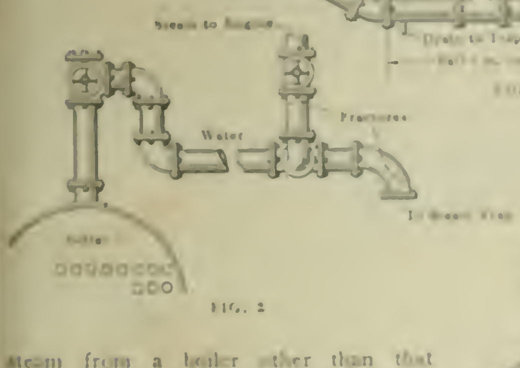

FIG. 2

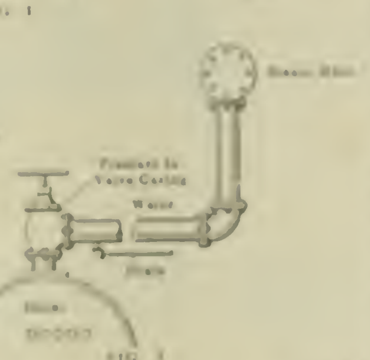

FIG. 3

Case 2—This was the fracture of a cast-iron elbow and a cast-iron well pipe at the lower end of a wrought-iron steam main connected with four boilers operating at a steam pressure of 160 pounds per square inch. The well pipe was drained by a steam trap and a drain cock. The stop valves on the boilers were left open during the shutdown of the plant on Sunday, and the lever or valve in the steam trap appeared to have stuck, so the trap failed to drain the lower end of the steam main. Fig. 2 shows the piping arrangement. On the opening of the drain cock to clear the pipes preparatory to starting the engine, a water hammer was set up which broke the bend and well pipe. The horizontal length of the pipe was filled with condensed steam. The fault was in assuming that the steam trap was keeping the system quite clear, and opening the valve to the engine without shutting the boiler stop valve. A well pipe fitted with a small test cock or a float telltale would have enabled the operating engineer to see if the pipe were clear.

Case 3—This was the fracture of a valve casing of the boiler valve by water hammer. The branch pipe connecting the boiler valve to the steam main, Fig. 3, which was similarly connected to twelve other boilers, was carried horizontally from the valve casing to an elbow, and thence vertically to join the main. The horizontal length was provided with a drain cock, which was usually left slightly open when the boiler valve was closed, as it had been for two days before the accident while the boiler was being cleaned, in order to keep the valve free from water. On this occasion the cock had either not been opened or had become closed by dirt, for a considerable quantity of water collected in the branch pipe. To clear the latter the cock was opened wide without shutting down the junction valves on the other boilers; the vertical part of the pipe was emptied and a considerable surface in the horizontal section exposed to the steam, when water hammer of sufficient force to break the valve casing occurred. The fault lay in opening the cock without first shutting the junction valves of all the boilers.

Where there is room over one boiler the pipes can better be installed as at A, in Fig. 4, or if this is impossible on account of head room, all the branches should be drained by large pipes without cocks or valves leading into an auxiliary pipe across the boilers, with a connection controlled by a cock to each boiler, so that when one boiler is opened its branch pipe will drain into the other boilers, as at B, in Fig. 4.

Case 4—This was the fracture of a cast-iron junction valve casing on a boiler, caused by admitting steam into a horizontal length of pipe half filled with water. There was a drain cock on the valve casing, but it was placed so high that no discharge took place until the pipe was half filled. The conditions, Fig. 5, were that one boiler was out of service for three weeks. The junction valve B was closed and the stop valve C, [illegible] boiler, was open at the time of the explosion. The drain to valve B was open and the stop valve A leading to the other boilers was shut 15 hours before the explosion. The construction [illegible] tained water, and possibly also the 7-inch pipe up to the level of the drain. The water hammer was produced when the stop valve *A* was opened to give steam to the engine, the fault being in opening the valve *A* before closing the valve *C*.

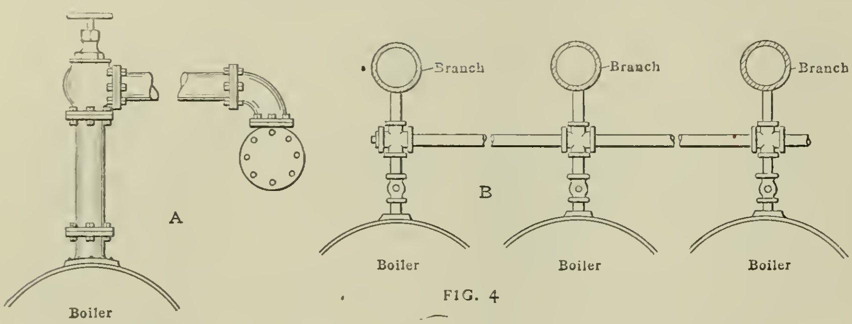

FIG. 4

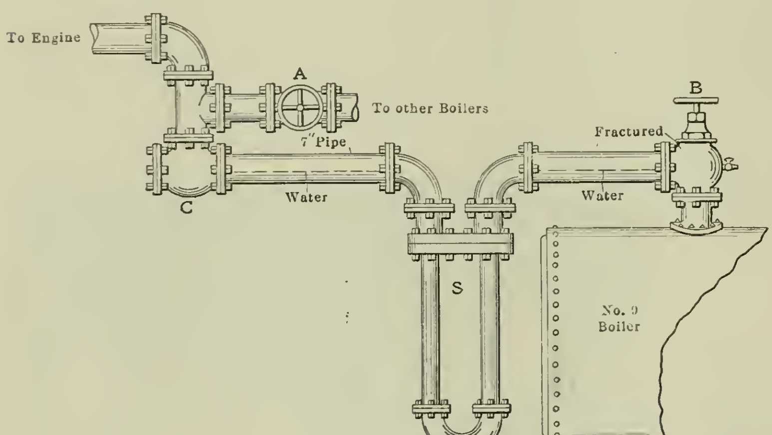

FIG. 5

Power, N.Y.

The engineer should have known that unless the valves *B* and *C* were absolutely tight there would probably be water in the superheater. He should have shut off the valve *C* before opening valve *A*, and left it closed, with the water in the superheater, until the fire was lighted in No. 9 boiler to evaporate it. The drain *d* should have been located at the lowest point of the pipe.

Case 5—This accident was the fracture of a cast-iron reducing valve by water hammer. The valve was placed at one end of the main steam pipe crossing a group of four boilers, Fig. 6, and could be shut off from the pipe by a wedge-shaped valve near to it. The steam main had a fall of about 3 inches toward the wedge-shaped valve, and at the time of the explosion the stop valve on the boiler next the wedge valve was shut, and the stop valves on the other three boilers open. The explosion occurred early in the morning and was caused by the night watchman's opening the wedge valve to admit steam to the reducing valve, and through it to the heating system in the mill. The steam main being partly filled with water, a violent water hammer was at once set up. If the drain had been cross-connected to the other boilers the steam main might have been kept free from water.

Case 6—This was the fracture of a cast-iron steam pipe by water hammer. Steam had been left to condense in 90 feet of new uncovered pipe varying from 9 to 6 inches in diameter. The engine valve *A*, Fig. 7, was shut, and the drain was shut. Water hammer occurred when the engine stop valve was opened. The pipes were new and well designed, having been in use but a week. The boiler-junction valves were shut at the nightly closure of the plant, but were left open during the stops for meals, and the condensation during the dinner hour on the day of the accident must have been sufficient to fill the well pipe and partially fill the 36-foot length of nearly horizontal pipe leading to it. The fault was in opening the engine stop valve before closing the boiler-junction valves and opening the drain. With the well pipe overflowing into the steam main, it would have been dangerous to open the drain without first shutting the boiler-junction valves. A try cock or a telltale float would have shown the conditions. The drain should have been opened when the engine was stopped, and left open until the engine was started again, or if left shut the junction valves on the boilers should have been closed before reopening it.

Case 7—This accident was the fracture of the cast-iron casing of the junction valve on a boiler line. The boiler, Fig. 8, was one of a group of nine, and the steam was conveyed from the junction valve to the steam main by a 7-inch branch pipe about 16 feet long, which was joined by a bend to the under side of the steam main, so that when the junction valve was shut, not only the steam condensed in the branch, but also water from the main would accumulate in this pipe. To prevent the accumulation of water a ½-inch drain pipe and valve were fitted to the lowest part of the branch near the junction valve. The pipe had originally been connected to a ¾-inch pipe leading to a drain in front of the boilers, but this was later disconnected and shortened to about 18 inches, so that when the valve on it was open it discharged upon the top of the side flue of the boiler. On a certain day the junction valve was shut down, and on the next day the water was run out and four men sent into the

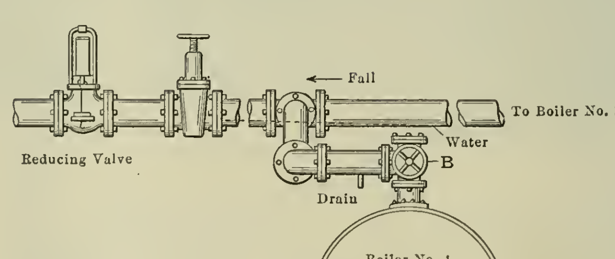

FIG. 6

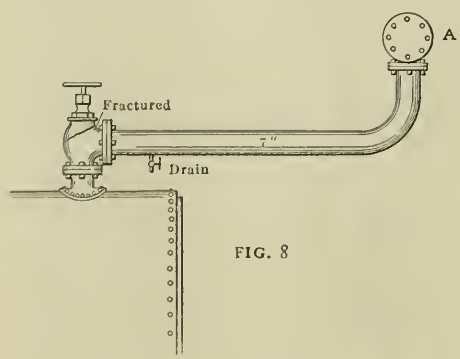

FIG. 8

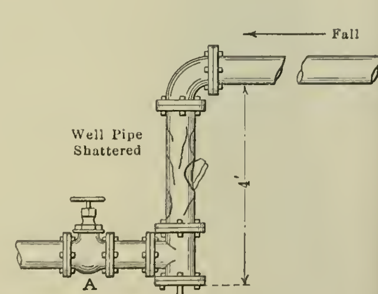

FIG. 7

Power, N.Y.

boiler to scale it, and four others into the external flues to sweep them preparatory to the annual examination. It was customary at this plant, when a boiler was laid off for cleaning, to insert a blank flange at the joint of the 7-inch branch pipe with the steam main, to prevent the men in the boiler being annoyed by the leakage of steam and hot water past the junction valve. On this occasion the precaution was omitted, but the ½-inch drain above referred to was opened to keep the branch clear of water. The discharge from this drain, running upon the brickwork, percolated through into the flue and annoyed the men sweeping it. The evidence was that someone shut the drain and later obtained an iron plate to lay upon the boiler top to lead the water away from the brickwork, had then opened the ½-inch drain and thus disturbed the surface of the water which had in the meantime accumulated in the branch pipe, and so caused the water hammer which broke the casing. The pressure in the pipe was 95 pounds per square inch.

At the investigation of the accident it was decided that the chief engineer and the foreman of the company were to blame for the explosion. They should have been aware that the ½-inch drain pipe had been shortened and was discharging water upon the brickwork, and so into one of the flues, and that the flue cleaners were adopting the clumsy expedient of using sheets of iron to divert the water, and also that it was highly probable that laborers of this class might temporarily close the valve of a drain pipe which was causing them annoyance through dripping. The drain pipe had remained in defective condition for over a year. It was clearly dangerous to allow

FIG. 10

men inside the boiler under the circumstances, for the main steam pipe should have been disconnected and a blank flange put on. The drain should have been cross-connected to at least one of the other boilers.

Case 8—This was the fracture of a steam stop valve, Fig. 9. The initial conditions were: Stop valve B shut, drain shut, and the 7-inch pipe full of condensed steam at low temperature. The water hammer was caused by opening the drain two turns, giving an opening of about ⅛ square inch for two minutes, or if this did not lower the water level in the 7-inch pipe to A A, opening the stop valve B after the drain had been open two minutes. Whichever of these acts lowered the water level in the 7-inch pipe to A A caused the water hammer. The fault was

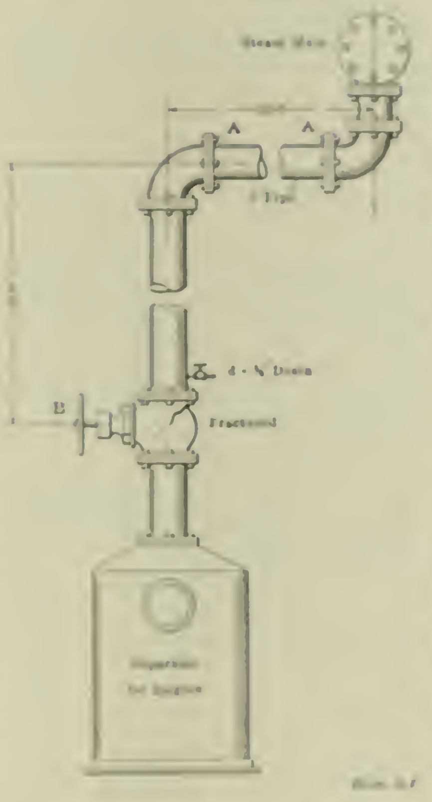

FIG. 9

in opening the drain or the valve without shutting off the steam main. The drain could have been trapped and left open, but the better plan would have been to place the stop valve B close under the steam main.

Case 9—This was the breaking of a cast-iron flange off the screwed end of a 7-inch wrought-iron pipe and knocking it by water hammer under a steam pressure of 95 pounds per square inch. Initially the stop valve C was shut, and D was open. The engine stop valve A was open and the drain shut. Condensed steam had accumulated and cooled in pipe E F. Water hammer was caused by closing valve D, opening the drain and valve C. The fault was in opening the valve C before closing the junction valves on the top boilers. To avoid the necessity of closing these valves before opening valve C, the pipe E F should have been fitted with a large drain leading to a steam trap, which would have kept the pipe clear as long as the trap acted. A still better plan would have been to have installed a well or tank pipe close to C, drained by a trap and fitted with a float telltale or small test cock to enable the engineer in charge to see that the pipe was free from water before opening the valve C, and to warn him that the junction valves on the boilers should be shut.

Museum of Safety Election

Announcement has just been made of the election of the following officers of the Museum of Safety and Sanitation: Acting president, Philip T. Dodge; vice-presidents, Charles Kirchhoff, T. C. Martin, Prof. F. R. Hutton, R. W. Gilder; treasurer, Robert A. Franks; plan and scope committee, Prof. F. R. Hutton, William J. Moran, Dr. Thomas Darlington, H. D. Whitfield, P. T. Dodge; director, William H. Tolman. Among the charter members are C. H. Dodge, Elbert H. Gary, Richard Watson Gilder, Dr. Thomas Darlington, Charles Kirchhoff, T. Commerford Martin, Philip T. Dodge, Prof. E. R. A. Seligman, Irving Fisher, William J. Moran, Henry D. Whitfield, A. R. Shattuck and Prof. F. R. Hutton.

The Museum of Safety and Sanitation has its office in the Engineering Societies' building, 29 West Thirty-ninth street, New York City. The objects of the museum are to study and promote means and methods of safety and sanitation and the application thereof to any and all public or private occupational environment; and of advancing knowledge of kindred subjects; and to that end to establish and maintain expositions, libraries and laboratories and their branches, wherein all devices, methods and means for improving the general condition of the people as to their safety and health may be studied, tested and promoted, with a view to lessening the number of casualties.

At the Greenwich station of the London County Council Tramways the external surface of the [illegible] was considered to be about [illegible] square feet, or about [illegible] square feet per kilowatt of normal capacity.

Three-phase Transformer Connections and Resulting Voltages

By A. D. Williams, Jr.

The accompanying Table 1 gives the voltage between the line and the neutral,

or ground, on a three-phase star-connected circuit, and by simple addition will give the voltage to the neutral or ground for any potential not included in the table.

Example—To find the potential between the ground and any phase of an 11,000-volt circuit:

$$5773.5 + 577.4 = 6350.9 \textit{ volts.}$$

The diagram of a three-phase, star-connected generator is shown in Fig. 2. The neutral wire makes this a three-phase, four-wire system. The usual method connects the neutral to the ground, and this is the three-phase, three-wire system used for most transmission lines. The neutral point of the star-connected circuit is not necessarily grounded, but where it is desired to operate without a ground connection or to ground one phase, a condition that occurs in three-phase railway work, the delta connection shown in Fig. 1 is more often used.

The method of connecting the transformers for delta, or triangle, circuits is shown in Fig. 3, and for star connection in Fig. 4; in the latter the neutral is shown dotted. These two methods are the usual three-phase connections and require three transformers or a three-phase transformer. This latter differs only from three single-phase transformers in having a magnetic circuit, certain portions of which are in common. Figs. 5 and 6 illustrate two forms of three-phase connection for transformers which are rarely

used, but which may be found of service in emergencies.

The three-phase V-connection, Fig. 5, is sometimes called an open-delta connection. This connection would result if one of the transformers shown in Fig. 3 were removed for some cause or other. This property of the three-phase delta circuit is of advantage in permitting continuous operation under practically any emergency that may arise, and is one of the reasons why the delta-connected circuit has been used in some transmission lines. In the three-phase V-connection, if the amount of current per phase be represented by 1, the current flowing through each transformer winding will be $\sqrt{3} = 1.73$, from which it can be seen that the copper loss of the transformers will be increased. The objection to this connection arises from the tendency of the transformer impedance to produce an unbalanced secondary voltage, which also produces unbalancing in the primary circuit.

The T-connection, Fig. 6, overcomes the disadvantage of the V-connection. The unbalancing is not as serious. The ratios given between the transformer taps on this diagram are the theoretical values. In practice the transformer marked with the ratio 0.867 may have the ratio 0.85 or 0.90 and will then operate satisfactorily.

Nearly all transformers made have taps taken out from the primary winding so

that they may be operated with 100, 95, 90 or 85 per cent. of the primary coils in service; and a top is usually connected to the middle of the primary winding. Occasionally they are arranged to operate with only 100, 95 or 90 per cent. of the primary in service. The schematic arrangements of these two cases are shown in Figs. 7 and 8, respectively. The percentage values given are the ratios between the total number of turns in the primary coils and the number of turns between the various taps.

If the ratio across the entire primary winding be taken to represent the potential in volts for which the primary winding is normally designed, the ratios given represent the various primary potentials upon which this winding can be connected to deliver the full secondary voltage. Thus the winding shown in Fig. 7 will deliver the normal secondary voltage when the primary voltage is 100, 95, 90, 85 or 50 per cent. of the normal or, with normal primary voltage, secondary voltages of

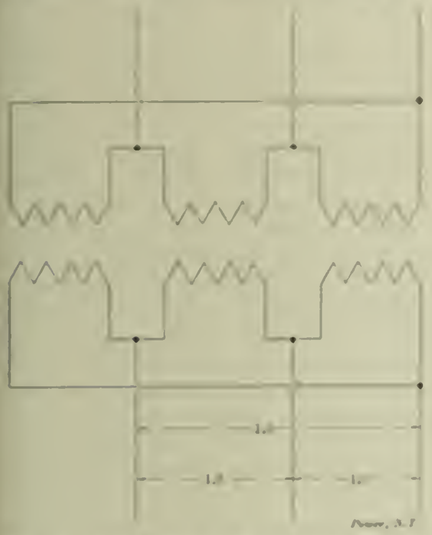

FIG. 3. THREE-PHASE DELTA CONNECTION OF TRANSFORMERS

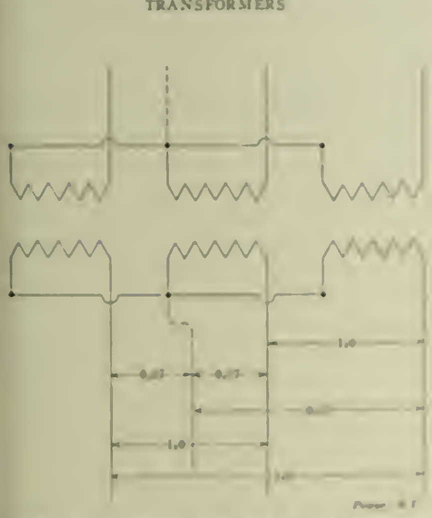

FIG. 4. THREE-PHASE STAR CONNECTION, NEUTRAL [illegible]

100, 105, 111 or 117 per cent. of normal voltage can be obtained. The winding shown in Fig. 8 will deliver the normal secondary voltage when the primary voltage is 100, 95, 90, 50 or 45 per cent. of normal or, with the normal primary voltage, can deliver a secondary voltage of 100, 105 or 111 per cent. of normal. The primary connections shown are those usual for distributing transformers and transmission transformers.

The secondary or low-tension winding usually found in distributing transformers is shown schematically in Fig. [illegible] and the four coils can be connected in series, multiple-series or multiple, giving secondary potentials of 100, 50 or 25 per cent. of the normal, or they can be used to operate two-, three- or five-wire circuits. As any of these combinations may be made in connection with any desired primary connection, it can be seen that a wide variety of transformation ratios can be obtained between the primary and the secondary voltages. Assuming that the normal ratio of the transformer from primary to secondary is 10 to 1, a common ratio in distributing transformers,

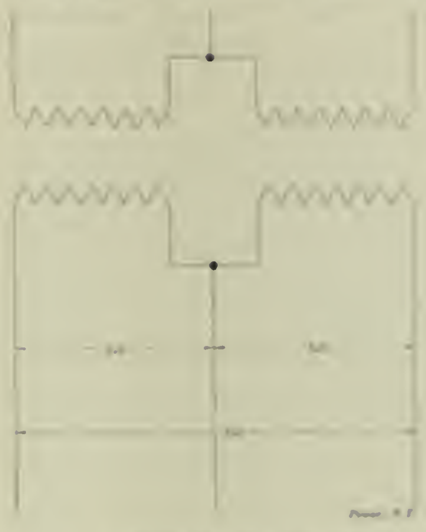

FIG. 5. THREE-PHASE V-CONNECTION

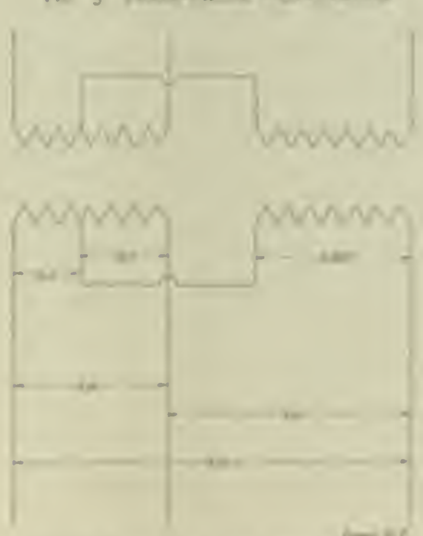

FIG. 6. THREE-PHASE T-CONNECTION

the following transformation ratios can be obtained, when the secondary shown in Fig. [illegible] is used in connection with the primary shown in Fig. 7: [illegible] and [illegible] to 1. Table [illegible] gives the ratios for various primary voltages using different taps of the primary. Table [illegible] gives the ratios obtainable when the primary shown in Fig. 8 is used in combination with the secondary shown in Fig. [illegible], the desired ratio between the primary and secondary winding being [illegible]

In some cases intermediary taps are brought out of the secondary winding similar in [illegible] to those shown in Figs. 7 and 8, but these are unusual. When taps are [illegible] in both, a wider variety of ratios can be obtained, as a greater number of combinations of connections can be made.

In the perfect transformer, that is, one in which no losses occurred, the primary amperes multiplied by the number of turns in the primary coil would be equal to the secondary amperes multiplied by the number of turns in the secondary coil. The watts drawn from the line would equal

FIG. 7. SCHEMATIC ARRANGEMENT OF PRIMARY WINDINGS

FIG. 8. ANOTHER ARRANGEMENT OF PRIMARY WINDINGS

FIG. 9. SCHEMATIC ARRANGEMENT OF SECONDARY WINDINGS

the number of watts delivered at the secondary circuit. In practice, the design of transformers is complicated by the [illegible] losses, due to hysteresis and eddy currents and the copper losses, due to [illegible] [illegible] and resistance, the latter being [illegible] [illegible] but [illegible] may be neglected. Transformers are rated on their kilowatt output [illegible] at some given [illegible] [illegible] that value. The [illegible] [illegible] practice. The Use of Indicators in Refrigeration

Limitations of the Diagram in Work of This Character; Its Meaning in Compression; Analogy to and Comparison with the Steam Diagram*

BY SAMUEL K. PATTESON

The indicator in steam-engine design and operation is in common use today in valve setting and in the determination of the efficiency of steam engines, and its value in this connection is well known. Its application to the steam engine and the details of its use are familiar facts, but its application to the compressor in refrigerating plants is not so common. In fact, ammonia-refrigerating machine manufacturers themselves advocate the use of a thermometer with their installations. Most engineers, however, who are thoroughly familiar with the workings of the indicator recognize its applicability to both cases.

Limitations of the Indicator Diagram

That the indicator diagram is just as useful in refrigeration as in steam-engine work is beyond doubt. In the steam engine it merely records the pressure in the cylinder depending on the cylinder stroke, and it acts in the same way in the ammonia compressor. Its limitations here are the same as in steam work. In steam work nothing can be learned from it about the degree of superheat in the steam, the amount of moisture in it, or the quantity of steam which passes through the cylinder at each stroke of the piston. In fact, it takes no account of the temperature of the steam. This can only be deduced from the pressure and the volume as shown on the diagram. These limitations hold in refrigeration work as well, and no record can be obtained by its use of the degree of superheat in the ammonia gas or its temperature, or the amount of liquid or vapor carried over in the gas or evaporated in the compressor itself. As to these points many of them can be obtained from the thermometer in both of these installations. The fact that these latter points have more influence in refrigeration work than in steam work is responsible for the opinion that the indicator is not applicable to this development. Steam should never enter the cylinder partially condensed and effort is made to avoid this condition. However, in refrigeration work, especially in wet compression, it is desirable that a part of the liquid should enter the cylinder in order to permit its further evaporation in the cylinder. These variations are due to the fact that in steam work the heat is desirable in the cylinder, while in refrigeration it must be gotten out as completely and as rapidly as possible. These conditions, of course, give an entirely different conception of the indicator work and its relative importance in the two developments.

Thus work is the end sought after with steam and the presence of heat is not of such importance. In the case of the refrigerating machine, heat, or rather the removal of it, is the object in view. The indicator performs the same duty in the one case as in the other. It is invaluable in both steam-engine practice and ammonia compression and it would be difficult to obtain adequate data in regard to these machines without it. Adequate data in regard to pressure and total work done in expansion and compression can be gotten in no other way. Of course, if no account is taken of the quantity of work done by the compressor in refrigeration, or of the amount of steam used, the indicator is not particularly useful in this development, and the thermometer answers very well, if the refrigeration alone is considered. The same may be said, however, of steam work. In the refrigeration machine the same information can be obtained by the use of the thermometer and metering the ammonia as can be gotten in steam work by the use of the thermometer and measuring the water consumed. The metering of the ammonia is done practically by measuring the refrigeration produced in the cooling coils. The refrigerating-machine manufacturers, as a general thing, have not considered the compressor as an efficient machine from a work point of view, and hence the low estimate placed upon the usefulness of the indicator in this field. There can be no doubt that a wider use of the indicator would result in showing where improvements are desirable and practicable.

Analogy of the Steam Diagram

A study of the steam diagram in its analogy and contrasts with the indicator diagram as used in refrigeration work, will aid in making more clear a description of the latter. The general shapes of the diagrams are the same. In both they should consist of horizontal lines, one above the other, the lower always being longer than the upper and the two connected on one side by a vertical line and on the other by a line curving toward the lower straight line. In steam work the object in view is to get the greatest amount of work with the least steam consumption. In compression the object is to get the greatest amount of compression with the least work. The upper straight line in the steam diagram represents the portion of the stroke during which steam enters the cylinder, and its distance from the lower line represents its pressure above that of the exhaust. Hence, the distance between the two lines must be as great as possible, or the pressure of the steam as it enters must be as high as possible, in order to get the maximum amount of work obtainable. Then, too, the line must be as short as possible, as its length is always proportional to the amount of steam that enters the cylinder per stroke of the piston. The area of the diagram being equal to the pressure times the change in volume represents work, and by making the upper line longer a larger area is secured and therefore more work done per stroke of the piston, but more steam is used, and the object here is to get the greatest possible proportionate amount of work from a given quantity of steam. In overloads, of course, the time of cutoff is extended and we have varying lengths of cutoff, in many cases automatically regulated by the governor. In these cases the engine does more work, but it uses a larger proportion of steam, and its efficiency is lowered.

In the best engines the cutoff is made to operate under normal circumstances, so that the greatest proportionate amount of work is accomplished at the best efficiency from a steam-consumption viewpoint. This is equivalent to stating that the rest of the curves in the diagram are so proportionate and have such relations that with this particular length of upper line, or steam consumption, the greatest area, or work done relatively, is obtained. After the cutoff is made, that portion of the expansion remaining should be adiabatic for most efficient work, or, in other words, the remainder of the upper line in the indicator diagram should be part of an adiabatic curve. An adiabatic curve is steeper than an isothermal one, and hence the latter would give a larger area to the diagram and, therefore, more work, but in this case heat would have to be added while the change was taking place, and this extra heat would not be made use of at its highest efficiency. On account of cylinder condensation and the accompanying loss of heat, this curve, in practice, is even steeper than an adiabatic. To eliminate the cylinder condensation, recourse is had to steam-jacketing the cylinder and this tends to make the curve isothermal as well.

The Standard Diagram and Its Meaning in Compression

In compression the upper half of the diagram represents the compression part of the stroke. The ammonia gas or air is compressed adiabatically. This compression continues until the valve opens and during the remainder of the stroke, while the gas is leaving the compressor and entering the condenser, the line should be horizontal. Now, the amount of refrigeration produced is proportional to the quantity of ammonia gas leaving the compressor. The amount of work done on the gas by the compressor is, of course, represented by the area of the diagram, and hence the object here is to get the upper line as long as possible. The area of the diagram, or the work done, becomes less the nearer the suction pressure is to the condensing pressure. The colder the condensing water and the larger the condenser the less will be this pressure; hence follows the great effect which the temperature has on the efficiency of a given plant and the amount of work required. If the condenser is too small to take the extra charge from the compressor without extra work, the upper straight line will not be horizontal, but will continue to rise with further compression; and this represents a loss in efficiency also, since the pressure at which the valve opens is the pressure at which the condenser can work if its capacity is not overcrowded. All this work done on the gas up to this time appears as heat, and the compression, therefore, is adiabatic.

As the adiabatic curve is steeper than the isothermal, the compression should be isothermal and the temperature of the ammonia gas should be kept down during the compression, in order that the area in the diagram, which represents the work done, shall be as little as possible. Water jacketing is resorted to to obtain this result, and the efficiency of this device is readily shown from the curve on the indicator diagram. This line is also affected by the speed of the compressor. The heat cannot escape from the gas to the water jacket fast enough if the compressor is operated too rapidly, and the curve becomes adiabatic and more work is done. Again, under these circumstances the entering cold gas on the next stroke reabsorbs this heat very rapidly from the cylinder walls and expands back into the cooling coils before the closing of the valves. This reduces the capacity of the condenser with a consequent loss in refrigeration produced. An analogous situation exists in the steam engine, which explains the fact that an increase in speed results in an increased efficiency in the steam engine, while in the ammonia compressor the reverse effect is in evidence. Thus, the indicator diagram becomes invaluable in showing the speed at which the best results can be obtained from the compressor.

In practice, however, an ammonia compressor is run at its maximum operating speed. This is often done without regard to the efficiency of the operation, but in order to secure the highest possible returns on the first cost investment. The excess refrigeration, however, is sometimes produced at a loss even when the first cost factor is given full consideration, and the point at which the loss begins should be positively known by the operator, and this point can only be obtained by intelligent use of the indicator diagram.

Dry versus Wet Compression

The conditions considered so far have been those which in refrigeration are similar to steam work, assuming a dry gas as the working substance and not a condensable one or one containing liquid which enters the cylinder with the gas. A consideration of these factors materially alters the conditions to be considered and also alters the indicator diagram. What has been considered thus far has dealt with dry compression. In what is known as wet compression an amount of water, varying with different conditions, is sucked into the cylinder. Under these conditions the cylinder volume available for gas to be compressed has been diminished by the presence of the water in the cylinder. The upper horizontal line in the indicator diagram, understood as being proportional to the quantity of gas compressed in the cylinder per stroke, can no longer be so considered, if this gas is measured in volumes as in the case of the previous gas with the existence of constant condensing pressure.

In dry compression the reheating effects in the cylinder walls constitute a very objectionable feature, and to eliminate these effects small quantities of liquid are injected into the compressor. This elimination, however, is not accomplished and it is present in both cases, probably even to a greater extent in the wet compression than in the dry. These reheating effects may cut the capacity of the compressor 40 per cent. This effect is present in the cylinder in the form of a rise in temperature followed by a diminution in density at constant pressure, and cannot be detected on the indicator card. On the other hand, in wet compression, when liquid enters the cylinder a portion of it is immediately evaporated, and the gas which results tends to diminish still further the capacity of the cylinder for the gas coming from the cooling coils. However, this evaporation takes place at a lower temperature and consequently with an increased amount of gas. The relative efficiency of these two methods is a much-mooted question, as the extent to which the two opposing tendencies counterbalance each other is not known. In dry compression the reheating effects sometimes become cumulative with high speeds if the water jacket does not act very efficiently in performing its duty of removing the heat from the cylinder. This factor is not present in wet compression, and if the proper amount of liquid for cooling is injected with each stroke of the piston, much higher speeds can be obtained, at least theoretically. The compression curve even in the wet compression is approximately an isothermal one, being below the adiabatic. Less work should be done per stroke by this method, and the only question is the relative efficiency of this work in the two cases.

The Suction Part of the Cycle

This brings us to the lower limb of the cycle, or in other words, the lower line of the diagram. In refrigeration it consists of the suction part of the cycle and the effect of clearance on the lowering of the pressure in the cylinder to that in the cooling coils. In the steam work it corresponds to the exhaust stroke and the return to the boiler pressure. In steam the lower line should be as far as possible from the upper, in order that the area inclosed in the diagram may be as large as possible. This merely means that the pressure at the exhaust should be as low as possible and the lower line should be horizontal in order that there may be no loss in area or a diminution in the available work, resulting from a rise in that line. This rise may be the effect of a number of different causes, such as insufficient condenser capacity, or the water may not be cold enough to counteract the tendency to increased pressure from the advent of additional steam, or a variety of other defects in the size of the exhaust ports or pipes, or the operation of the valves. All these defects can be recognized with facility by the form of that line with relation to the remainder of the diagram. The line should be vertical for the remainder of its length, and should appear only at the end of the stroke, when the pressure is again raised to boiler pressure. Any variation in this line from the normal means a loss in efficiency due to a variety of causes, such as errors in the proper size of ports, leakages or improper closing of the exhaust valves. All these causes can be easily diagnosed as variations and combinations of variations in the form of the diagram.

In compression, on the other hand, the lower line involves in its vertical component the expansion of the gas which remains in the cylinder after the compression is finished, and is known as clearance gas. Then comes the condensation of the suction valve and the horizontal line of suction pressure. This line should be such close to the upper line for greatest efficiency, since under these conditions the area is smallest or the work done is at a minimum. This result is obtained first when the suction pressure is high. This pressure, however, depends on the temperature of the boiling ammonia in the cooling coils and hence it may be seen why the temperature required in the refrigerator affects so greatly the efficiency, and also why the lower the temperature required the less efficient will be its production. The lower line should be horizontal. Any lowering of this line means increased work on account of stiff valves, too small ports or pipes, or a leak of sufficient extent in the cooling coils to produce this effect. A vertical clearance denotes the complete absence of ammonia remaining in the cylinder from the compression stroke, and this, of course, is desirable. Leaky valves or abnormal clearance on the pressure side causes this line to curve over. This results in less work being done in a cycle, since the area inclosed is smaller. However, some of the work done in this case is repeated work, and the efficiency is thus diminished. Clearance in the cylinder has the same effect that a spring would have if inserted between the piston and piston head. Work is lost here, resulting in extra heat in both cases.

The usefulness of the indicator extends over a wide range, and a large amount of knowledge thus becomes available in regard to the internal behavior of the ammonia compressor and of the conditions governing its efficiency. The chief value of the indicator is in valve setting, as a slight change in the position of the eccentric produces variations in the times of operation of the valves which very materially affect the efficiency. By means of the diagram a complete study of the valve mechanism is possible, and in addition it is the principal, as well as the best, method for getting the best efficiency and proper operation in this department.

An Interesting Low Pressure Pumping Installation

By Albert E. Guy

There has lately been completed by a large steel company a pump installation of considerable interest, particularly so as it is the first of its kind in this country. It consists of a combination high- and low-pressure steam turbine of 150 horsepower capacity driving two 16-inch single-stage pumps connected in series, Fig. 1. This installation is quite noticeable in view of the extremely difficult conditions that the turbine was required to meet, as it was necessary that this machine operate continuously without attention, on the failure of the low-pressure steam supply.

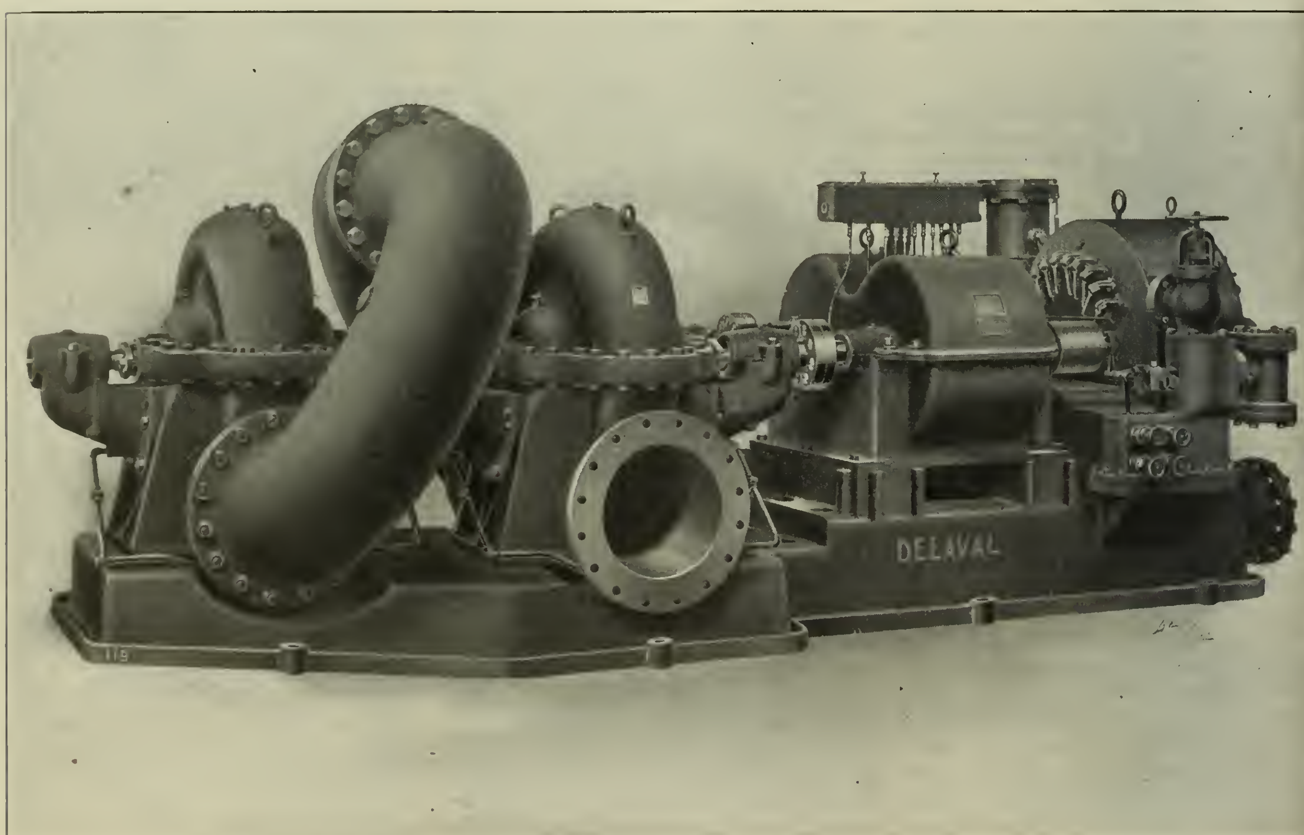

FIG. 1. COMBINATION HIGH- AND LOW-PRESSURE TURBINE DRIVING TWO 16-INCH PUMPS IN SERIES

The steam for the turbine is collected from a number of hydraulic pumps, air pumps and other auxiliary machines, all of which exhaust into a common header from which the turbine draws its supply. No large receiver was installed in the header, the capacity of the header being deemed sufficient for the needs of the turbine. Neither was there any heat accumulator installed, as on failure of the low-pressure steam supply the machine is arranged to operate on steam at boiler pressure.

In view of obtaining continuous operation it was necessary to devise a machine that would operate under a number of conditions. The turbine was to be located near and in connection with a large central condensing plant in use for numerous engines, a number of which were reversing rolling-mill engines, so that the vacuum was very irregular, varying from 18 to 27 inches and averaging about 22 inches. The vacuum was also lost at times due to trouble on the engines or air leaks, making it necessary to operate the turbine noncondensing as an emergency. The turbine was accordingly purchased to meet the following conditions: To carry full load when using steam at atmospheric pressure, exhausting into a vacuum of 22 inches; also to carry full load when operating with steam at 120 pounds, exhausting into a vacuum of 22 inches; also to operate condensing with steam at 90 pounds pressure, exhausting into a vacuum of 22 inches. In case of emergency it must operate noncondensing with steam at 90 pounds pressure; all of these variations to be handled automatically, with the exception of the emergency noncondensing condition.

The machine is used for pumping water from the hotwell of a central condensing plant to the purifying tanks of a large water-purification system, supplying all the boilers of the steel plant with purified water. The conditions for this work are to deliver 5000 gallons of water per minute against a total head of 65 feet. However, as the water-purification plant requires but one hour of work out of three, if used for this service only, a pump would have been in operation only one-third of the time. In order to keep the machine in continuous operation to obtain the greatest returns from the investment, and also to assist in obtaining lower costs on the main water-supply system, it was determined to use this pump, for the two thirds of the time that it was not supplying the purifying system, on the main standpipe system. The total water consumption of the plant is so large that the small amount of heat contained in the hotwell water handled by the turbine pump was of no importance.

The machine was accordingly connected to the main water works system in the following manner: The total head for the purifying tanks is 65 feet, as stated above. The total head of the standpipe system is 95 feet. The purifying system was at a considerable distance from the pump so that it would be impossible for an attendant to go from the purifying system to the pumping plant. The machine was piped into both systems with a check valve between the standpipe system and the pump, and a gate valve directly at the purifying plant in charge of the purifying-plant attendant. As the purifying-plant head was less than the standpipe head, when it was desired to fill one of the tanks, the attendant simply opened the valve and the water from the turbine would at once flow into the purifying system. During this period the check valve of the standpipe system would close, but on closing the purifying-system valve the pressure in the pump would at once increase and as soon as it exceeded 95 feet the water would flow into the standpipe through the check valve. In order that the pump would work automatically on both systems, the impellers were so designed that they would give practically the same efficiency when pumping against either 65 or 95 feet, in one case delivering 5000 and in the other case 4000 gallons per minute.

The machine was most carefully tested by representatives of the steel company before leaving the factory, and later tested after installation at the plant. The results of these tests were very interesting in showing the number of conditions that can be successfully handled by a De Laval turbine. Fig. 2 shows characteristic curves for a 10-inch turbine centrifugal pump designed to deliver 5000 gallons per minute against a head of 65 feet when making 2900 revolutions per minute. On test the turbine operated on steam at atmospheric pressure, exhausting into a vacuum of 26 to 28 inches. It also operated with steam at 5 inches of vacuum below atmosphere, exhausting into a vacuum of 26 inches. It also operated on steam at 150 pounds pressure exhausting into a vacuum of 26 inches and steam at 150 pounds pressure, exhausting into the atmosphere. The alternative noncondensing condition was successfully carried with 50 pounds of steam. The resulting economies of all the conditions were nearly equal to the economy of a turbine designed for each one of these particular conditions.

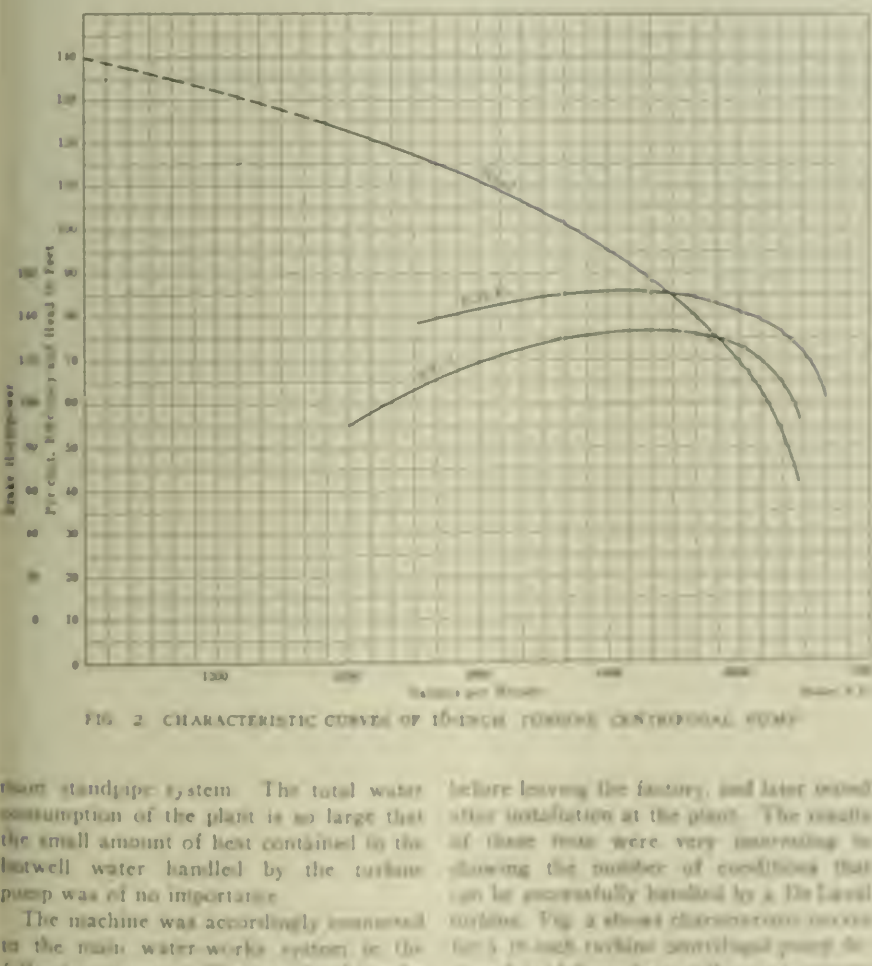

FIG. 2. CHARACTERISTIC CURVES OF 10-INCH TURBINE CENTRIFUGAL PUMP

The arrangement of the turbine is as follows: It is supplied with two governor valves and two governors, one for high-pressure steam and the other for low-pressure steam. The high-pressure governor is set at a few revolutions below normal speed and at this point keeps the high-pressure governor valve tightly closed. The low-pressure governor is set for normal speed and regulates the turbine by means of the low-pressure governor valve. On the failure of the low-pressure steam supply the machine drops a few revolutions in speed, thus releasing the high-pressure governor valve and admitting steam at boiler pressure into the turbine. The steam nozzles in the turbine for the high- and low-pressure conditions are in separate compartments and each nozzle is correct for the ratio of expansion of the conditions it has to meet, thus allowing of good economy with the variable conditions. The noncondensing condition being for emergency only was not made automatic, and to operate the turbine noncondensing it was necessary to open a bypass valve admitting steam from the high-pressure steam compartment to the low-pressure nozzles. The ratio of expansion in the nozzle with steam at atmospheric pressure exhausting into a vacuum of 26 inches is practically the same as steam entering the nozzle at 150 pounds pressure and exhausting at atmosphere, thus giving very good results under either condition. The speed regulation obtained when changing from one steam supply to the other was less than 2 per cent.

In operation there is a very considerable fluctuation of the exhaust steam pressure due to the large hydraulic pumps running rather slowly and exhausting heavily when they do exhaust. The exhaust steam pressure varies from 2 pounds above atmosphere to 5 inches of vacuum, but the regulating mechanism of the turbine handles this variation without trouble.

A bill has been introduced into the Pennsylvania legislature prohibiting the emission of smoke. One thickness of gray glass of sufficient opacity to cut off 80 per cent. of the light from a flame having the diffuse power of 16 candles is taken as the basis on this basis, and four thicknesses of such glass are designated as No. 4 of the scale. It is forbidden and declared to be nuisance to emit or permit the emission or escape of smoke of a greater degree of darkness than No. 2 of the scale, and is the darkness produced by the passage of light through two glasses of the said density.

TABLE FOR CONVERTING HORSEPOWER INTO WATTS.

1 Horsepower = 745.65 Watts.

Horsepower and Kilowatts

One of the most frequent computations made in connection with electrical power-plant work is the conversion of kilowatts into horsepower, or the reverse. While the calculation is a very simple one, consisting of the division or multiplication of a given number by 746, it is sufficiently tedious to cause the average worker to use 750 watts as the horsepower equivalent in order to reduce the irksomeness of computation. In view of these well-known facts, the preparation of the labor-saving tables on the opposite page appeared to be worth while, and they are accordingly presented to our readers.

The exact equivalent of a horsepower is 745.65 watts, and this value has been used in computing the tables. While the equivalents in both tables are expressed in numbers of four and five figures, it is seldom advantageous to use more than three in ordinary practice.

By shifting the decimal point, the tables are applicable, of course, to numbers of any magnitude, and the "additional tenths" have been included to facilitate such applications and to insure the accuracy of conversions thus made. For example, the horsepower equivalent of 500 kilowatts could be easily determined by taking the equivalent of 50 kilowatts (67.06 horsepower) and moving the decimal point one figure to the right, giving 670.6 horsepower. But without the additional nine columns it would be much more troublesome to get at the equivalent of 5270 kilowatts, the procedure being thus:

5200 kilowatts = 100 × 69.74 H.P. = 6974	h.p.
70 kilowatts =	93.88 h.p.
5270 kilowatts =	7067.88 h.p.

With the additional columns, however, the desired equivalent can be taken directly from the table without any arithmetical work whatever. Thus, 527 kilowatts = 70.68 horsepower; hence, 5270 kilowatts = 7068 horsepower.

Sometimes it will be found more convenient to use one of the tables "backward" than the other one "forward." Thus, if 1215 horsepower is to be converted into kilowatts, the use of the horsepower-watts table would require two conversions and an addition, thus:

1200 horsepower =	894,800 watts
15 horsepower =	11,185 watts
1215 horsepower =	905,965 watts

or 906 kilowatts. By finding 121.5 in the body of the other table, the kilowatt equivalent is read directly. Thus, 121.5 is in line 90, column 0.6; its equivalent, therefore, is 90.6 kilowatts, and, consequently, 1215 horsepower = 906 kilowatts.

The tables are useful also in ascertaining the relation between motor output and intake and that between the output of a generator and the indicated engine horsepower required to drive it. For example, a 15-horsepower motor is of 90 per cent. efficiency; how many watts will it take from the supply circuit? From the horsepower-watts table, 15 horsepower = 11,185 watts, which would be the intake at 100 per cent. efficiency. At 90 per cent. the intake would be

$$11,185 \div 0.9 = 12,427.8$$

watts, or 12.43 kilowatts.

Again a motor delivering 18 brake horsepower takes 15,200 watts from the line; what is its efficiency? Referring to the horsepower-watts table, 18 horsepower = 13,422 watts. The intake being 15,200 watts, the efficiency is

$$\frac{13,422}{15,200} = 0.883,$$

or 88.3 per cent.

A generator is rated at 900 kilowatts and the combined efficiency of the machine and its engine is 84 per cent.; what will be the indicated horsepower at full load?

From the kilowatt-horsepower table, 900 kilowatts = 1207 horsepower, and $1207 \div 0.84 = 1436.9$ indicated horsepower.

Again, a motor delivering 18 brake generator shows 957 indicated horsepower when the generator is delivering 585 kilowatts; what is the combined efficiency of the outfit at that load? From the horsepower-watts table, 957 horsepower = 713,590 watts or 713.59 kilowatts. The efficiency, therefore, is

$$\frac{585}{713.59} = 0.8198,$$

or practically 82 per cent. In such a case, the division would be less tedious if the kilowatts were reduced to horsepower, because the divisor in the efficiency fraction will be 957 instead of 713.59. Thus:

585 kilowatts = 784.6 horsepower,

and

$$\frac{784.6}{957} = 0.8198,$$

or 82 per cent.

A 7-foot flywheel upon a Russell engine went to pieces the other day at the station of the Allegheny Valley Lighting Company, at Creighton, Penn., causing about $2000 worth of property damage, but no personal injuries.

Correction

In the article on "Some Useful Lessons of Limewater," last paragraph of the first column of page 692 of the April 13 number, there was an error. Instead of stating: "If you should carry this experiment of the gas bag farther you could mix one volume of hydrogen with two volumes of oxygen," etc., the volumes should be transposed, making it two of hydrogen and one of oxygen.

Catechism of Electricity

1025. *Is it generally necessary to use starting resistance in starting an induction motor?*

It is necessary with all single-phase motors and with polyphase motors required to start under considerable load. Small polyphase motors and large ones not required to start under load can be started by simply closing the supply-line switch, as in these the simple "squirrel-cage" form of rotor winding is sufficient. In the others it is necessary to modify the "squirrel-cage" type as explained in answer No. 1023 to permit the use of a starting resistance.

1026. *Explain the resemblance between the starting conditions of an induction motor and those of a shunt-wound direct-current motor when starting resistance is used.*

These types of motor behave very much alike. If the field and armature of a shunt-wound motor are both switched on the supply circuit at once, the armature, on account of its comparatively low resistance, takes a relatively large starting current and its magnetic reaction against the field cuts down the starting torque. The large starting current is, of course, lowered and the torque is increased as soon as the armature speeds up; but if, as is customary, a resistance is inserted in the armature circuit at the time of starting, the results are much more satisfactory. So in the case of an induction motor a resistance inserted in the rotor or armature circuit at the beginning enables the motor to receive its magnetizing current and start with a good high torque. As the motor speeds up, the starting resistance in the rotor or armature circuit is cut out, as in the case of a shunt-wound motor.

1027. *How is the alteration of the starting resistance made easy in many modern types of induction motors?*

By having the starting resistance mounted within the rotor. As the rotor speeds up after starting, a sliding collar on the shaft, actuated by means of a hand lever, cuts out the starting resistance and short circuits the rotor circuit.

1028. *What other common forms of starting devices are used?*

In some induction motors the starting resistance is separate from the machine and is introduced in the rotor circuit through "brushes" bearing upon collector rings to which the rotor winding is connected. A small single-pole, double-throw switch is used in this circuit and is closed in one direction to start and then thrown in the opposite direction after the motor has reached its normal speed. This switch is usually marked "Starting" and "Running" to designate the two operating positions. The switch should not be thrown from the "starting" to the "running" position until the armature has reached normal speed.

There is also an "oil-immersed" type of starting device which comprises a hand-

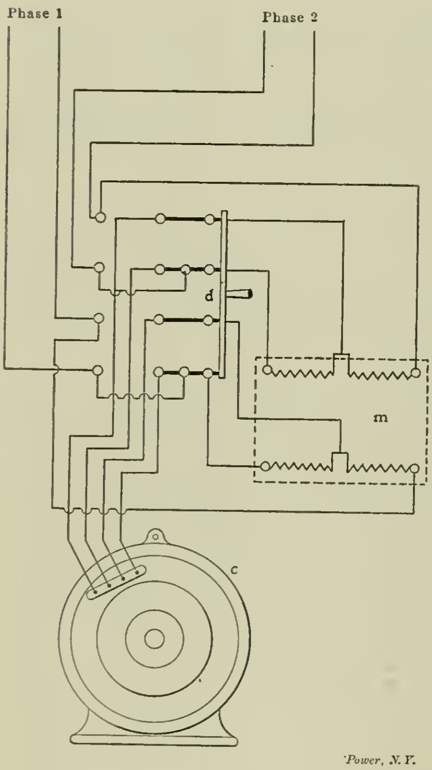

FIG. 287. ARRANGEMENT FOR STARTING A TWO-PHASE INDUCTION MOTOR AT LOW VOLTAGE

wheel or lever controlling a revolving type of switch which makes the required connections in proper sequence. The various positions of the switch are shown by an index plate which indicates the "starting," "running" and "stop" positions. The handwheel or lever of the switch should be moved slowly from the "starting" to the "running" position to allow the armature gradually to reach normal speed without an excessive rush of current through the machine. The switch should always be left either on the "running" or the "stop" position.

1036. *Is any special arrangement necessary for starting an induction motor on a lower voltage than the normal voltage?*

Step-down transformers are used for this purpose. For a two-phase motor they are connected as shown in Fig. 287. In starting, the four-pole switch *d* is closed to the right-hand contacts, which introduces the two step-down transformers at *m* in circuit. When the motor *c* is up to speed, the switch *d* is closed to the left-hand contacts. This cuts out the step-down transformers and applies the line voltage directly to the motor.

1037. *How should the step-down transformers be connected for starting a three-phase motor?*

It is advisable to use three transformers connected in "delta" through a three-pole switch, as represented in Fig. 288. As in the previous case *d* represents the switch, *m* the transformers and *c* the motor. If one transformer breaks down, it may be cut entirely out of circuit and the motor may be operated at a reduced load on the remaining two while the injured one is being repaired. In this case, the voltage of each transformer should be the same as the voltage from wire to wire of the line.

It is possible to install only two transformers to carry the full load of the motor, but in this case the capacity of each transformer must be 173 per cent. of the capacity of each of the three transformers when three are used; hence no great saving, if any, in first cost, and the certainty of a complete shutdown if one transformer breaks down.

1038. *What should be the capacity of the step-down transformers with respect to that of the induction motor?*

The total capacity of the transformers, in kilowatts, should equal the horsepower capacity of the motor.

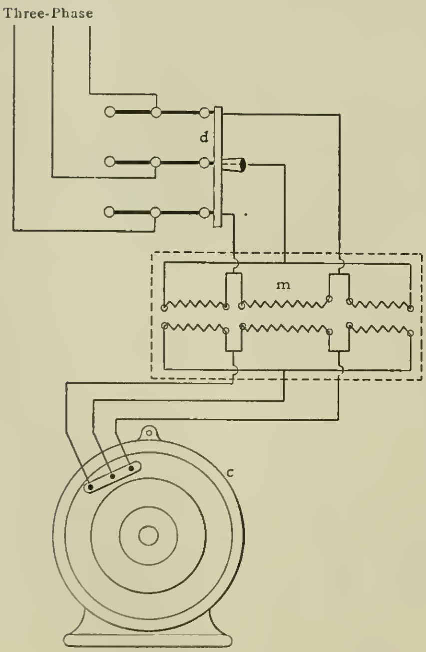

FIG. 288. ARRANGEMENT FOR STARTING A THREE-PHASE INDUCTION MOTOR AT LOW VOLTAGE

1039. *When is the resistance method of starting induction motors preferred to the low-voltage method?*

For work where a very large starting torque is required, as in elevator or hoisting work, the resistance method is always used. In factories where the motor starts only the shafting and the load comes on subsequently, the low-voltage method is satisfactory.

1040. *Is there any other method of starting an induction motor with a good torque?*

Yes, by lowering the frequency of the applied current; because with a reduced frequency there is not as great a slip at low speeds. This method is not as common as the other two because it is not possible to reduce the frequency received from the line. It can be employed, however, when two induction motors are used.

Polytechnic Institute Student Section of the A. S. M. E.

The Polytechnic Institute student section of the American Association of Mechanical Engineers held a regular monthly meeting in the Institute chapel Saturday evening, April 3. After the transaction of regular business, Prof. William D. Ennis, head of the mechanical-engineering department, introduced the speaker of the evening, Harrington Emerson, who talked on "Efficiency." He explained the wage systems in use in different shops and the results obtained. The main thing in an engineer's work, he said, is the ability to size up a new problem and apply old methods to its solution. Then he went on to say that efficiency is a moral, rather than an engineering question; its basis is that of the square deal; unless that principle prevails it is impossible to obtain high efficiency in any direction. Mr. Emerson gave as apropos a quotation from Ruskin: "Every man his chance, every man his certainty; certainty that if he does well he will be honored and advanced, and equal certainty that if he does ill, he will be judged and corrected, for the only thing of consequence is what we do." He ended by illustrating on the blackboard the relations between cost and profit as varied by efficiency.

Mr. Emerson was asked: "What is the practical result, in amount of wages received, of working under the ordinary piece-work system and under the bonus or efficiency system?" He replied that "it is always difficult to turn from piece work to bonus. In one plant I know of they put in the bonus system and paid for a certain piece of work $6. In another plant, using the piece-work system, a man did the same work at a cost of $12 to the company. In the latter shop they found by a time test that the man in question was earning $4.25 per day. They decided to abolish the piece-work system, give him $4.25 per day and a chance to make a bonus. The result was that he made a 20 per cent. bonus and cost his employers less than the $6 man mentioned."

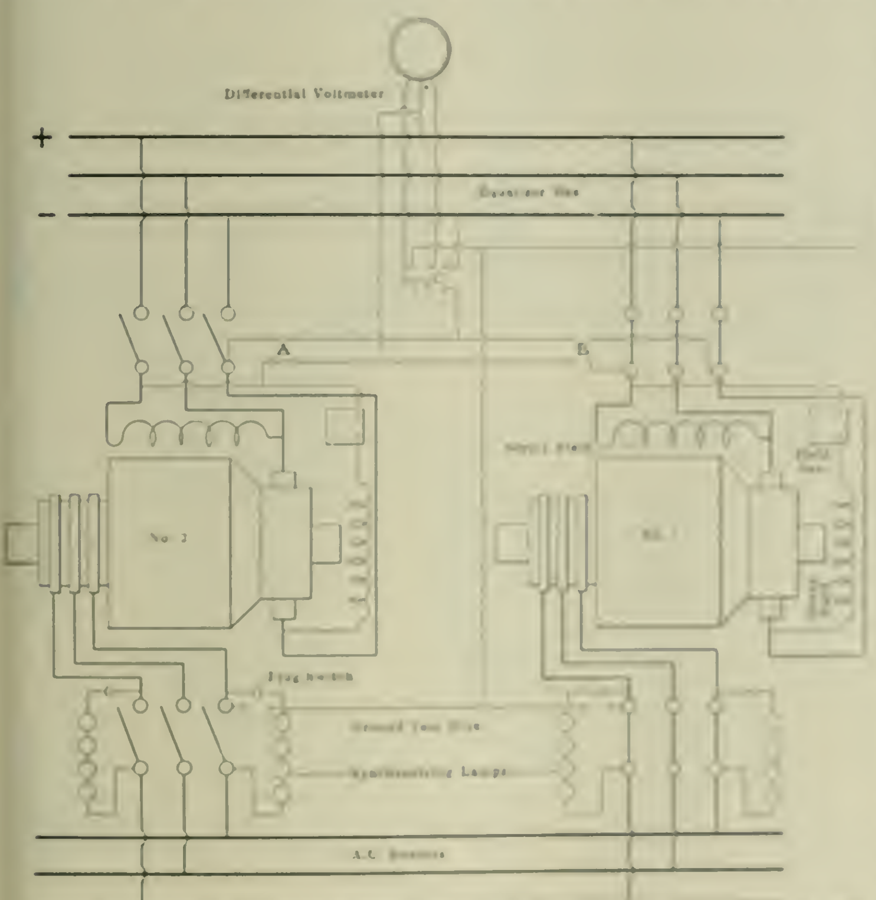
A Peculiar Synchronizing Trouble

The accompanying sketch shows the connections of a rotary-converter installation which, under certain conditions, develops a peculiar state of affairs. In the actual installation there are three converters, but only two are shown in the sketch. The alternating-current voltage is [illegible] and the reactance coils (not shown) are between the converters and the alternating-current supply circuit.

There are voltmeter receptacles for connecting the differential voltmeter across the direct-current busbars or across the terminals of either machine. This voltmeter has a double scale, with the zero point in the center. If a double-fused plug is inserted at *C* the busbar voltage will be read, the indicator going onto the right-hand scale. If a double-fused plug is inserted at *A*, or *B* and *C* at the same time the voltmeter will register zero, due to the impulses in the two coils of the voltmeter being equal and opposite. It is understood that both machines are in operation when the two plugs are inserted.

If a single fused plug is placed in the proper position at *C*, the busbar voltage will be read. If the plug at *C* is reversed and a plug inserted at *A* or *B* the terminal voltage will be registered on the side opposite to the one which registered the busbar voltage. This last method is the one used, as the voltage of the incoming rotary may be read directly.



CONNECTION OF ROTARY-CONVERTER INSTALLATION

Let us suppose that Nos. 1 and 2 machines (the latter not shown) are operating, and No. 3 is to be brought to synchronism and connected to the alternating-current supply circuit. (The voltmeter plugs are all out.) If but one of the plug switches in the synchronizing lamp circuit is closed, the lamps on one side will blink, burning extremely bright when they come up. If plug *A* is removed there will be no synchronizing circuit until the second plug switch is closed, after which the lamps will behave in the usual manner because they will be operating under normal conditions.

With plug *A* in place and with one or both plug switches closed, the lamps will blink as though indicating synchronism, but will burn with dazzling brilliancy when at their brightest, showing the lamps to be burning above their normal voltage.

In synchronizing it is the practice to remove plug *A* before connecting the machine to the alternating-current circuit, but in one instance plug *C* was removed instead, and when the machine was "thrown in" a display of fireworks resulted, plug *A* being burned up, the switchboard blackened for a space of 18 inches around the receptacle and machines 1 and 2 burned in the connections from the busbars.

Why do the lamps on one side burn with but one synchronizing plug switch closed? Why do they "blink" under this condition, and why did plug *A* burn when the machine was connected to the alternating-current circuit?

What Will Happen if the Belt Breaks?

One plant consists of two [illegible]-kilowatt alternating-current and two [illegible]-kilowatt direct-current generators. The alternators are direct-connected to two [illegible] Fleming four-valve engines and are arranged for parallel operation. The exciters are driven by belts from pulleys on the ends of the engine shaft and are not arranged for parallel operation; that is, each alternator drives its own exciter.

Suppose I have the alternating-current machines in parallel, coupled through main switches, and one of the belts were to break or slip off, what effect would it have on the alternating-current generator whose belt was broken while it is still coupled to the other machine through the main generator switch?

Blowoff Valves

I have had splendid success with wedge gate valves, as the wedges can be taken out and ground true with a piece of oiled sandpaper placed on a perfectly flat surface.

My rule is to have two valves and always to open the outside valve first and close it last, using the inside valves to cut off the pressure. In this way the outside valve is blown free from scale and can seat firmly.

Probable Cause of Air Compressor Explosions

I can hardly agree with Frank Richards in his criticism of F. W. Holman's letter on "Probable Cause of Air Compressor Explosions." I think Mr. Holman is nearly right in assigning leaky discharge valves as a possible cause. Everybody knows that when a volume of air is forced through a passage it generates heat, and there is no other place about an air-compressor plant that generates more heat than where the air passes through the discharge valves.

Leaky discharge valves and lack of sufficient radiation will undoubtedly cause the air to reach an abnormally high temperature in a very short time.

I think Mr. Richards is wrong when he says: "This air which has leaked back becomes an inseparable part of the cylinderful, and when the mass is compressed and discharged it is carried along together, and no portion of it can be isolated, and worked back and forth, as assumed, to have its temperature cumulatively augmented."

As Mr. Richards does not state whether the compressor has mechanically driven intake valves, I assume it has not. No air will pass into the cylinder until the pressure has equalized and fallen below atmospheric pressure. If on account of leaky discharge valves the intake, or suction, valve on that end does not lift, is it not an evident fact that as the piston moves back and forth there is a continual displacement, or churning of air going on? One way a leaky discharge valve can be detected is by the abnormally high temperature on the leaky end.

If the compressor has a Corliss, or any kind of driven intake valve, it would be impossible to maintain, or even raise, any pressure in the system, for while the intake valve would be open to receive air, the discharge valve remaining open at the same time, the air would have a free passage to the atmosphere.

Mr. Richards is undoubtedly right in stating that oil will burn bodily in the pipes and system, and that this combustion is frequently going on without our knowledge.

One main fault which should be overcome is the tendency of operators having charge of air compressors to place too much oil in the air cylinder. An air cylinder needs some lubrication, but if only enough oil were admitted properly to lubricate it, I am sure we would never hear of explosions. It is surprising what a small amount of oil is actually required in an air cylinder and what a large amount is frequently used. Oil entering an air cylinder does not become atomized and held in suspension, neither is it washed away by cylinder condensation; but it remains on the cylinder walls until worn away. It acts as a lubricant the same as engine oil on the guides of an engine; but only a good quality of pure mineral oil of a high fire test, say 600 degrees Fahrenheit, should be used. This warning is, of course, needless to nearly everyone who has charge of compressors.

Graphite has of late thoroughly proved itself an ideal lubricant for air cylinders. I gave one of the compressors in the plant I have charge of a thorough test with graphite, using only a very small amount of oil, merely to hold the graphite together until it reached the cylinder. This machine is used to furnish air to lift water out of driven wells, and during a recent dry spell it was run from the middle of April until the first of October, twenty-four hours per day, and was never stopped, except to adjust wearing parts, repack, etc. The cylinder head was taken off several times and its condition noted, and at the end of the season the cylinder walls had attained a deep, black polish, with a coating that absolutely resists any wear. But graphite, as oil, must be used sparingly, and the longer it is used the less must be used, as very little of it passes beyond the cylinder, but remains and forms an almost nonwearing coating.

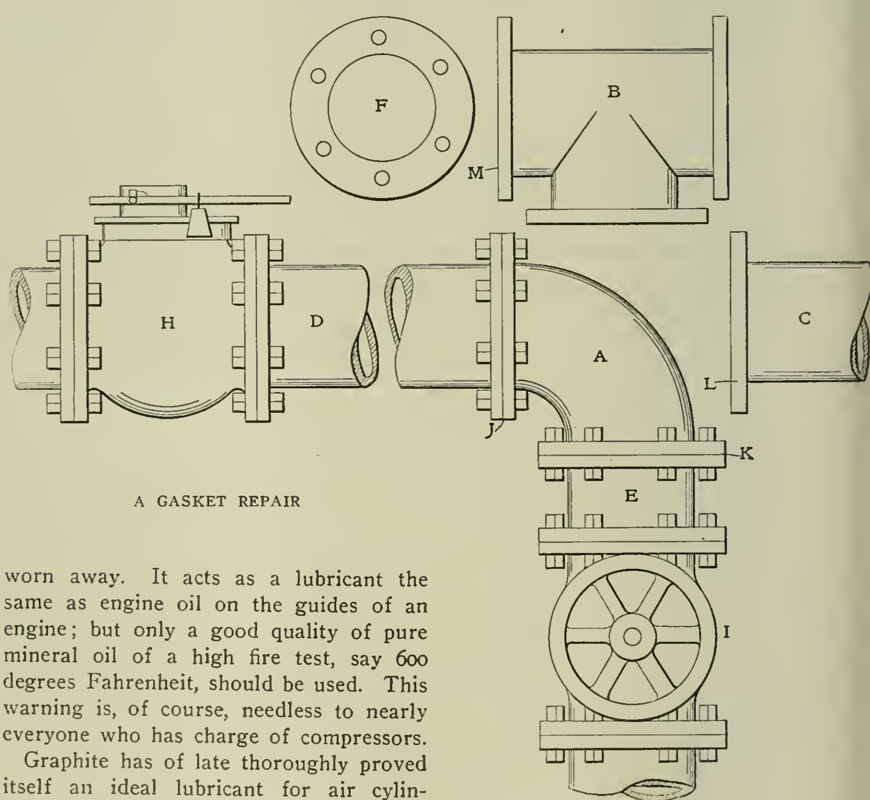
A Gasket Repair Job

I was once employed in a plant where it was necessary to replace the ell at *A* (see illustration) in a 16-inch header, with a tee to receive the exhaust from a new engine. The plant had to run night and day and could not be shut down while we made the change.

The valve *I* leading to the heating system was closed and the exhaust from the engines turned to the atmosphere through the atmospheric valve *H*. We procured a piece of 1/16-inch sheet iron and cut a disk *F* of the same diameter as the flange at the joint *J*.

Holes ¼ inch in diameter were drilled



A GASKET REPAIR

in the disk to coincide with the holes in the flange, and a rubber gasket was glued to one side of it. The other side of the gasket was painted with oil and graphite to keep it from sticking to the flange *J*.

The joint *A* was broken and sprung apart a little. The gasket, being of copper, dropped out and the disk *F* was put in with the gasket next to the flange *J*. The disk was then bolted to the flange with small bolts, the heads of which were small enough to pass through the holes in the flange of the ell *A*, and washers were used under the nuts on the other end. The joint *K* was broken and the ell taken out. The tee *B* was put in place and the joints *K* and *L* made up tight. The small bolts holding the disk were then removed and the disk and gasket pushed out. The tee, having had a gasket glued to its flange *M* was sprung against the flange *J*, the bolts put in and drawn up and the job was complete.
